The most commonly reported adverse drug reactions are diarrhea, rash, acne, pruritus, dry skin, nausea, vomiting, and anorexia (Basela et al., 2002; Ranson et al., 2002). A higher rate of most of these adverse events is observed in patients treated with 500 mg per day of gefitinib as compared to treatment with 250 mg per day. Most adverse events are of mild-to-moderate grade. Less than 2% of patients have permanently discontinued therapy. Adverse drug reactions usually occur within the first month of therapy and generally are reversible. Asymptomatic increases in liver transaminases have been observed and periodic liver function testing should be performed. Interstitial lung disease, which may be acute in onset, has been observed uncommonly in patients receiving gefitinib, and some cases have been fatal. The overall frequency of interstitial lung disease is approximately 0.3% outside of Japan (39,000 patients exposed) and approximately 2% in Japan (27,000 patients exposed) (Cohen et al., 2004).

**Therapeutic Uses.** Gefitinib is approved for the treatment of patients with non–small cell lung cancer who have failed standard chemotherapy. Single-agent responses in these heavily pretreated patients are in the 12% to 18% range (Fukuoka et al., 2003; Kris et al., 2003). However, there is a subset of patients who responded dramatically to gefitinib and these are predominantly non-smoking women with bronchoalveolar tumors (Miller et al., 2004). It has been shown that this subset of patients has EGFR mutations that render the EGFR hypersensitive to ligand and to gefitinib (Lynch et al., 2004; Paez et al., 2004). Tumors from patients responding to other EGFR inhibitors in clinical development, such as erlotinib (TARCEVA), display EGFR mutations. The recommended dose of gefitinib is one 250-mg tablet daily, taken with or without food.

**Clinical Toxicity.** The most commonly reported adverse drug reactions are diarrhea, rash, acne, pruritus, dry skin, nausea, vomiting, and anorexia (Basela et al., 2002; Ranson et al., 2002). A higher rate of most of these adverse events is observed in patients treated with 500 mg per day of gefitinib as compared to treatment with 250 mg per day. Most adverse events are of mild-to-moderate grade. Less than 2% of patients have permanently discontinued therapy. Adverse drug reactions usually occur within the first month of therapy and generally are reversible. Asymptomatic increases in liver transaminases have been observed and periodic liver function testing should be performed. Interstitial lung disease, which may be acute in onset, has been observed uncommonly in patients receiving gefitinib, and some cases have been fatal. The overall frequency of interstitial lung disease is approximately 0.3% outside of Japan (39,000 patients exposed) and approximately 2% in Japan (27,000 patients exposed) (Cohen et al., 2004).

**Thalidomide**

Thalidomide originally was developed in the 1950s for the treatment of pregnancy-associated morning sickness, but withdrawn from the market due to the tragic consequences of teratogenicity and dysmyelia (stunted limb growth) (Franks et al., 2004). However, it has since been reintroduced to clinical practice, initially because of its clinical efficacy as an oral agent for the management of erythema nodosum leprosum, which the FDA approved in 1998 (see Chapter 47). Meanwhile, the realization of thalidomide’s antiangiogenic and immunomodulatory effects, including the inhibition of TNF-α signaling, triggered an expansion of thalidomide uses in other disease settings, most notably multiple myeloma (MM) (Franks et al., 2004). Indeed, significant clinical experience has been acquired on the activity of thalidomide in both newly diagnosed and heavily pretreated relapsed/refractory MM patients. In addition, thalidomide has shown clinical activity in patients with myelodysplastic syndromes and ongoing clinical studies are addressing the potential role of thalidomide in the therapeutic management of other neoplasias. Although the precise mechanism(s) of antitumor activity of thalidomide remain(s) to
be fully elucidated, substantial insight has been generated by extensive preclinical studies in MM. New analogs derived from thalidomide now are in clinical trials for MM and myelodysplasia.

Chemistry and Pharmacology of Thalidomide and Its Derivatives. Thalidomide (Figure 51–17) exists at physiologic pH as a nonpolar racemic mixture of cell permeable and rapidly interconverting S(−) and R(+) isomers, the former being associated with the teratogenic, and the latter with the sedative properties of thalidomide. Thalidomide absorption from the GI tract is slow and highly variable (4 hours mean time to reach peak concentration [τₘₚₙ], with a range of 1 to 7 hours) (Figg et al., 1999). Thalidomide is widely distributed throughout most tissues and organs, without significant binding to plasma proteins, and with a large apparent volume of distribution (Vₐ). Importantly, thalidomide is detected in the semen of patients after a period of 4 weeks of therapy, with levels that correlate with serum levels. Thalidomide metabolism via the hepatic CYP system is limited, and no induction of its own metabolism is noted with prolonged use. However, thalidomide undergoes rapid and spontaneous nonenzymatic hydrolytic cleavage at physiologic pH, generating >50 metabolites, most of which are unstable in vitro or in vivo. Importantly, there are substantial species-specific differences in the patterns and profiles of thalidomide metabolites in mice compared with humans, which likely explains why teratogenicity of thalidomide was not detected in preclinical murine models (Lenz, 1962).

Elimination of thalidomide is mainly by spontaneous hydrolysis, which occurs in all body fluids, with an apparent mean clearance of 10 L/hour for the (R)-enantiomer and 21 L/hour for the (S)-enantiomer in adult subjects. This leads to higher blood concentrations of the (R)-enantiomer compared to those of the (S)-enantiomer. Thalidomide and its metabolites appear to be rapidly excreted in the urine, while the nonabsorbed portion of the drug is excreted unchanged in feces, but clearance is primarily nonrenal. Studies of both single and multiple dosing of thalidomide in elderly prostate cancer patients showed significantly longer half-life at higher doses (1200 mg daily) versus lower doses (200 mg daily) (Figg et al., 1999). Conversely, no effect of increased age on elimination half-life was identified in the age range of 55 to 80 years. The impact of renal or hepatic dysfunction on thalidomide clearance remains to be fully elucidated.

Thalidomide’s interactions with other drugs have not been systematically addressed, except for lack of significant interaction with oral contraceptives (Franks et al., 2004) and thalidomide’s effect in enhancing the sedative effects of barbiturates and alcohol and the catatonic effects of chlorpromazine and reserpine. Conversely, CNS stimulants (such as methamphetamine and methylphenidate) counteract the depressant effects of thalidomide.

Pharmacology of Thalidomide Derivatives. Lenalidomide (Figure 51–17) constitutes a lead compound in the new class of immunomodulatory thalidomide derivatives (IMiDs) and exhibits a constellation of pharmacological properties, including stimulation of T cells and NK cells, inhibition of angiogenesis and tumor cell proliferation, and modulation of hematopoietic stem cell differentiation (Corral and Kaplan, 1999; Hideshima et al., 2000; Davies et al., 2001). This orally administered agent has been tested in MM, myelodysplastic syndrome, and an expanding array of other clinical settings, because of preclinical data suggesting more potent activity than its parent compound, as well as less toxicity and a lack of teratogenic effects as compared to thalidomide (Franks et al., 2004). Lenalidomide is rapidly absorbed following oral administration, with peak plasma levels occurring between 0.6 and 1.5 hours postdose. The Cₘₚₙ and AUC values increased proportionately with increasing dose, both over a single-dose range of 5 to 400 mg and after multiple dosing with 100 mg daily. The half-life increases with dose, from approximately 3 hours at the 5-mg dose, to approximately 9 hours at the 400-mg dose (the higher dose is believed to provide a better estimate of the half-life due to the prolonged elimination phase). Approximately 70% of the orally administered dose of lenalidomide is excreted by the kidney. Ongoing studies are characterizing the adverse-effect profile of lenalidomide use and are addressing the potential for drug interactions with other agents. More extensive clinical experience is required to determine whether lenalidomide is completely devoid of some of thalidomide’s side effects.

Mechanism(s) of Action of Thalidomide and Its Immunomodulatory Derivatives. The precise mechanisms responsible for thalidomide’s clinical activity remain to be completely elucidated. Its enantiomeric interconversion and spontaneous cleavage to multiple short-lived and poorly characterized metabolites, as well as its species-specific in vivo metabolic activation, confound the interpretation of preclinical in vitro and in vivo mechanistic studies. At least four distinct, but potentially complementary, mechanisms (Figure 51–18) have been proposed to explain the antitumor activity of thalidomide and its derivatives: (1) direct antiproliferative/proapoptotic antitumor effects (Hideshima et al., 2000), probably mediated by one or more metabolites of thalidomide, that include inhibition of the transcriptional activity of NF-κB and its antiapoptotic target genes, including the caspase inhibitors FLIP, cIAP-2 (cellular inhibitor of apoptosis-2), or the antiapoptotic Bcl-2 family member A1/Bfl-1 (Mitsiades et al., 2002a); (2) indirect targeting of tumor cells by abrogation of the protection conferred to tumor cells by their cell adhesion molecule— or cytokine (e.g., IL-6)—mediated interactions with bone marrow stromal cells (Hideshima et al., 2000); (3) inhibition of cytokine production, release, and signaling, leading to antiangiogenic effects (D’Amato et al., 1994); and (4) immunomodulatory effects, including enhanced natural killer (NK) cell–mediated cytotoxicity against tumor cells (Davies et al., 2001), contributing to potentiated antitumor immune response. It is conceivable that because NF-κB protects MM cells from the proapoptotic effects of steroids or cytotoxic chemotherapeutics (Mitsiades et al., 2002b), the inhibitory effect of thalidomide and its derivatives on NF-κB activity could account for the ability of its combination with dexamethasone or cytotoxic chemotherapeutics to achieve synergistic antitumor responses (Weber et al., 2003).

Adverse Effects. Generally, thalidomide is well tolerated at doses below 200 mg daily. The most common adverse effects reported in
Figure 51–18. Schematic overview of proposed mechanisms of antmyeloma activity of thalidomide and its derivatives. Some biological hallmarks of the malignant phenotype are indicated in light gray boxes. The proposed sites of action for thalidomide (dark blue letters within circles) are hypothesized to be operative for thalidomide derivatives also. A. Direct anti-MM effect on tumor cells including G1 growth arrest and/or apoptosis, even against MM cells resistant to conventional therapy. This is due to the disruption of the anti-apoptotic effect of Bcl-2 family members, blocking NF-κB signaling, and inhibition of the production of IL-6. B. Inhibition of MM cell adhesion to bone marrow stromal cells due partially to the reduction in IL-6 release. C. Decreased angiogenesis due to the inhibition of cytokine and growth factor production and release. D. Enhanced T-cell production of cytokines, such as IL-2 and IFN-γ, that increase the number and cytotoxic functionality of natural killer (NK) cells.

ESRAMUSTINE

Pharmacology and Cytotoxic Effects. Estramustine (EMCYT) is a combination of estradiol coupled to normustine (nitromustine) (normustine) by a carbamate link. Respectively, estramustine has weaker estrogenic and antineoplastic activity than estradiol and other alkylating agents. While the intent of the combination was to enhance the uptake of the alkylating agent into estradiol-sensitive prostate cancer cells, estramustine does not appear to function in vivo as an alkylating agent. Rather, estramustine binds to β-tubulin and microtubule-associated proteins, causing microtubule disassembly and antimitotic actions.

Resistance to estramustine has been described (Laing et al., 1998). Estramustine is used for the treatment of metastatic or progressive prostate cancer (Kitamura, 2001) at a usual initial dose of 10 to 16 mg/kg daily in three or four divided doses.
Absorption, Fate, and Excretion. Following oral administration, at least 75% of a dose of estramustine is absorbed from the gastrointestinal tract and rapidly dephosphorylated. Estramustine is found in the body mainly as its oxidized 17-keto analog isomer, estromustine; both forms accumulate in the prostate. Some hydrolysis of the carbamate linkage occurs in the liver, releasing estradiol, estrone, and the normustine group. Estramustine and estromustine have plasma half-lives of 10 to 20 hours, respectively, and are excreted with their metabolites, mainly in the feces (Bergenheim and Henriksson, 1998).

Clinical Toxicities. In addition to myelosuppression, estramustine also possesses estrogenic side effects (gynecomastia, impotence, and elevated risk of thrombosis, and fluid retention) and is associated with hypercalcemia, acute attacks of porphyria, impaired glucose tolerance, and hypersensitivity reactions including angioedema.

Bortezomib

Chemistry. Bortezomib (VELCADE) is [(1R)-3-methyl-1-[[[(2S)-1-oxo-3-phenyl-2-[(pyrazinylcarbonyl)amino]propyl]amino]butyl]boronic acid, and its structure is:

![Bortezomib Molecular Structure](image)

Mechanism of Action. Bortezomib binds to the 20S core of the 26S proteasome and is a reversible inhibitor of its chymotrypsin-like activity (Orlowski et al., 2002). Inhibition of the proteasome disrupts multiple signaling cascades within the cell, often leading to cell death. Most important consequences of proteasome inhibition are believed to result from downregulation of NF-κB, a key transcription factor that promotes cell survival. Generally, NF-κB is bound to IκB in the cytosol, thus preventing transfer to the nucleus and binding to DNA. In response to “environmental” stress such as hypoxia, chemotherapy, and DNA damage, IκB becomes ubiquitinilated, resulting in its degradation via the proteasome and subsequent release of NF-κB to the nucleus. NF-κB is thought to be responsible for the activation of cell adhesion proteins E-selectin, ICAM-1, VCAM-1, and VEGF. NF-κB also activates cyclin-D1, cIAPs, IL-6, and BCL-2, promoting cell proliferation and survival (Aghajanian et al., 2002). Bortezomib blocks degradation of IκB so that NF-κB is silenced. In a similar manner, bortezomib disrupts the ubiquitin-proteasome regulation of p21, p27, and p53, which are key regulatory proteins in the cell cycle and initiators of apoptosis. The antineoplastic activity of bortezomib in tumors is likely due to a greater dependence on certain cell proliferating and promoting pathways in cancer relative to normal tissues.

General Toxicity and Cytotoxic Action. Animal and human toxicity studies have shown that escalating doses of bortezomib have resulted in dose-limiting toxicities in the following organ systems: gastrointestinal, hematopoietic, lymphatic, and renal.

Absorption, Fate, and Excretion. After intravenous administration of 1 to 1.3 mg/m² of bortezomib in animals and patients without renal or hepatic impairment, there is a rapid distribution phase (<10 minutes), followed by a longer elimination phase of 5 to 15 hours (Papandreou et al., 2001). The median peak plasma concentration was 509 ng/ml after a 1.3-mg/m² bolus injection. Plasma protein binding averaged 83%. The mean terminal elimination in phase I and II studies was 5.45 hours, with an average clearance of 65.9 L/hour following a 2-compartment model. Peak pharmacodynamic activity (proteasome inhibition) occurred at 1 hour with a mean of 61% inhibition and a half-life of approximately 24 hours (Aghajanian et al., 2002; Orlowski et al., 2002). Inhibition of the 20S subunit was 10% to 30% at 96 hours. Proteasome inhibition is very sensitive to bortezomib concentrations, inhibition being 0% to 60% over a range of concentrations of 0.5 to 2 ng/ml.

In vivo studies and work with human liver microsomes has shown that bortezomib is primarily metabolized to an inactive metabolite by the CYP system and not by glucuronidation or sulfation. Deboronation accounts for greater than 90% of total metabolism, with CYP3A4 being more active than CYP2D6. Studies in patients with hepatic or renal impairment are being conducted and should help guide dose reduction in such patients, and pathways of elimination in humans. No formal drug interaction studies have been performed, but bortezomib is known to be a poor inhibitor of human liver microsome cytochrome P450 enzymes.

Preparations. Bortezomib is available for intravenous injection only. Each vial contains 3.5 mg of bortezomib as a sterile lyophilized powder and 35 mg of mannitol. Prior to use, the contents of each vial must be reconstituted with 3.5 ml of normal (0.9%) saline. The reconstituted product should be clear and colorless, and should be administered to patients within 8 hours.

Dosage and Routes of Administration. The recommended starting dose of bortezomib is 1.3 mg/m² given as an intravenous bolus, and this should be given on days 1, 4, 8, and 11 of every 21-day cycle (10-day rest period per cycle). At least 72 hours should elapse between doses. For grade 3 nonhematologic toxicities and grade 4 hematologic toxicities, drug administration should be held until resolution and subsequent doses should be reduced 25%. In clinical trials some patients have received 2 mg/m² without severe toxicity, and extravasation of bortezomib has occurred without tissue damage.

Therapeutic Uses and Clinical Toxicity. Bortezomib was approved by the FDA in 2003 for use in patients with MM who have received two prior therapies and are progressing on their current therapy (Kane et al., 2003). In a phase II trial in such patients the complete response rate was 4%, the partial response rate was 24%, and the minor response rate was 7% (Richardson et al., 2003). The drug currently is being studied in combination with other drugs in MM as well as other hematologic neoplasms and solid tumors.

Toxicities from the use of bortezomib have been well characterized (Orlowski et al., 2002; Richardson et al., 2003). At the stan-
dard dose and schedule, grade 4 toxicities were rare (<4%) and grade 3 toxicities encountered in >5% of patients were as follows: thrombocytopenia (28%), fatigue (12%), peripheral neuropathy (12%), neutropenia (11%), anemia (8%), vomiting (8%), diarrhea (7%), limb pain (7%), dehydration (7%), nausea (6%), and weakness (5%). Peripheral neuropathy was encountered more frequently in patients with a prior history of neuropathy or preexisting numbness, pain, or burning. Dose reductions of bortezomib are recommended for these patients. Usually, the neuropathy improves or resolves completely after several months off treatment. Hypotension associated with the injection of bortezomib has been rarely encountered, and caution should be taken with patients who are volume-depleted, have a history of syncope, or who are on antihypertensive medications. Cardiac toxicity in the form of hypotension and failure has been encountered in animal studies at twice the recommended dose. Very little cardiac toxicity has been encountered in human studies.

Zoledronic Acid

*Zoledronic acid* (ZOMETA) is a bisphosphonate (see Chapter 61) indicated both for the treatment of patients with bony metastases and for patients with multiple myeloma. A direct antitumor effect on myeloma cells has been suggested (Aparicio et al., 1998) and preclinical data suggest the possibility that inhibition of bone matrix–degrading proteases may inhibit tumor cell invasion in breast and prostate cancers (Bossier et al., 2000).

Mitotane

The principal application of *mitotane* (o,p′-DDD), a compound chemically similar to the insecticides DDT and DDD, is in the treatment of neoplasms derived from the adrenal cortex. In studies of the toxicology of related insecticides in dogs, it was noted that the adrenal cortex was severely damaged, an effect caused by the presence of the o,p′ isomer of DDD, whose structural formula is as follows:

![Structure of Mitotane](image)

**Cytotoxic Action.** The mechanism of action of mitotane has not been elucidated, but its relatively selective attack on adrenocortical cells, normal or neoplastic, is well established. Thus, administration of the drug causes a rapid reduction in the levels of adrenocorticosteroids and their metabolites in blood and urine, a response that is useful both in guiding dosage and in following the course of hyperadrenocorticism (Cushing’s syndrome) resulting from an adrenal tumor or adrenal hyperplasia. Damage to the liver, kidneys, or bone marrow has not been encountered.

**Absorption, Fate, and Excretion.** Approximately 40% of mitotane is absorbed after oral administration. After daily doses of 5 to 15 g, concentrations of 10 to 90 μg/ml of unchanged drug and 30 to 50 μg/ml of a metabolite are present in the blood. After discontinuation of therapy, plasma concentrations of mitotane are still measurable for 6 to 9 weeks. Although the drug is found in all tissues, fat is the primary site of storage. A water-soluble metabolite of mitotane is found in the urine; approximately 25% of an oral or parenteral dose is recovered in this form. About 60% of an oral dose is excreted unchanged in the stool.

**Therapeutic Uses.** Mitotane (LYSODREN) is administered in initial daily oral doses of 2 to 6 g, usually given in three or four divided portions, but the maximal tolerated dose may vary from 2 to 16 g per day. Treatment should be continued for at least 3 months; if beneficial effects are observed, therapy should be maintained indefinitely. *Spironolactone* should not be administered concomitantly, since it interferes with the adrenal suppression produced by mitotane (Wortsman and Soler, 1977).

Treatment with mitotane is indicated for the palliation of inoperable adrenocortical carcinoma, producing symptomatic benefit in 30% to 50% of such patients.

**Clinical Toxicity.** Although the administration of mitotane produces anorexia and nausea in approximately 80% of patients, somnolence and lethargy in about 34%, and dermatitis in 15% to 20%, these effects do not contraindicate the use of the drug at lower doses. Since this drug damages the adrenal cortex, administration of adrenocorticosteroids is indicated, particularly in patients with evidence of adrenal insufficiency, shock, or severe trauma (Hogan et al., 1978).

**BIOLOGICAL RESPONSE MODIFIERS**

In contrast to small molecules, biological response modifiers include biological agents or approaches that beneficially affect the patient’s biological response to a neoplasm. Included are agents that act indirectly to mediate their antitumor effects (e.g., by enhancing the immunologic response to neoplastic cells) or directly on the tumor cells (e.g., differentiating agents). Recombinant DNA technology has greatly facilitated the identification and production of a number of human proteins with potent effects on the function and growth of both normal and neoplastic cells. Proteins that currently are in clinical trials include the interferons (see Chapters 49 and 52), interleukins (see Chapter 52), hematopoietic growth factors (see Chapter 53) such as *erythropoietin*, filgrastim (granulocyte colony-stimulating factor [G-CSF]), and *sargramostim* (granulocyte-macrophage colony-stimulating factor [GM-CSF]), *tumor necrosis factor* (TNF), and
monoclonal antibodies such as trastuzumab, cetuximab, and rituximab.

Among the agents now approved for clinical use because of their activity in specific neoplastic diseases are interferon-alfa for use in hairy cell leukemia, condylomata acuminata, CML, and Kaposi’s sarcoma associated with AIDS; interleukin-2 (IL-2) for kidney cancer; trastuzumab for breast cancer; and rituximab for B-cell lymphomas.

### Interleukin-2 (IL-2, ALDESEUKIN, PROLEUKIN)

The isolation of a cytokine initially named T-cell growth factor, subsequently renamed IL-2, allowed the first attempts to treat cancer by producing lymphocytes specifically cytolytic for the malignant cell (Morgan et al., 1976). IL-2 is not directly cytotoxic; rather, it induces and expands a T-cell response cytolytic for tumor cells. Clinical trials have studied the antitumor activity of IL-2 both as a single agent and with adoptive cellular therapy using IL-2–stimulated autologous lymphocytes obtained by leukopheresis, termed lymphokine-activated killer (LAK) cells. Randomized trials have not shown that the addition of LAK cells to the treatment regimen improves overall response rates (Rosenberg et al., 1989). Later studies in adoptive cellular therapy have used expanded populations of lymphocytes obtained from tumor biopsies and expanded in vitro, so-called tumor-infiltrating lymphocytes (Rosenberg et al., 1994).

Because the half-life of IL-2 in humans is short (13 minutes for α and 85 minutes for β) (Konrad et al., 1990), most clinical schedules have explored either continuous infusion or multiple intermittent dosing. Others have explored the use of liposome-encapsulated IL-2 or conjugation of IL-2 with polyethylene glycol to extend the half-life of IL-2 and to enhance its delivery to immune cells in tumors. These alternative forms of IL-2 therapy are experimental at this time (Bukowski et al., 2001). The most significant antitumor activity has been demonstrated with the most intense dosing schedules: continuous intravenous infusion for 5 days every other week for 2 cycles, or intravenous bolus every 8 hours daily for 5 days every other week.

The toxicities of IL-2 are likely related to the activation and expansion of cytotoxic lymphocytes in organs and within vessels, resulting in inflammation and vascular leak, and to the secondary release by activated cells of other cytokines, such as tumor necrosis factor and interferon. When given at maximally tolerated doses of 600,000 units/kg every 8 hours for up to 5 days, IL-2 causes hypotension, arrhythmias, peripheral edema, prerenal azotemia, elevated liver transaminases, anemia, thrombocytopenia, nausea, vomiting, diarrhea, confusion, and fever (Rosenberg et al., 1989).

Reproducible antitumor activity has been reported in advanced MM and renal cell cancer, where response rates (partial and complete) are seen in 20% to 30% of patients. Complete responses, seen in approximately 5% to 10% of patients, appear to be durable, with some patients now free of disease beyond 5 years of treatment.

IL-2 currently is being studied in the treatment of AML, where it is capable of inducing remission in relapsed patients (Meloni et al., 1994). In some studies where IL-2 is given following bone marrow transplantation, it appears that IL-2 can lengthen the remission duration as compared to historical controls (Fefer et al., 1993). Randomized trials are in progress to test this hypothesis prospectively.

### Monoclonal Antibodies

Since the discovery of methods for fusing mouse myeloma cells with B lymphocytes, it has been possible to produce a single species of antibody that recognizes a specific antigen. Cancer cells express a variety of antigens that are attractive targets for monoclonal antibody–based therapy (Table 51–3). The development of monoclonal antibodies against specific targets has been largely accomplished by the empiric method of immunizing mice against human tumor cells and screening the hybridomas for antibodies of interest. This technology has led to the production of therapeutic monoclonal antibodies for the treatment of cancer. Because murine antibodies have a short half-life and induce a human anti-mouse antibody immune response, they usually are chimerized or humanized when used as therapeutic reagents. Presently, several monoclonal antibodies have received FDA approval for lymphoid and solid tumor malignancies, and include rituximab and alemtuzumab for lymphoid malignancies, and trastuzumab for breast cancer (Keating et al., 2002; Vogel et al., 2002; Cobleigh et al., 1999). The nomenclature adopted for naming therapeutic monoclonal antibodies is to terminate the name in -ximab for chimeric antibodies and -umab for humanized antibodies. A variety of mechanism(s) of cell killing have been described for monoclonal antibodies, including antibody-dependent cellular cytotoxicity (ADCC), complement-dependent cytotoxicity (CDC) and direct induction of apoptosis, but the clinically relevant mechanisms remain uncertain (Shan et al., 1998).

Monoclonal antibodies also may be engineered to combine the antibody with a toxin (immunotoxins), such as gemtuzumab ozogamicin (MYLOTARG) or denileukin difitox (ONTAK), or combined with a radioactive isotope, as in the case of 90Y-ibritumomab tiuxetan (ZEVALIN) (Table 51–3). More recently, antibodies have been engineered to contain a second specificity, known as bispecific antibodies (Onda et al., 2004; Silverman et al., 2004). For example, an antibody with specificity to B-cell lymphomas and to CD3, which binds to and acti-

vates normal T cells, may enhance T-cell mediated lysis of the lymphoma cell. Monoclonal antibodies raised against the immunoglobulin idotype on a B-cell lymphoma represent another therapeutic strategy (Miller et al., 1982).

Naked Monoclonal Antibodies

**Rituximab.** Rituximab (RITUXAN) is a chimeric monoclonal antibody that targets the CD20 B-cell antigen (Tables 51–3 and 51–4) (Maloney et al., 1997a; Maloney et al., 1994; Maloney et al., 1997b). CD20 is found on cells from the pre-B-cell stage through terminal differentiation to plasma cells and is expressed on 90% of B-cell neoplasms (Stashenko et al., 1980; Bhan, 1981). The biological functions of CD20 are uncertain, although incubation of B cells with anti-CD20 antibody has variable effects on cell-cycle progression, depending on the monoclonal antibody type (Tedder et al., 1986; Smeland et al., 1985). Monoclonal antibody binding to CD20 generates transmembrane signals that produce autophosphorylation and activation of serine/tyrosine protein kinases, and induction of c-myc oncogene expression and major histocompatibility complex class II molecules (Deans et al., 1993). Studies have shown that CD20 also is associated with transmembrane Ca\(^{2+}\) conductance, through its possible function as a Ca\(^{2+}\) channel (Deans et al., 1993). These studies demonstrate the importance of CD20 in B-cell regulation, but do not in themselves indicate how ligation of the receptor produces cell death independent of ADCC or complement-mediated pathways.

Rituximab is the first monoclonal antibody to receive FDA approval and initially was approved for relapsed indolent lymphomas. However, it has shown activity in a wide variety of clinical settings (Coiffier et al., 1998; Foran et al., 2000). In the initial phase II study of rituximab in 37 patients with relapsed low-grade lymphoma, 46% responded with a median time to progression of 10 months (Maloney et al., 1997a). Notably, rituximab also was shown to be effective in 40% of patients who had previously responded to rituximab, but has a longer median time to progression of 18 months (Davis et al., 2000). Recent studies also have demonstrated significant activity of rituximab in mantle cell lymphoma, relapsed aggressive B-cell lymphomas, and CLL (Coiffier et al., 1998; O’Brien et al., 2001). The use of maintenance rituximab has gained increased acceptance, based on demonstration of delayed time to progression, but effects on survival have not been demonstrated (Hainsworth, 2004). Increasingly evident are the synergistic effects of rituximab and chemotherapy, suggesting it sensitizes lymphoma cells to the apoptotic effects of chemotherapy by directly acting on tumor cells (Maloney et al., 2002). Based on in vitro studies showing synergistic effects of chemotherapy and rituximab, rituximab is being clinically combined with agents such as fludarabine and combinations such as CHOP (Savage et al., 2003). Of great importance is the recent finding that the addition of rituximab to CHOP chemotherapy significantly improves the event-free survival of diffuse large B-cell lymphoma (Coiffier et al., 2002; Wilson et al., 2003).

Rituximab demonstrates dose-dependent pharmacokinetics. At a dose of 375 mg/m\(^2\), the mean serum half-life was 76.3 hours (range, 32 to 153 hours) after one dose and 205.8 hours (range, 84 to 407 hours) after the last dose (Maloney et al., 1997a; Maloney et al., 1997b). The wide range of half-lives likely reflects differences in patient tumor burden and normal B-cell populations. Rituximab toxicities are mostly related to infusion reactions, although there are increasing reports of late-onset neutropenia and rare reports of severe skin toxicity (Table 51–4) (Maloney et al., 1994; Lemieux, 2004).

**Alemtuzumab.** Alemtuzumab (CAMPATH) is a humanized monoclonal antibody targeting the CD52 antigen present on normal neutrophils and lymphocytes as well as most B- and T-cell lymphomas (Tables 51–3 and 51–4) (Kumar et al., 2003). CD52 is expressed at reasonable levels and does not modulate with antibody binding, making it a good target for unconjugated monoclonal antibodies. Mechanistically, alemtuzumab can induce tumor cell death through antibody-dependent cellular cytotoxicity (ADCC) and complement-dependent cytotoxicity (CDC) (Table 51–4) (Villamor et al., 2003). Clinical activity has been demonstrated in low-grade lymphomas and CLL, including in patients with purine analog-refractory disease (Keating et al., 2002; Rai et al., 2002). In refractory CLL, response rates from 33% to 59% have been described, with higher rates in untreated CLL patients (Osterborg et al., 1997).

Alemtuzumab demonstrates dose-dependent pharmacokinetic behavior. In clinical studies, alemtuzumab had a mean half-life of 12 days and steady-state levels were reached at approximately week 6 of treatment, although there was significant interpatient variability. The most concerning side effects are from acute infusion reactions and the depletion of hematopoietic cells and T cells (Table 51–4). Patients also may develop severe pancytopenia and death. Opportunistic infections are a serious side effect, particularly in patients who have received purine analogs, and have resulted in patient deaths (Tang et al., 1996). The broad expression of CD52 in T cells has led to the testing of alemtuzumab in T-cell lymphomas. Recent studies have shown a high response rate in mycosis fungoides, and combination chemotherapy trials are being conducted in aggressive T-cell lymphomas (Kennedy et al., 2003).

**Trastuzumab.** Trastuzumab (HERCEPTIN) is a humanized monoclonal antibody against the HER2/neu (ErbB-2) member of the epidermal growth factor family of cellular receptors (Noonberg and Benz, 2000). The internal domain of the HER2/neu glycoprotein encodes a tyrosine kinase that activates downstream signals and enhances metastatic potential and inhibits apoptosis.

Abbreviations: ADCC, antibody-dependent cellular cytotoxicity; CDC, complement-dependent cytotoxicity; EGFR, epidermal growth factor receptor; VOD, veno-occlusive disease.
HER2/neu is overexpressed in up to 30% of breast cancers and is associated with clinical resistance to cytotoxic and hormone therapy (Slamon et al., 1989). A number of mechanisms of action have been proposed, which may lead to both cytostatic and cytotoxic effects (Nahta and Esteva, 2003). Downregulation of HER2/neu expression may inhibit cell proliferation, potentially through induction of p27 and reduction of cyclin D1, and is associated with antiangiogenic effects (Izumi et al., 2002). Trastuzumab also can initiate Fcy receptor–mediated antibody-dependent cellular cytotoxicity and directly induce apoptosis.

Trastuzumab is the first monoclonal antibody to be approved for the treatment of a solid tumor. Currently, trastuzumab is approved for HER2/neu overexpressing metastatic breast cancer in combination with paclitaxel as initial treatment or as monotherapy following chemotherapy relapse (Vogel et al., 2002; Cobleigh et al., 1999). Trastuzumab also is synergistic with other cytotoxic agents, but expectedly, this is only observed in HER2/neu–overexpressing cancers (Slamon et al., 2001; Seidman et al., 2001; Baselga et al., 1998; Baselga, 2000). Phase III studies are randomizing patients between chemotherapy with or without trastuzumab to assess the optimum regimen (Hinoda et al., 2004). HER2/neu expression also is found in other solid tumors and responses have been reported in colorectal and non–small cell lung cancer (Vogel et al., 2002; Langer et al., 2004). Clinical trials of trastuzumab in other tumors that express HER2/neu at relatively high frequency, such as pancreas and stomach, are likely.

Trastuzumab has dose-dependent pharmacokinetics with a mean half-life of 5.8 days at the 2-mg/kg maintenance dose. Steady-state levels were achieved between the 16th and the 32nd weeks with mean trough and peak concentrations of approximately 79 and 123 μg/ml, respectively (Cobleigh et al., 1999; Baselga, 2000). The infusional effects of trastuzumab are typical of other monoclonal antibodies and include fever, chills, nausea, dyspnea, and rashes. Allergic reactions also may be observed. Cardiac dysfunction is an unexpected and potentially serious side effect that was observed in the pivotal trial of trastuzumab and chemotherapy (Seidman et al., 2002). Left ventricular dysfunction was seen most commonly in those patients who received doxorubicin and cyclophosphamide. In a murine model, mice with a ventricular-restrictive deletion of the HER2/neu gene developed cardiomyopathy, indicating that HER2/neu signaling is important for cardiac muscle (Crone et al., 2002).

Cetuximab. Cetuximab (ERBITUX) is a chimeric monoclonal antibody that recognizes the epidermal growth factor receptor (EGFR; also ERBB1 or HER1) (Mendelsohn and Baselga, 2000; Grunwald and Hidalgo, 2003). Activation of EGF receptor signaling through its intracellular tyrosine kinase domain produces multiple cellular events associated with proliferation, survival, and angiogenesis (Kim et al., 2001). EGFR expression is found in 60% to 75% of colorectal cancers, where it has been linked to tumor progression and a poor prognosis (Mayer et al., 1993). Multiple epithelial cancers, such as breast, lung, kidney, prostate, brain, pancreas, bladder, and head and neck malignancies, also express EGFR and are potential therapeutic targets of cetuximab (Mendelsohn and Baselga, 2000; Kim et al., 2001). Although the mechanism of tumor cell kill for cetuximab is uncertain, it is likely to involve inhibition of EGF binding and signaling, which may lead to inhibition of pro-angiogenic factors and apoptosis (Petit et al., 1997). The role of more classical immune mechanisms, such as ADCC, is unclear.

Cetuximab was approved by the FDA in 2004 for the treatment of EGFR-positive metastatic colorectal cancer as a single agent in patients who could not tolerate irinotecan-based therapy, or in combination with irinotecan for refractory patients (Saltz et al., 2004; Cunningham et al., 2004). In part, this approval was based on a randomized study of cetuximab alone versus cetuximab and irinotecan in patients with refractory colorectal cancer. The combined therapy group had a significantly higher response rate (22.9%) compared to the monotherapy group (10.8%), and a longer median time to progression (4.1 vs. 1.5 months). However, the median survival times of 8.6 months and 6.9 months, respectively, were not significantly different (Cunningham et al., 2004). Studies in head and neck cancer in combination with radiation therapy suggest that cetuximab improves local control.

Cetuximab displays nonlinear characteristics (Thomas and Grandis, 2004). Following the recommended dose regimen, steady-state levels were achieved by the third weekly infusion, with mean peak and trough concentrations ranging from 168 to 235 and 41 to 85 μg/mL, respectively. The mean half-life was 114 hours (range, 75 to 188 hours). Toxic side effects observed with cetuximab are typical of other monoclonal antibodies and include infusion reactions. The incidence of skin rash is significantly greater than that observed with other monoclonal antibodies; it may occur in 75% of patients, and may be severe in 16% (Saltz et al., 2004). Interestingly, there is a correlation between development of a rash and its intensity with duration of benefit from cetuximab.

Bevacizumab. Bevacizumab (AVASTIN) is a humanized monoclonal antibody against vascular-endothelial growth factor (VEGF) and inhibits its interaction with the VEGFR1 and VEGFR2 receptors (Rosen, 2002). Functionally, VEGF is an angiogenic growth factor that regulates vascular proliferation and permeability and inhibits apoptosis of new blood vessels (Ferrara et al., 1992; Aotake et al., 1999). VEGF expression is increased in a variety of tumor types, including breast, ovarian, non–small cell lung, and colorectal cancer, and its expression correlates with neovascularization within tumor masses (Vermeulen et al., 1999). Furthermore, in colorectal cancer, microvessel density is associated with progression of adenomas to carcinomas and with metastatic potential and a poor prognosis (Vermeulen, 1999; Choi et al., 1998).
Bevacizumab is approved by the FDA for treatment of metastatic colorectal cancer in combination with 5-FU (Kabbinavar et al., 2003; Hurwitz et al., 2004). A phase III study of irinotecan/5-FU/leucovorin with or without bevacizumab for the initial treatment of advanced colorectal cancer showed a significant, albeit modest, benefit in median survival (20.3 vs. 15.6 months) and progression-free survival (10.6 vs. 6.2 months) for patients receiving bevacizumab (Hurwitz et al., 2004). There also is evidence of biological activity of bevacizumab in clear-cell renal cancer as a single agent and in non–small cell lung cancer and breast cancer in combination with chemotherapy (Yang et al., 2003; Cobleigh et al., 2003).

The pharmacokinetics of bevacizumab vary by sex, body weight, and tumor burden. Clearance is higher in patients with greater tumor burden, but the relationship with clinical outcome has not been explored. Bevacizumab has an estimated half-life of 20 days (range, 11 to 50 days) and a predicted time to reach steady state of 100 days at the therapeutic dose (Zondor and Medina, 2004). Infusion-related toxicities are relatively uncommon. However, this agent has a number of unique and potentially serious toxicities including severe hypertension, proteinuria, and congestive heart failure (Hurwitz et al., 2004). It also has been reported to cause hemorrhage and gastrointestinal perforation.

**Monoclonal Antibody-Cytotoxic Conjugates**

**Gemtuzumab Ozogamicin.** Gemtuzumab ozogamicin (MYLOTARG) comprises a humanized monoclonal antibody against CD33 that is covalently linked to a semisynthetic derivative of calicheamicin, a potent enediyne antitumor antibiotic (Bernstein, 2000). The CD33 antigen is found on most hematopoietic cells and on more than 80% of AML and in most myelodysplasias (Wellhausen and Peiper, 2002). However, it has little expression on other cell types, making it attractive for targeted therapy. The function of CD33 is unknown, although monoclonal antibody cross-linking inhibits normal and myeloid leukemia cell proliferation (Bernstein, 2000). Following binding to CD33, gemtuzumab ozogamicin undergoes endocytosis with cleavage of calicheamicin within the lysosome, which then enters the nucleus (van Der Velden et al., 2001) and causes double-strand DNA breaks and cell death (Zein et al., 1988).

Gemtuzumab ozogamicin is approved by the FDA for the treatment of CD33-positive AML in first relapse, which occurs in patients at least 60 years old and who are not candidates for conventional cytotoxic therapy. The approval was based on its single-agent activity in refractory AML, where 20% of patients had reductions in blast counts (Sievers et al., 2001). However, there are no controlled studies demonstrating clinical benefit compared with other treatments. There are multiple studies exploring new roles for gemtuzumab ozogamicin, such as in combination with chemotherapy or stem cell transplant and as maintenance treatment. These studies are being conducted in a variety of clinical settings including refractory and previously untreated AML (Amadori et al., 2004; Damle, 2004).

Pharmacokinetics of gemtuzumab ozogamicin at the standard 9 mg/m² dose showed a half-life of total and unconjugated calicheamicin of 41 and 143 hours, respectively (Dowell et al., 2001). Following a second dose, the half-life increased to 64 hours and the area under the curve was twice that of the initial dose. Serious toxicities may occur with gemtuzumab ozogamicin. Like other monoclonal antibodies, infusion-related toxicities occur with the first infusion but are ameliorated by glucocorticoids. The primary toxicities are bone marrow suppression and hepatic toxicity. Hepatic toxicity can be serious and may lead to fatal veno-occlusive disease. In the phase II study, grade 3 or 4 hyperbilirubinemia was observed in 23% of patients and may represent subclinical veno-occlusive disease in some cases (Sievers et al., 2001).

**Radioimmuno-Conjugates**

Radioimmuno-conjugates provide monoclonal antibody targeted delivery of radioactive particles to tumor cells (Tables 51–3 and 51–4) (Kaminski et al., 2001). 131Iodine (131I) is a commonly used radioisotope, as it is readily available, relatively inexpensive, and easily conjugated to a monoclonal antibody. The gamma particles emitted by 131I can be used for both imaging and therapy, but have the drawbacks of releasing free 131I and 131I-tyrosine into the blood, presenting a potential health hazard to caregivers. The β-emitter, 90Yttrium (90Y), has emerged as an attractive alternative to 131I, based on its higher energy and longer path length, which may be more effective in tumors with larger diameters. It also has a short half-life and remains conjugated, even after endocytosis, providing a safer profile for outpatient use. However, disadvantages include its inability to image, limited availability, and its expense.

Clinically, radioimmuno-conjugates have been developed with murine monoclonal antibodies against CD20 conjugated with 131I (131I-tositumomab or BEXXAR) and 90Y-ibrutinomab tiuxetan (ZEVALIN). Both drugs have shown response rates in relapsed lymphoma of 65% to 80% (Kaminski et al., 2001). These agents have been well tolerated with most toxicity attributable to bone marrow suppression. However, there have been worrisome reports of secondary leukemias (Table 51–4).

Pretargeting has been used to increase the therapeutic index of radioimmuno-conjugates by taking advantage of the high binding affinity of avidin and biotin. Patients initially are treated with avidin-labeled monoclonal antibody, followed 1 to 2 days later, after maximal binding of the monoclonal antibody to the target, by administration of yttrium-conjugated biotin. This technique may improve the specificity of radioisotope delivery to tumor cells and increase the therapeutic index.

**Immunotoxin**

**Denileukin Diftitox.** Denileukin diftitox (ONTAK) is an immunotoxin made from the genetic recombination of IL-2 and the catalytically active fragment of diphtheria...
toxin (Foss, 2001). The human IL-2 receptor (IL-2R) consists of three discrete subunits, CD25 (α chain, Tac, p55), CD122 (β chain, p70), and CD132 (γ chain, p64), assembled as a trimolecular complex to generate the high-affinity IL-2R. CD25, the low-affinity IL-2R, is incapable of internalizing IL-2, whereas CD122, the β chain of the IL-2R, internalizes IL-2 and has an intermediate affinity. In a complex with CD25, CD122 produces the high-affinity IL-2R with an affinity 100-fold greater than that of the intermediate-affinity receptor. The high affinity IL-2R is not expressed on resting T cells, but is upregulated by antigen activation and is constitutively expressed on malignant lymphocytes of both T-cell and B-cell origin. The limited tissue expression of the high-affinity IL-2R makes this an attractive target for cancer treatments, as cells that do not express the IL-2R or express only the intermediate- or low-affinity types are significantly less sensitive to this agent.

Denileukin diftitox is FDA approved for the treatment of recurrent/refractory cutaneous T-cell lymphomas. Response rates of 30% to 37% have been achieved in such patients with denileukin diftitox, with a median response duration of 6.9 months in one study (Olsen et al., 2001). A larger proportion of patients showed clinical benefit but did not meet the objective criteria for response. Denileukin diftitox is being evaluated in patients with CD25-negative tumors and modulators of CD25 expression are being combined in an attempt to increase response rates. This latter approach may allow higher levels of intracellular toxin to be delivered. Bexarotene increases the level of CD25 expression on malignant T cells and provides a rationale for combining these agents (Gorgun and Foss, 2002).

The systemic exposure to denileukin diftitox is variable but proportional to dose (LeMaistre et al., 1998). It has a distribution half-life of 2 to 5 minutes with a terminal half-life of approximately 70 minutes. Immune-logic reactivity to denileukin diftitox can be detected in virtually all patients after treatment but does not preclude clinical benefit with continued treatment. Denileukin diftitox clearance in later cycles of treatment is accelerated by two- to threefold as a result of development of antibodies, but serum levels are greater than that required to produce cell death in IL-2R–expressing cell lines (1 to 10 ng/ml for more than 90 minutes). Patients with a history of hypersensitivity reactions to diphtheria toxin or IL-2 should not be treated. Significant toxicities associated with denileukin diftitox are typically acute hypersensitivity reactions, a vascular leak syndrome, and constitutional toxicities; glucocorticoid premedication significantly decreases toxicity (Table 51–4) (Foss, 2001).

**Colony-Stimulating Factors**

As noted above, many agents used for cancer chemotherapy suppress the production of multiple types of hematopoietic cells, and bone marrow suppression often has limited the delivery of chemotherapy on schedule and at prescribed doses. The availability of recombinant growth factors for erythrocytes (i.e., erythropoietin), granulocytes (i.e., granulocyte colony-stimulating factor), and granulocytes and macrophages (i.e., granulocyte-macrophage colony-stimulating factor) have enormously advanced the ability to use combination therapy or high-dose therapy with diminished complications such as febrile neutropenia. Whether this will result in improved survival rates for specific cancers remains to be determined by clinical trials. The individual growth factors and specifics of therapy are described in detail in Chapter 53.

### V. Hormones and Related Agents

#### GLUCOCORTICOIDS

The pharmacology, major therapeutic uses, and toxic effects of the glucocorticoids are discussed in Chapter 59. Only the applications of the hormones in the treatment of neoplastic disease are considered here. Because of their lympholytic effects and their ability to suppress mitosis in lymphocytes, the greatest value of these steroids as cytotoxic agents is in the treatment of acute leukemia in children and malignant lymphoma in children and adults.

In acute lymphoblastic or undifferentiated leukemia of childhood, glucocorticoids may produce prompt clinical improvement and objective hematological remissions in up to 30% of children. Although these responses frequently are characterized by complete disappearance of all detectable leukemic cells from the peripheral blood and bone marrow, the duration of remission is brief. Remissions occur more rapidly with glucocorticoids than with antimetabolites, and there is no evidence of cross-resistance to unrelated agents. For these reasons, therapy is initiated with prednisone and vincristine, often followed by an anthracycline or methotrexate, and L-asparaginase. Glucocorticoids are a valuable component of curative regimens for Hodgkin’s disease and non-Hodgkin’s lymphoma, as well as for treatment of multiple myeloma and CLL. Glucocorticoids are extremely helpful in controlling autoimmune hemolytic anemia and thrombocytopenia associated with CLL.

The glucocorticoids, particularly dexamethasone, are used in conjunction with radiotherapy to reduce edema related to tumors in critical areas such as the superior mediastinum, brain, and spinal cord. Doses of 4 to 6 mg every 6 hours have dramatic effects in restoring neurological function in patients with cerebral metastases, but these effects are temporary. Acute changes in dexamethasone dosage can lead to a rapid recrudescence of symptoms. Dex-
amethasone should not be discontinued abruptly in patients receiving radiotherapy or chemotherapy for brain metastases. Gradual tapering of the dosage may be undertaken if a clinical response to definitive antitumor therapy has been achieved. The antitumor effects of glucocorticoids are mediated by their binding to the glucocorticoid receptor, which activates a program of gene expression that leads to apoptosis.

Several glucocorticoids are available and at equivalent dosages exert similar effects (see Chapter 59). Prednisone, for example, is usually administered orally in doses as high as 60 to 100 mg, or even higher, for the first few days and gradually reduced to levels of 20 to 40 mg/day. A continuous attempt should be made to establish the lowest possible dosage required to control the manifestations of the disease. These agents, when used chronically, exert a wide range of side effects, including glucose intolerance, immunosuppression, osteoporosis, and psychosis (see Chapter 59).

PROGESTINS

Progestational agents (see Chapter 57) have been used as second-line hormonal therapy for metastatic hormone-dependent breast cancer and in the management of endometrial carcinoma previously treated by surgery and radiotherapy. In addition, progestins stimulate appetite and restore a sense of well-being in cachectic patients with advanced stages of cancer and AIDS. While progesterone itself is poorly absorbed when given orally and must be used with an oil carrier when given intramuscularly, there are synthetic progestosterone preparations.

Hydroxyprogesterone usually is administered intramuscularly in doses of 1000 mg one or more times weekly; medroxyprogesterone (DEPO-PROVERA) can be administered intramuscularly in doses of 400 to 1000 mg weekly. An alternative and more commonly used oral agent is megestrol acetate (MEGACE, others; 40 to 320 mg daily, in divided doses). Beneficial effects have been observed in approximately one-third of patients with endometrial cancer. The response of breast cancer to megestrol is predicted by both the presence of hormonal receptors and the evidence of response to a prior hormonal treatment. The effect of progestin therapy in breast cancer appears to be dose-dependent, with patients demonstrating second responses following escalation of megestrol to 1600 mg/day. Clinical use of progestins in breast cancer has been largely superceded by the advent of the aromatase inhibitors (see below). Responses to progestational agents have also been reported in metastatic carcinomas of the prostate and kidney.

ESTROGENS AND ANDROGENS

Discussions of the pharmacology of the estrogens and androgens appear in Chapters 57 and 58, respectively. They are of value in certain neoplastic diseases, notably those of the prostate and the mammary gland, because these organs are dependent upon hormones for their growth, function, and morphological integrity. Carcinomas arising from these organs often retain some of the hormonal responsiveness of their normal counterparts for varying periods of time. By changing the hormonal environment of such tumors, it is possible to alter the course of the neoplastic process.

Androgen-Control Therapy of Prostatic Carcinoma

The development of anti-androgenic therapy for prostatic carcinoma is largely the contribution of Huggins and associates. Although the hormonal treatment of metastatic prostate carcinoma is palliative, life expectancy is increased and thousands of patients have enjoyed its benefit.

Localized prostate cancer is curable with surgery or radiation therapy. However, when distant metastases already are present, hormonal therapy becomes the primary treatment. Standard approaches to reduce the concentrations of endogenous androgens or inhibit their effects include bilateral orchiectomy, antiandrogens, or most commonly, the administration of gonadotropin-releasing hormone (GnRH) agonists or antagonists with or without antiandrogens (see below).

Subjective and objective improvements rapidly follow the institution of androgen-control therapy of prostatic carcinoma in the majority of patients with metastatic disease, and these benefits last an average of 1 year. From the patient’s point of view, the most gratifying may be relief of bone pain. This is associated with an increase in appetite, weight gain, and a feeling of well-being. Objectively, there are regressions of the primary tumor and soft tissue metastases, but neoplastic cells do not disappear completely. The concentration of prostate-specific antigen (PSA) in plasma is a useful marker of response. Eventually prostatic tumors become insensitive to androgen deprivation through loss or mutation of the androgen receptor, which in some patients recognizes androgen antagonists such as flutamide as agonists (see below and Chapter 58). In such cases, withdrawal of the antagonist may lead to a response.

Estrogens and Androgens in the Treatment of Mammary Carcinoma

Despite remissions of disease being noted with pharmacologic doses of estrogen therapy in breast cancer patients, unwanted side effects prompted the development of alternate strategies. Paradoxically, antagonizing the effects of estrogen also is frequently effective as exemplified by
remission of disease achieved with oophorectomy. Thus, because of a relative paucity of side effects and equivalence of efficacy, the use of anti-estrogens such as tamoxifen replaced treatment with estrogens or androgens as hormonal therapy of breast cancer. The detection of the estrogen receptors (ER) and progesterone receptors (PR) by monoclonal antibodies has led to improved selection of patients for hormone therapies. A significant minority of patients with ER- or PR-positive tumors have a response to hormonal therapy, and furthermore have a better overall prognosis independent of the type of therapy. In contrast, ER- and PR-negative carcinomas do not respond to hormonal therapy.

Clinically detectable responses to hormone therapy can be slow and usually take 8 to 12 weeks to detect. If the disease responds or remains stable on a given treatment, the medication typically is continued indefinitely until the disease progresses or unwanted toxicities develop. The duration of an induced remission averages 6 to 12 months but sometimes can last for many years.

**Anti-Estrogen Therapy**

Anti-estrogen approaches for the therapy of hormone-receptor positive breast cancer include the use of selective estrogen-receptor modulators (SERMs), selective estrogen-receptor downregulators (SERDs), and aromatase inhibitors (AIs).

**Selective Estrogen-Receptor Modulators.** Tamoxifen citrate is the lead compound of the SERM class. These agents bind to the estrogen receptor and exert either estrogenic or anti-estrogenic effects depending on the specific organ. Tamoxifen is the most widely studied anti-estrogenic treatment in breast cancer. The recent decline in breast cancer mortality in Western countries is believed to be in part due to the widespread utilization of tamoxifen (Hermon and Beral, 1996). However, in addition to its estrogen antagonist effects on breast cancer, tamoxifen also exerts estrogenic agonist effects in nonbreast tissues, which influences the overall therapeutic index of the drug. Therefore several novel anti-estrogen compounds have been developed that offer the potential for enhanced efficacy and reduced toxicity compared with tamoxifen. These novel antiestrogens can be divided into tamoxifen analogues (e.g., toremifene, droloxifene, and idoxifene), “fixed ring” compounds (e.g., raloxifene, lasofoxifene, arzoxifene, miproxifene, levormeloxifene, and EM652), and the selective estrogen-receptor downregulators (SERDs) (e.g., fulvestrant, SR 16234, and ZK 191703, the latter also termed “pure antiestrogens”) (Howell et al., 2004a).

**Tamoxifen.** Tamoxifen is the most broadly used anti-estrogen therapy. It was first synthesized in 1966 and initially developed as an oral contraceptive but was found to induce ovulation. For over three decades, tamoxifen has been studied and developed for use in various stages of breast cancer. Its broad use is related to its anticancer activity and good tolerability profile to allow for chronic daily dosing. Tamoxifen is prescribed for the prevention of breast cancer in high-risk patients, for the adjuvant therapy of early-stage breast cancer, and for the therapy of advanced breast cancer.

**Mechanism of Action.** Tamoxifen is a competitive inhibitor of estradiol binding to the ER. There are two subtypes of estrogen receptors: ER α and ER β, which have different tissue distributions and can either homodimerize or heterodimerize. Binding of estradiol and SERMs to the estrogen-binding sites of the ERs initiates a series of events that includes change in altered conformation of the ER, dissociation of heat-shock proteins, and ER dimerization. Dimerization facilitates the binding of the ER to specific DNA estrogen-response elements (EREs) in the vicinity of estrogen-regulated genes. As detailed in Chapter 57, many coregulator proteins interact with the receptor to act as corepressors or coactivators, while at least 50 transcriptional activating factors modulate the effects of estrogen on target genes. Differences in tissue distribution of ER subtypes, the function of coregulator proteins, and the various transcriptional activating factors may explain the variable response to tamoxifen in hormone-receptor positive breast cancer. Other organs that are affected by the administration of tamoxifen include the uterine endometrium (endometrial hypertrophy, vaginal bleeding, and endometrial cancer), the coagulation system (thromboembolism), bone metabolism (modulation of bone mineral density), and liver function (alterations of blood lipid profile) (Ellis and Swain, 2001).

**Absorption, Fate, and Excretion.** Tamoxifen is readily absorbed following oral administration, with peak concentrations measurable after 3 to 7 hours and steady-state levels being reached at about 4 to 6 weeks (Jordan, 1982). The drug is metabolized predominantly to N-desmethyltamoxifen and to 4-hydroxytamoxifen, a more potent metabolite. Both of these metabolites can be further converted to 4-hydroxy-N-desmethyltamoxifen, which retains high affinity for the ER. The parent drug has a terminal half-life of 7 days, while the half-lives of N-desmethyltamoxifen and 4-hydroxytamoxifen are significantly longer at about 14 days (Ellis and Swain, 2001). After enterohepatic circulation, glucuronides and other metabolites are excreted in the stool; excretion in the urine is minimal.

**Therapeutic Uses.** The usual oral dose of tamoxifen (NOLVADEX) in the United States is 10 mg twice a day. Doses as high as 200 mg per day have been used in the therapy of breast cancer, but high doses are associated with retinal degeneration.

Tamoxifen is used for the endocrine treatment of women with ER-positive metastatic breast cancer or following primary tumor excision as adjuvant therapy, where it is used either alone or in sequence with adjuvant chemotherapy.

Tamoxifen also is used in premenopausal women with ER-positive tumors. Disease response rates are similar to those seen in postmenopausal patients. Alternative or additional antiestrogen strategies
in premenopausal women include oophorectomy or gonadotropin-releasing hormone analogs (see Chapter 55). The combined use of tamoxifen and a gonadotropin-releasing hormone analog (to reduce high estrogen levels resulting from tamoxifen effects on the gonadal-pituitary axis) has been shown to yield better response rates and improved overall survival than has either drug alone (Klijn et al., 2000).

The NOLVADEX Adjuvant Trial Organization (NATO) study indicated an overall disease-free survival advantage for patients receiving tamoxifen. Five years of adjuvant therapy with tamoxifen yielded superior results compared to 1 or 2 years of therapy (Swedish Breast Cancer Cooperative Group, 1996; Early Breast Cancer Trialists’ Collaborative Group, 1998). Therefore, although the optimal duration of tamoxifen has not been fully determined, randomized trials have demonstrated superiority of 5 years over shorter durations. One clinical trial evaluating the administration of tamoxifen for more than 5 years failed to show benefit of continued therapy, and a trend toward worse outcomes in women who received a longer duration (Fisher et al., 2001).

Tamoxifen also has shown effectiveness in initial trials for preventing breast cancer in women at increased risk (Strasser-Weippl and Goss, 2004). These studies were prompted by preclinical experiments showing prevention of tumors in animal models and also by the observation of reduced contralateral new primary breast tumors in women receiving adjuvant tamoxifen for early-stage breast cancer (Early Breast Cancer Trialists’ Collaborative Group, 1998; Fisher et al., 2001). Tamoxifen only reduces ER-positive tumors without affecting ER-negative tumors, which contribute disproportionately to breast cancer mortality. Additional clinical studies are ongoing (Riggs and Hartmann, 2003).

Clinical Toxicity. The common adverse reactions to tamoxifen include vasomotor symptoms (hot flushes), atrophy of the lining of the vagina, hair loss, nausea, and vomiting. These may occur in as many as 25% of patients and are rarely sufficiently severe to require discontinuation of therapy. Menstrual irregularities, vaginal bleeding and discharge, pruritus vulvae, and dermatitis occur frequently, depending on the menopausal state of the patient. Although side effects are common in women taking tamoxifen, overall quality of life appears not to be impaired (Day et al., 1999).

Tamoxifen also increases the incidence of endometrial cancer by two- to threefold, particularly in older postmenopausal women who receive 20 mg per day for 2 years or longer. In general, tamoxifen-associated endometrial cancers are reported as low-grade and early-stage tumors (O’Regan and Jordan, 2001). Standard practice guidelines from the National Comprehensive Cancer Network recommend monitoring and reporting of abnormal vaginal bleeding with prompt evaluation for endometrial cancer in women with an intact uterus (National Comprehensive Cancer Network Clinical Practice Guidelines in Oncology, 2004).

Tamoxifen increases the risk of thromboembolic events, but this is age dependent and also frequently related to operative procedures. Hence, it is recommended to discontinue tamoxifen prior to elective surgery. Because tamoxifen is associated with thromboembolism, consideration of screening evaluation of factor V Leiden and activated protein C levels has been suggested for women considering tamoxifen, though this has not become a standard of clinical practice (Cushman et al., 2003). Like estrogen, tamoxifen is a hepatic carcinogen in animals, although increases in primary hepatocellular carcinoma have not been reported in patients on the drug. Tamoxifen causes retinal deposits, decreased visual acuity, and cataracts in occasional patients, although the frequency of these changes is uncertain.

In addition to its ability to prevent recurrence or the development of primary breast cancer, tamoxifen has other end-organ benefits related to its partial estrogenic action. For example, it may slow the development of osteoporosis in postmenopausal women (Fornander et al., 1990). In addition, like certain estrogens, tamoxifen lowers total serum cholesterol, LDL cholesterol, and lipoproteins, and raises apolipoprotein A-I levels, potentially decreasing the risk of myocardial infarction (Love et al., 1994).

Toremifene. Toremifene (FARESTON) is a triphenylethylene derivative of tamoxifen and has a similar pharmacological profile. Toremifene is indicated for the treatment of breast cancer in women with tumors that are ER-positive or of unknown receptor status.

In preclinical models, toremifene has activity against breast cancer cells in vitro and in vivo similar to that of tamoxifen. Unlike tamoxifen, however, toremifene is not hepatocarcinogenic in experimental animals. Two adjuvant studies were initiated to compare efficacy of these two agents, and in particular long-term tolerability and safety, in early-stage breast cancer. In the largest of these studies, 1480 postmenopausal patients with lymph node–positive disease were randomized to receive adjuvant tamoxifen (20 mg daily) or toremifene (40 mg daily) for 5 years. Although longer follow-up is needed, there were no significant differences in efficacy or tolerability after a median follow-up of 4.4 years, and the number of subsequent second cancers was similar (Howell et al., 2004a). Other head-to-head comparisons of toremifene and tamoxifen in prospective, randomized clinical trials have shown that toremifene has generally similar efficacy and adverse events to tamoxifen (Riggs and Hartmann, 2003). However, in vitro in a low-estrogen environment, toremifene has approximately 40 times lower estrogen agonist effect than tamoxifen. This may make toremifene more effective in combination with an aromatase inhibitor than tamoxifen (Di Salle et al., 1990) and this is the subject of ongoing clinical trials.

Selective Estrogen-Receptor Downregulators

SERDs, also termed “pure anti-estrogens,” include compounds such as fulvestrant, RU 58668, SR 16234, ZD 164384, and ZK 191703. SERDs, unlike SERMs, are devoid of any estrogen agonist activity. The lead compound of this class currently approved for the treatment of advanced breast cancer is fulvestrant.

Fulvestrant. Fulvestrant (FASLODEX) is the first FDA approved agent in the new class of estrogen-receptor downregulators, which were hypothesized to have an improved safety profile, faster onset, and longer duration of action than the SERMs due to their pure ER antagonist activity (Robertson, 2002). Fulvestrant was approved in
2002 for postmenopausal women with hormone receptor-positive metastatic breast cancer that has progressed despite antiestrogen therapy. 

**Mechanism of Action.** Fulvestrant is a steroidal antiestrogen that binds to the ER with an affinity more than 100 times that of tamoxifen, inhibits its dimerization, and increases its degradation. This appears to occur because fulvestrant’s long, bulky side-chain at the 7α position sterically hinders receptor dimerization, leading to increased ER turnover and disruption of nuclear localization. Unlike tamoxifen, which stabilizes or even increases ER expression, fulvestrant reduces the number of ER molecules in cells, both in vitro and in vivo (Howell et al., 2004b).

Preclinical studies suggest that as a consequence of this ER “downregulation,” ER-mediated transcription is abolished, completely suppressing the expression of estrogen-dependent genes (Howell et al., 2004b). This difference in the activity of fulvestrant likely explains why fulvestrant demonstrates efficacy against tamoxifen-resistant breast cancer. However, the hypothesis that fulvestrant provides more effective antiestrogen activity than tamoxifen was not confirmed by a clinical trial comparing fulvestrant (250 mg intramuscularly monthly) with tamoxifen (20 mg orally daily) as first-line therapy in metastatic breast cancer (Howell et al., 2004a).

**Absorption, Fate, and Excretion.** Maximum plasma concentrations are reached about 7 days after intramuscular administration of fulvestrant and are maintained over a period of 1 month. The plasma half-life is approximately 40 days. Steady-state concentrations are reached after 3 to 6 monthly injections. There is extensive and rapid distribution, predominantly to the extravascular compartment.

Various pathways, similar to those of steroid metabolism including oxidation, aromatic hydroxylation, and conjugation, extensively metabolize fulvestrant. CYP3A4 appears to be the only CYP isoenzyme involved in the oxidation of fulvestrant. Several preclinical and clinical studies have confirmed that fulvestrant is not subject to CYP3A4 interactions that might affect the safety or efficacy of the drug. The putative metabolites possess no estrogenic activity and only the 17-keto compound demonstrates a level of antiestrogenic activity about 4.5 times less than that of fulvestrant. The major route of excretion is via the feces, with less than 1% being excreted in the urine (Robertson and Harrison, 2004).

**Therapeutic Uses.** Fulvestrant typically is administered as a 250-mg intramuscular injection at monthly intervals. It is used in postmenopausal women as antiestrogen therapy of hormone receptor-positive metastatic breast cancer after progression on first-line antiestrogen therapy such as tamoxifen (Strasser-Weippl and Goss, 2004). Fulvestrant is at least as effective in this setting as the third-generation aromatase inhibitor anastrozole.

F fulvestrant 250 mg (administered as a once-monthly 5-ml intramuscular injection) also has been compared with tamoxifen 20 mg (orally once daily) in a trial of postmenopausal women with ER-positive and/or progesterone receptor (PR)-positive or ER/PR-unknown metastatic breast cancer who had not previously received endocrine or chemotherapy. There was no difference between fulvestrant and tamoxifen in time to disease progression in either the entire study population or the subset of patients with ER- and/or PR-positive disease. Observed differences in other efficacy endpoints favored tamoxifen, and fulvestrant equivalence was not demonstrated (Vergote and Robertson, 2004). The long time to steady-state plasma levels for fulvestrant has brought into question the results of existing studies, and trials are in progress to test the relative efficacy of giving an initial loading dose followed by regular monthly injections.

**Clinical Toxicity.** Fulvestrant generally is well tolerated with the most common adverse events being nausea, asthenia, pain, vasodilatation (hot flushes), and headache. Injection site reactions, seen in about 7% of patients, are reduced by giving the injection slowly. In the study comparing anastrozole and fulvestrant, quality-of-life outcome measures were maintained over time with no significant difference between the drugs (Vergote and Robertson, 2004).

### AROMATASE INHIBITORS

Aromatase is the product of the *CYP19* gene. CYP19 is highly expressed in human placenta and in granulosa cells of ovarian follicles, where its expression depends on cyclical gonadotropin stimulation. Aromatase also is present, at lower levels, in several nonglandular tissues, including subcutaneous fat, liver, muscle, brain, normal breast, and breast-cancer tissue (Smith and Dowsett, 2003). The aromatase enzyme is responsible for the conversion of androstenedione and testosterone to the estrogens, estrone (E1) and estradiol (E2), respectively. In postmenopausal women, this conversion occurs primarily in peripheral tissues while estrogen production in premenopausal women is primarily from the ovary.

Aromatase inhibitors (AIs) are a newer class of drugs that inhibit the function of the aromatase enzyme. In postmenopausal women, AIs can suppress most of the peripheral aromatase activity, leading to profound estrogen deprivation. This strategy of estrogen deprivation of ER-positive breast cancer cells is in contrast to the ER-binding antagonistic activity that SERMs and SERDs exert.

Based on when they were developed, AIs are classified as first-, second-, or third-generation. In addition, they are further classified as type 1 (steroidal aromatase inactivator) or type 2 (nonsteroidal aromatase inhibitor) inhibitors according to their mechanism of action. Type 1 inhibitors are steroidal analogs of androstenedione. Androstenedione analogs bind to the same site on the aromatase molecule, but unlike androstenedione, they bind irreversibly because of their conversion to reactive intermediates by aromatase. Thus, they commonly are known as aromatase inactivators. Type 2 inhibitors are nonsteroidal and bind reversibly to the heme group of the enzyme by way of a basic nitrogen atom (Smith and Dowsett, 2003) (Figure 51–19).
First- and Second-Generation Aromatase Inhibitors

Aminogluthethimide (CYTADREN; AG), a first-generation type 2 AI, originally was developed as an anticonvulsant but was subsequently found to inhibit the synthesis of adrenocortical steroids (see Chapter 59). AG is a nonspecific weak AI, administered as a 250-mg dose four times daily with hydrocortisone supplementation because of unwanted adrenal suppression. Because of significant toxicities related to its anticonvulsant structure and its relatively weak inhibition of aromatase, its use has declined considerably with the advent of newer AIs.

Second-generation AIs include formestane (4-hydroxy-androstenedione; LENTARON), a type 1 steroidal inactivator; fadrozole, a type 2 imidazole; and rogletimide (pyridogluthethimide), a type 2 inhibitor structurally similar to aminogluthethimide. Formestane was the first steroidal aromatase inactivator widely used for the treatment of breast cancer patients (Goss, 1986). Because of better aromatase inhibition in vivo following parenteral administration, it is administered as an intramuscular depot injection. However, formestane has also been shown to be active when given orally. It suppresses plasma sex hormone–binding globulin (SHBG), which is interpreted as an androgenic side effect. The response rates in phase II and III trials were about 25% to 40%. Due to the introduction of novel compounds, especially exemestane, formestane is not widely used today (Geisler, 2003).

Third-Generation Aromatase Inhibitors

The third-generation inhibitors, developed in the 1990s, include the type 1 steroidal agent exemestane and the type 2 nonsteroidal imidazoles anastrozole and letrozole. Currently, third-generation AIs are most commonly used for the treatment of early-stage and advanced breast cancer.

Anastrozole. Mechanism of Action. Anastrozole is a potent and selective triazole AI. Anastrozole, like letrozole, binds competitively and specifically to the heme of the CYP19. Anastrozole 1 or 10 mg administered once daily for 28 days reduces total body aromatization by
96.7% and 98.1%, respectively. In addition, anastrozole reduces local aromatization in large, ER-positive breast tumors.

Anastrozole has no clinically significant effect on adrenal glucocorticoid or mineralocorticoid synthesis in postmenopausal women. Anastrozole also has no effect on the adrenocorticotropic hormone–stimulated release of cortisol or aldosterone, or on plasma concentrations of luteinizing hormone or follicle-stimulating hormone. Anastrozole, unlike AG, has no effect on thyroid-stimulating hormone (Wellington and Faulds, 2002).

Absorption, Fate, and Excretion. Anastrozole is absorbed rapidly after oral administration with maximal plasma concentration occurring after 2 hours. Repeated dosing increases plasma concentrations of anastrozole and steady-state is attained after 7 days. Although the rate of absorption is delayed after a high-fat breakfast, steady-state concentrations are not generally affected upon multiple dosing. Anastrozole is metabolized by N-dealkylation, hydroxylation, and glucuronidation. The main metabolite of anastrozole is a triazole. In addition, several other metabolites with no pharmacological activity are formed. Less than 10% of the drug is excreted as the unmetabolized parent compound. The principal excretory pathway is via the liver. The pharmacokinetics of anastrozole, which can be affected by drug interactions via the CYP system, is unaffected by coadministration of tamoxifen or cimetidine (Köberle and Thürlimann, 2001).

Therapeutic Uses. Anastrozole (ARIMIDEX), 1 mg oral daily dose, has shown efficacy in the treatment of postmenopausal women with early-stage or advanced, hormone-receptor positive breast cancer. In early-stage breast cancer, anastrozole was significantly more effective than tamoxifen in terms of time to tumor recurrence and odds of a primary contralateral tumor (Baum et al., 2002).

In the setting of advanced breast cancer, the results of two large, randomized trials in postmenopausal women with disease progression while taking tamoxifen showed a statistically significant survival advantage for anastrozole 1 mg/day over megestrol acetate 40 mg four times daily. In another phase III clinical trial involving >1000 postmenopausal women with advanced breast cancer, anastrozole showed a statistically significant advantage over tamoxifen in median time to disease progression in >600 patients who were known to have ER- or PR-positive disease.

Clinical Toxicity. Anastrozole has been associated with a significantly lower incidence of vaginal bleeding, vaginal discharge, hot flushes, endometrial cancer, ischemic cerebrovascular events, venous thromboembolic events, and deep vein thrombosis, including pulmonary embolism. Tamoxifen is associated with a lower incidence of musculoskeletal disorders and fracture. In the advanced disease setting, anastrozole is as well tolerated as megestrol, while weight gain is significantly increased by megestrol compared to anastrozole. In addition, anastrozole is as well tolerated as tamoxifen, with a low rate of withdrawal due to drug-related adverse events (2%). In addition, anastrozole is associated with fewer thromboembolic events and episodes of vaginal bleeding than tamoxifen (Wellington and Faulds, 2002; Nabholtz and Reese, 2002).

Letrozole. Mechanism of Action. In postmenopausal women with primary breast cancer, letrozole inhibits whole body aromatization and reduces local aromatization within the tumors. The drug has no significant effect on the synthesis of adrenal steroids or thyroid hormone and does not alter levels of a range of other hormones. Letrozole also reduces cellular markers of proliferation to a significantly greater extent than tamoxifen in human estrogen-dependent tumors that overexpress human epidermal growth factor receptors (HER)1 and/or HER2/neu.

Letrozole increases the levels of bone resorption markers in healthy postmenopausal women and in those with a history of breast disease but without current active disease. Letrozole has not demonstrated a consistent effect on serum lipid levels in healthy women or postmenopausal women with breast cancer (Simpson et al., 2004).

Absorption, Fate, and Excretion. Letrozole is rapidly absorbed after oral administration and maximum plasma levels are reached about 1 hour after ingestion. Letrozole has a bioavailability of 99.9%. Steady-state plasma concentrations of letrozole are reached after 2 to 6 weeks of treatment. Following metabolism by CYP2A6 and CYP3A4, letrozole is eliminated as an inactive carbinol metabolite mainly via the kidneys. Due to the low total body clearance (2.21 L/h), the elimination half-life is about 40 to 42 hours (Geissler, 2003).

Therapeutic Uses. Letrozole (FEMARA), 2.5 mg administered orally once daily, has shown efficacy in the treatment of postmenopausal women with early-stage or advanced, hormone-receptor positive breast cancer.

In early-stage disease, extending adjuvant endocrine therapy with letrozole (beyond the standard 5-year period of tamoxifen) improved disease-free survival compared with placebo (Goss et al., 2003) and improved overall survival in the subset of patients with positive axillary nodes (Goss et al., 2004).

In advanced breast cancer, letrozole is superior to tamoxifen as first-line treatment; time to disease progression is significantly longer and objective response rate is significantly greater with letrozole, but median overall survival is similar between groups. As second-line therapy of advanced breast cancer that has progressed on antiestrogen therapy, letrozole shows efficacy equivalent to that of anastrozole and similar to or better than that of megestrol (Simpson et al., 2004).

Clinical Toxicity. Similarly to tamoxifen, letrozole generally is well tolerated; the most common treatment-related adverse events are hot flushes, nausea, and hair thinning. In patients with tumors that progressed on antiestrogen therapy, letrozole was tolerated at least as well as, or better than, megestrol. In the trial of extended adjuvant therapy, adverse events reported more frequently with letrozole than placebo were hot flushes, arthralgia, myalgia, and arthritis, but cessation of letrozole was no more frequent than placebo in this double-blind trial. A greater number of new diagnoses of osteoporosis occurred among women receiving letrozole, but the long-term effects on bone mineral density or lipid metabolism have yet to be determined.

Exemestane. Mechanism of Action. Exemestane (AROMASIN) is a more potent, orally administered analog of the natural substrate androstenedione that lowers estrogen.
levels more effectively than does formestane. In contrast to the reversible competitive inhibitors, anastrozole and letrozole, exemestane irreversibly inactivates the enzyme, and therefore is referred to as a “suicide substrate.” Doses of 25 mg per day inhibit aromatase activity by 98% and lower plasma estrone and estradiol levels by about 90%. It has less androgenic activity than formestane, but otherwise has a similar toxicity profile.

Absorption, Fate, and Excretion. Exemestane is rapidly absorbed from the gastrointestinal tract, reaching maximum plasma levels after 2 hours. Its absorption is increased by 40% after a high-fat meal. Exemestane is extensively protein-bound in plasma and has a terminal half-life of approximately 24 hours. It is extensively metabolized in the liver to inactive metabolites. A key metabolite, 17-hydroxyexemestane, which is formed by reduction of the 17-oxo group via 17-β-hydroxysteroid dehydrogenase, has weak androgenic activity, which also could contribute to antitumor activity (Lønning et al., 2000). Excretion is distributed almost equally between the urine and feces. Since significant quantities of active metabolites are excreted in the urine, exemestane doses should be adjusted in patients with renal dysfunction.

Therapeutic Uses. Exemestane has been tested in a randomized clinical trial in postmenopausal women with estrogen-receptor positive breast cancer. Women who had completed 2 to 3 years of adjuvant tamoxifen were randomized to complete a total of 5 years of adjuvant treatment with tamoxifen or exemestane (Coombes et al., 2004). The unadjusted hazard ratio in the exemestane group vs. the tamoxifen group was 0.68, representing a 32% reduction in risk and corresponding to an absolute benefit in terms of disease-free survival of 4.7% at 3 years after randomization. Overall survival was not significantly different in the two groups.

In advanced breast cancer, exemestane has been evaluated in a phase III trial against megestrol in women with disease progressing on prior antiestrogen therapy. Patients receiving exemestane had a similar response rate but improved time to disease progression, time to treatment failure, and longer duration of survival compared with those taking megestrol acetate. Responses to treatment also have been shown in women with disease progressing on prior nonsteroidal aromatase inhibitors.

Clinical Toxicity. Exemestane generally is well tolerated. Discontinuations due to toxicity are not common (2.8%). Hot flushes, nausea, fatigue, increased sweating, peripheral edema, and increased appetite have been reported. In the trial comparing exemestane to tamoxifen in early-stage breast cancer, exemestane was associated with more frequent arthralgia and diarrhea, but gynecologic symptoms, vaginal bleeding, and muscle cramps were more frequent with tamoxifen. Visual disturbances and clinical fractures were more common with exemestane (Coombes et al., 2004).

ANTHOCYANIN THERAPY
IN PROSTATE CANCER

Carcinoma of the prostate is uniquely dependent upon hormonal stimulation with androgens. Huggins and colleagues pioneered the use of anti-androgenic therapy in treating prostate cancer more than half a century ago. Early studies noted that either surgical castration (bilateral orchiectomy) or the administration of injectable hormonal therapies that induced medical castration were effective forms of treatment. Androgen deprivation therapy (ADT) through either surgical or medical castration has been the mainstay of treatment for advanced prostate cancer since that time.

Among men with metastatic prostate cancer, >90% have an initial favorable response to primary hormonal therapy with ADT. This is manifest as disease regression or stabilization and relief of cancer-related symptoms. The average time to progression is 18 to 36 months, making ADT one of the longest-lasting beneficial treatments in any advanced solid tumor. A large trial found a survival benefit to ADT (Byar and Corle, 1988; Seidenfeld et al., 2000). In numerous trials of ADT, its positive effects were diluted to some extent by increased cardiovascular toxicity in men receiving high doses of estrogen as the primary form of ADT (Seidenfeld et al., 2000; Hedlund and Henriksson, 2000).

Disease progression after ADT signifies an androgen-independent state, with subsequent median survival of only 12 months. However, many men will respond to secondary hormonal therapy even after failure of ADT. Secondary hormonal treatments include androgen receptor (AR) blockers, adrenal androgen synthesis inhibitors, and estrogenic agents. Responses are more variable than to primary hormonal therapy, but a substantial portion of men benefit from these well-tolerated forms of treatment. When patients become refractory to any form of hormonal therapy, their management usually involves chemotherapeutic agents.

Common side effects of all forms of antiandrogen hormonal therapy include vasomotor flushing, loss of libido, gynecomastia, increased weight, loss of bone mineral density (BMD), and loss of muscle mass. There is variability to these side effects. For example, AR blockers compared with GnRH agonists cause more gynecomastia, but less bone loss, vasomotor flushing, and loss of BMD (Spetz et al., 2001; Smith et al., 2004). Importantly, the increased cardiovascular toxicity observed with high doses of estrogen is not observed with other forms of ADT.

Gonadotropin-Releasing Hormone Agonists and Antagonists

The most common form of ADT involves chemical suppression of the pituitary with gonadotropin-releasing hormone (GnRH) agonists. GnRH agonists cause an initial surge in levels of luteinizing hormone (LH) and follicle-stimulating hormone (FSH), followed by inhibition of gonadotropin release (see Chapter 55). This results in reduction of testicular production of testosterone to castrate levels. GnRH agonists in common use include leuprolide (LUPRON, others), goserelin (ZOLADEX), triptorelin (TRELSTAR), and buserelin (SUPREFACT; not
available in the United States). Randomized trials have shown that GnRH analogs are as effective as diethylstilbestrol and bilateral orchiectomy in the treatment of men with prostate cancer (Seidenfeld et al., 2000). One important side effect, a transient flare of disease, may result from the initial surge of gonadotropins, and can be avoided by temporary (2 to 4 weeks) administration of AR blockers or by the use of GnRH antagonists (see below).

Complete androgen blockade (CAB) refers to combination therapy with androgen-receptor blockers and GnRH agonists. However, the advantages of long-term CAB over GnRH agonists alone are questionable. Large meta-analyses of numerous trials show a small advantage to CAB that is clinically insignificant (Prostate Cancer Trialists’ Collaborative Group, 2000; Samson et al., 2002).

Treatment with GnRH antagonists rapidly reduces serum testosterone levels, without the transient initial increase observed after GnRH agonists (Tomera et al., 2001). One such compound is abarelix (PLENAXIS), which effectively reduces serum testosterone to castrate levels within a week in most men (Trachtenberg et al., 2002). Other than avoidance of the initial flare, GnRH antagonist therapy offers no advantage compared with GnRH agonists, and GnRH antagonists currently are available only in the 1-month depot formulation.

Androgen Receptor Blockers

Compounds that competitively inhibit the natural ligands of the androgen receptor (AR) are called AR blockers, often referred to simply as anti-androgens. As discussed above, when given with GnRH agonists, the combination therapy is called CAB, since androgens from the adrenals are blocked, in addition to gonad-derived androgens. Currently, AR blockers as monotherapy are not indicated as routine, first-line treatment for patients with advanced prostate cancer, although some evidence points to reduced adverse effects of AR blockers relative to GnRH agonists on bone density and body composition (Smith et al., 2004).

From a structural standpoint, AR blockers are classified as steroidal, including cyproterone (ANDROCUR) and megestrol, or nonsteroidal, including flutamide (EULEXIN, others), nilutamide (NILANDRON), and bicalutamide (CASODEX) (Reid et al., 1999). The nonsteroidal AR blockers (Figure 51–20) are more commonly used in clinical practice. They inhibit ligand binding and consequent AR translocation from the cytoplasm to the nucleus. Unlike the steroidal agents, nonsteroidal AR blockers interrupt the negative feedback of testosterone to the pituitary-hypothalamic axis, resulting in increased serum testosterone levels, thus attenuating the loss of libido and potency (Knuth et al., 1984).

All of the nonsteroidal AR blockers may cause vasomotor flushing, gynecomastia, mastodynia, and variable degrees of decreased libido and potency. Bicalutamide has a serum half-life of 5 to 6 days, and is administered at a dose of 50 mg/day when given in combination with GnRH agonist therapy. Bicalutamide is well tolerated at higher doses as well, with rare additional side effects. Both enantiomers of bicalutamide undergo glucuronidation to inactive metabolites, and the parent compounds and metabolites are eliminated in bile and urine. The elimination half-life of bicalutamide is increased in severe hepatic insufficiency and is unchanged in renal insufficiency. Flutamide is administered at 250 mg three times a day, and may cause diarrhea, nausea, and reversible liver abnormalities. It has one major metabolite, hydroxyflutamide, that is biologically active, and at least five other minor metabolites. The parent compound and metabolites are mainly excreted in the urine. The elimination half-life of nilutamide is 38 to 40 hours, which allows once-daily dosing at 150 mg/day.
The therapy of cancer has improved dramatically during the past half century. This improvement can be traced to a number of factors: a better understanding of cancer’s causes and natural history, better technologies for early detection and diagnosis, improved control of primary tumors through better surgery and radiation therapy, and more effective drugs. It is instructive to remember that at the end of World War II, there were no drugs to treat this group of diseases (Chabner and Roberts, 2005). The evolution of drug therapy for cancer has progressed rapidly, from alkylating agents and antimetabolites to natural products, and most recently, molecularly targeted drugs such as imatinib and gefitinib. As our understanding of the biology of cancer improves, new targets for therapy are being identified daily, and small molecules and monoclonal antibodies are being developed to test the validity of these targets in human cancer.

Although imatinib has been a spectacular success in controlling the chronic phase of CML, it clearly does not eradicate the disease. CML cells develop resistance through point mutations in the target protein or through amplification of the expression of the target gene, the BCR-ABL kinase gene. Importantly, these resistance mutations exist prior to drug exposure and reflect the inherent mutability of cancer cells, as previously reflected in the experience with cytotoxic agents. Thus, it seems likely that single agents, whether cytotoxic or molecularly targeted, will not cure cancer. Future endeavors will include determining how to use the growing list of potential agents in combination, the only strategy that can address the inherent ability of cancer to escape single agents.

There are two challenges standing in the way of more effective cancer treatment. The first is the search for better drugs based on our rapidly evolving knowledge of cancer biology. The second challenge, one that has never been adequately addressed in the age of cytotoxic chemotherapy, is to identify the determinants of response (Roberts and Chabner, 2004) and to select drugs for individual patients. Traditionally, cytotoxic therapies were administered based on regimens devised for broad histologic categories of cancer, such as lung, breast, or colon cancer. Single-agent response rates rarely exceeded 30% for these tumors. Increasingly, however, with the advent of technologies for measurement of targets in tumor samples, it has become possible to select patients with higher rates of response to hormonal agents, monoclonal antibodies, and now targeted therapies such as gefitinib. Thus, in the future, therapies will be selected based both on histology and on the molecular features of the tumor. Furthermore, through characterization of genetic polymorphisms, it also will be possible to predict individual susceptibility to toxicity. Thus, drug selection will be guided by molecular testing of both patient and tumor. The result will be more effective, less wasteful, and less toxic therapy for cancer.

THE IMMUNE RESPONSE

The immune system evolved to discriminate self from nonself. Multicellular organisms were faced with the problem of destroying infectious invaders (microbes) or dysregulated self (tumors) while leaving normal cells intact. These organisms responded by developing a robust array of receptor-mediated sensing and effector mechanisms broadly described as innate and adaptive. Innate, or natural, immunity is primitive, does not require priming, and is of relatively low affinity, but is broadly reactive. Adaptive, or learned, immunity is antigen-specific, depends upon antigen exposure or priming, and can be of very high affinity. The two arms of immunity work closely together, with the innate immune system being most active early in an immune response and adaptive immunity becoming progressively dominant over time. The major effectors of innate immunity are complement, granulocytes, monocytes/macrophages, natural killer cells, mast cells, and basophils. The major effectors of adaptive immunity are B and T lymphocytes. B lymphocytes make antibodies; T lymphocytes function as helper, cytolytic, and regulatory (suppressor) cells. These cells are important in the normal immune response to infection and tumors, but also mediate transplant rejection and autoimmunity (Janeway et al., 2001; Paul, 1999). Immunoglobulins (antibodies) on the B lymphocyte surface are receptors for a large variety of specific structural conformations. In contrast, T lymphocytes recognize antigens as peptide fragments in the context of self major histocompatibility complex (MHC) antigens (called human leukocyte antigens [HLA] in human beings) on the surface of antigen-presenting cells, such as dendritic cells, macrophages, and other cell types expressing MHC class I (HLA-A, -B, and -C) and class II antigens (HLA-DR, -DP, and -DQ) in human beings. Once activated by specific antigen recognition via their respective clonally restricted cell-surface receptors, both B and T lymphocytes are triggered to differentiate and divide, leading to release of soluble mediators (cytokines, lymphokines) that perform as effectors and regulators of the immune response.

The impact of the immune system in human disease is enormous. Developing vaccines against emerging infectious agents such as human immunodeficiency virus (HIV) and Ebola virus is among the most critical challenges facing the research community. Immune system-mediated diseases are significant medical problems.
Immunological diseases are growing at epidemic proportions that require aggressive and innovative approaches to develop new treatments. These diseases include a broad spectrum of autoimmune diseases such as rheumatoid arthritis, type 1 diabetes mellitus, systemic lupus erythematosus, and multiple sclerosis; solid tumors and hematologic malignancies; infectious diseases; asthma; and various allergic conditions. Furthermore, one of the great therapeutic opportunities for the treatment of many disorders is organ transplantation. However, immune system-mediated graft rejection remains the single greatest barrier to widespread use of this technology. An improved understanding of the immune system has led to the development of new therapies to treat immune system-mediated diseases.

This chapter briefly reviews drugs used to modulate the immune response in three ways: immunosuppression, tolerance, and immunostimulation. Four major classes of immunosuppressive drugs are discussed: glucocorticoids (see Chapter 59), calcineurin inhibitors, antiproliferative and antimetabolic agents (see Chapter 51), and antibodies. The “holy grail” of immunomodulation is the induction and maintenance of immune tolerance, the active state of antigen-specific nonresponsiveness. Approaches expected to overcome the risks of infections and tumors with immunosuppression are reviewed. These include costimulatory blockade, donor-cell chimerism, soluble human leukocyte antigens (HLA), and antigen-based therapies. A general discussion of the limited number of immunostimulant agents is presented, followed by an overview of active and passive immunization, and concluding with a brief case study of immunotherapy for multiple sclerosis.

**IMMUNOSUPPRESSION**

Immunosuppressive drugs are used to dampen the immune response in organ transplantation and autoimmune disease. In transplantation, the major classes of immunosuppressive drugs used today are: (1) glucocorticoids, (2) calcineurin inhibitors, (3) antiproliferative/antimetabolic agents, and (4) biologics (antibodies). These drugs have met with a high degree of clinical success in treating conditions such as acute immune rejection of organ transplants and severe autoimmune diseases. However, such therapies require lifelong use and nonspecifically suppress the entire immune system, exposing patients to considerably higher risks of infection and cancer. The calcineurin inhibitors and glucocorticoids, in particular, are nephrotoxic and diabetogenic, respectively, thus restricting their usefulness in a variety of clinical settings.

Monoclonal and polyclonal antibody preparations directed at reactive T cells are important adjunct therapies and provide a unique opportunity to target specifically immune-reactive cells. Finally, newer small molecules and antibodies have expanded the arsenal of immunosuppressives. In particular, mTOR (mammalian target of rapamycin) inhibitors (sirolimus, everolimus) and anti-CD25 [interleukin (IL)-2 receptor] antibodies (basiliximab, daclizumab) target growth factor pathways, substantially limiting clonal expansion and thus potentially promoting tolerance. Immunosuppressive drugs used more commonly today are described below. Many more selective therapeutic agents under development are expected to revolutionize immunotherapy in the next decade.

**General Approach to Organ Transplantation Therapy**

Organ transplant therapy is organized around five general principles. The first principle is careful patient preparation and selection of the best available ABO blood type–compatible HLA match for organ donation. Second, a multitiered approach to immunosuppressive drug therapy, similar to that in cancer chemotherapy, is employed. Several agents are used simultaneously, each of which is directed at a different molecular target within the allograft response (Table 52–1; Hong and Kahan, 2000a). Synergistic effects permit use of the various agents at relatively low doses, thereby limiting specific toxicities while maximizing the immunosuppressive effect. The third principle is that greater immunosuppression is required to gain early engraftment and/or to treat established rejection than to maintain long-term immunosuppression. Therefore, intensive induction and lower-dose maintenance drug protocols are employed. Fourth, careful investigation of each episode of transplant dysfunction is required, including evaluation for rejection, drug toxicity, and infection, keeping in mind that these various problems can and often do coexist. Organ-specific problems (e.g., obstruction in the case of kidney transplants) must also be considered. The fifth principle, which is common to all drugs, is that a drug should be reduced or withdrawn if its toxicity exceeds its benefit.

**Biologic Induction Therapy.** Induction therapy with polyclonal and monoclonal antibodies (mAbs) has been an important component of immunosuppression dating back to the 1960s, when Starzl and colleagues demonstrated the beneficial effect of antilymphocyte globulin (ALG) in the prophylaxis of rejection in renal transplant recipients. Over the past 40 years, several polyclonal antilymphocyte preparations have been used in renal transplantation; however, only 2 preparations are currently FDA approved: lymphocyte immune globulin (ATGAM) and antithymocyte globulin (THYMOGLOBULIN) (Howard et al., 1997; Monaco, 1999). Another important milestone in biologic therapy was the development of mAbs and the introduction of the murine anti-CD3 mAb (muromonab-CD3 or OKT3) (Ortho Multicenter Transplant Study Group, 1985).

In many transplant centers, induction therapy with biologic agents is used to delay the use of nephrotoxic calcineurin inhibitors or to intensify the initial immunosuppressive therapy in patients at high risk of rejection (i.e., repeat transplants, broadly presensi-
mediated T-cell activation by binding to the anti–IL-2R mAbs, do not deplete T lymphocytes, but rather block IL-2–
tion and antigen presentation. The second group of biologic agents, the
to deplete the recipient's CD3-positive cells at the time of transplanta-
produces immune modulation); their efficacy derives from their ability
modulators. The depleting agents consist of lymphocyte immune globu-

randomized double-blind prospective trials (Vincenti et al., 1998; Nashan et al., 1997; Nashan et al., 1999; Kahan et al., 1999b).
Biologic agents for induction therapy in the prophylaxis of rejection
currently are used in approximately 70% of de novo transplant patients
and have been propelled by several factors, including the introduction of the safe anti–IL-2R antibodies and the emergence of antithymocyte globulin as a safer and more effective alternative to lymphocyte immune globulin or muromonab-CD3 mAb. Biologics for induction can be divided into 2 groups: the depleting agents and the immune modulators. The depleting agents consist of lymphocyte immune globulin, antithymocyte globulin, and muromonab-CD3 mAb (the latter also produces immune modulation); their efficacy derives from their ability to deplete the recipient’s CD3-positive cells at the time of transplantation and antigen presentation. The second group of biologic agents, the anti–IL-2R mAbs, do not deplete T lymphocytes, but rather block IL-2–mediated T-cell activation by binding to the α-chain of IL-2R.
For patients with high levels of anti-HLA antibodies, humoral rejection mediated by B cells can be modified by plasmapheresis, usually given every other day for 4 to 5 treatments followed by intravenous immunoglobulin to suppress antibody production (Akalin et al., 2003; Zachary et al., 2003).

**Maintenance Immunotherapy.** The basic immunosuppressive protocols in most transplant centers use multiple drugs simultaneously.

**Adrenocortical Steroids**

The introduction of glucocorticoids as immunosuppressive drugs in the 1960s played a key role in making organ transplantation possible. Their chemistry, pharmacokinetics, and drug interactions are described in Chapter 59. Prednisone, prednisolone, and other glucocorticoids are used alone and in combination with other immunosuppressive agents for treatment of transplant rejection and autoimmune disorders.

**Mechanism of Action.** The immunosuppressive effects of glucocorticoids have long been known, but the specific mechanism(s) of their immunosuppressive action remains somewhat elusive. Glucocorticoids lyse (in some species) and induce the redistribution of lymphocytes, causing a rapid, transient decrease in peripheral blood lymphocyte counts. To effect longer-term responses, steroids bind to receptors inside cells; either these receptors, glucocorticoid-induced proteins, or interacting proteins regulate the transcription of numerous other genes (see Chapter 59). Additionally, glucocorticoid-receptor complexes increase 1XB expression, thereby curtailing activation of NF-κB, which increases apoptosis of activated cells (Auphan et al., 1995). Of central importance, key proinflammatory cytokines such as IL-1 and IL-6 are downregulated. T cells are inhibited from making IL-2 and proliferating. The activation of cytotoxic T lymphocytes is inhibited. Neutrophils and monocytes display poor chemotaxis and decreased lysosomal enzyme release. Therefore, glucocorticoids have broad antiinflammatory effects on multiple components of cellular immunity. In contrast, they have relatively little effect on humoral immunity.
**Therapeutic Uses.** There are numerous indications for glucocorticoids (Zoorob and Cender, 1998). They commonly are combined with other immunosuppressive agents to prevent and treat transplant rejection. High dose pulses of intravenous methylprednisolone sodium succinate (SOLU-MEDROL, A-METHAPRED) are used to reverse acute transplant rejection and acute exacerbations of selected autoimmune disorders (Shinn et al., 1999; Laan et al., 1999). Glucocorticoids also are efficacious for treatment of graft-versus-host disease in bone-marrow transplantation. Glucocorticoids are used routinely to treat autoimmune disorders such as rheumatoid and other arthritides, systemic lupus erythematosus, systemic dermatomyositis, psoriasis and other skin conditions, asthma and other allergic disorders, inflammatory bowel disease, inflammatory ophthalmic diseases, autoimmune hematologic disorders, and acute exacerbations of multiple sclerosis (see below). In addition, glucocorticoids limit allergic reactions that occur with other immunosuppressive agents and are used in transplant recipients to block first-dose cytokine storm caused by treatment with muromonad-CD3 and to a lesser extent thymoglobulin (see below).

**Toxicity.** Unfortunately, the extensive use of steroids often results in disabling and life-threatening adverse effects. These effects include growth retardation in children, avascular necrosis of bone, osteopenia, increased risk of infection, poor wound healing, cataracts, hyperglycemia, and hypertension (see Chapter 59). The advent of combined glucocorticoid/cyclosporine regimens has allowed reduced doses of steroids, but steroid-induced morbidity remains a major problem in many transplant patients.

**Calcineurin Inhibitors**

Perhaps the most effective immunosuppressive drugs in routine use are the calcineurin inhibitors, cyclosporine and tacrolimus, which target intracellular signaling pathways induced as a consequence of T-cell–receptor activation (Schreiber and Crabtree, 1992). Although they are structurally unrelated (Figure 52–1) and bind to distinct, albeit related molecular targets, they inhibit normal T-cell signal transduction essentially by the same mechanism (Figure 52–2). Cyclosporine and tacrolimus do not act *per se* as immunosuppressive agents. Instead, these drugs bind to an immunophilin (cyclophilin for cyclosporine or FKBP-12 for tacrolimus), resulting in subsequent interaction with calcineurin to block its phosphatase activity. Calcineurin-catalyzed dephosphorylation is required for movement of a component of the nuclear factor of activated T lymphocytes (NFAT) into the nucleus (Figure 52–2). NFAT, in turn, is required to induce a number of cytokine genes, including that for interleukin-2 (IL-2), a prototypic T-cell growth and differentiation factor.

**Cyclosporine. Chemistry.** Cyclosporine (cyclosporin A), a cyclic polypeptide consisting of 11 amino acids, is produced by the fungus species *Beauveria nivea*. Of note, all amide nitrogens are either hydrogen bonded or methylated, the single t-amiac acid is at position 8, the methyl amide between residues 9 and 10 is in the *cis* configuration, and all other methyl amide moieties are in the *trans* form (Figure 52–1). Because cyclosporine is lipophilic and highly hydrophobic, it is formulated for clinical administration using castor oil or other strategies to ensure solubilization.

**Mechanism of Action.** Cyclosporine suppresses some humoral immunity, but is more effective against T-cell–dependent immune mechanisms such as those underlying transplant rejection and some forms of autoimmunity (Kahan, 1989). It preferentially inhibits antigen-triggered signal transduction in T lymphocytes, blunting expression of many lymphokines including IL-2, and the expression of antiapoptotic proteins. Cyclosporine forms a complex with cyclophilin, a cytoplasmic receptor protein present in target cells. This complex binds to calcineurin, inhibiting Ca^{2+}-stimulated dephosphorylation of the cytosolic component of NFAT (Schreiber and Crabtree, 1992). When cytoplasmic NFAT is dephosphorylated, it translocates to the nucleus and complexes with nuclear components required for complete T-cell activation, including transactivation of IL-2 and other lymphokine genes. Calcineurin phosphatase activity is inhibited after physical interaction with the cyclosporine/cyclophilin complex. This prevents NFAT dephosphorylation such that NFAT does not enter the nucleus, gene transcription is not activated, and the T lymphocyte fails to respond to specific antigenic stimulation. Cyclosporine also increases expression of transforming growth factor-β (TGF-β), a potent inhibitor of IL-2–stimulated T-cell proliferation and generation of cytotoxic T lymphocytes (CTL) (Khanna et al., 1994).

**Disposition and Pharmacokinetics.** Cyclosporine can be administered intravenously or orally. The intravenous preparation (SANDIMMUNE Injection) is provided as a solution in an ethanol-polyoxyethylated castor oil vehicle that must be further diluted in 0.9% sodium chloride solution or 5% dextrose solution before injection. The oral dosage forms include soft gelatin capsules and oral solutions. Cyclosporine supplied in the original soft gelatin capsule (SANDIMMUNE) is absorbed slowly with 20% to 50% bioavailability. A modified microemulsion formulation (NEORAL) is available (Noble and Markham, 1995). It has more uniform and slightly increased bioavailability compared to SANDIMMUNE and is provided as 25-mg and 100-mg soft gelatin capsules and a 100-mg/ml oral solution. Since SANDIMMUNE and NEORAL are not bioequivalent, they cannot be used interchangeably without supervision by a physician and monitoring of drug concentrations in plasma. Comparison of blood concentrations in published literature and in clinical practice must be performed with a detailed knowledge of the assay system employed.
Generic preparations of both NEORAL and SANDIMMUNE are available that are bioequivalent by FDA criteria. The generic preparations for NEORAL have been shown to be bioequivalent in normal volunteers, and, in some studies, also in transplant recipients. A consensus conference held under the auspices of the American Society of Transplantation recommended that generic preparations of cyclosporine could be used de novo in transplantation to substitute for NEORAL (Alloway et al., 2003). However, when switching between generic and NEORAL formulations, increased surveillance is recommended to ensure that drug levels remain in the therapeutic range. This need for increased monitoring is based on anecdotal experience rather than validated differences. In fact the generic preparations were comparable to NEORAL for immunosuppressive purposes in most studies. Since SANDIMMUNE and NEORAL differ in terms of their pharmacokinetics and are definitely not bioequivalent, their generic versions cannot

---

**Figure 52–1.** Chemical structures of immunosuppressive drugs: azathioprine, mycophenolate mofetil, cyclosporine, tacrolimus, and sirolimus.
be used interchangeably. This has been a source of confusion to pharmacists and patients. Transplant units need to educate patients that SANDIMMUNE and its generics are not the same as NEORAL and its generics, such that one preparation cannot be substituted for another without risk of inadequate immunosuppression or increased toxicity.

Both radioimmunoassays and high-performance liquid chromatography assays for cyclosporine and tacrolimus are available. Because these methods differ, the prescribing physician should ensure that the methods are consistent when monitoring an individual patient. Blood is most conveniently sampled before the next dose, namely a C0 or trough level. While this is convenient, it has been shown repeatedly that C0 concentrations do not reflect the area under the curve (AUC) for cyclosporine exposure in individual patients. As a practical solution to this problem and to better measure the overall exposure of a patient to the drug, it has been proposed that levels be taken 2 hours after a dose administration, so-called C2 levels (Cole et al., 2003). Some studies have shown a better correlation of C2 with the AUC, but no single time point can simulate the exposure as measured by more frequent drug sampling. In complex patients with delayed absorption, such as diabetics, the C2 level may underestimate the peak cyclosporine level obtained, and in others who are rapid absorbers the C2 level may have peaked before the blood sample is drawn. In practice if a patient has clinical signs or symptoms of toxicity, or there is unexplained rejection or renal dysfunction, a pharmacokinetic profile can be used to estimate that person’s exposure to the drug. Many clinicians, particularly those caring for transplant patients some time after the transplant, monitor cyclosporine blood levels only when a cli-
cal event (e.g., renal dysfunction or rejection) occurs. In that setting, either a C0 or C2 level helps to ascertain whether inadequate immunosuppression or drug toxicity is present. As described above, cyclosporine absorption is incomplete following oral administration and varies with the individual patient and the formulation used. The elimination of cyclosporine from the blood is generally biphasic, with a terminal half-life of 5 to 18 hours (Faulds et al., 1993; Noble and Markham, 1995). After intravenous infusion, clearance is approximately 5 to 7 ml/min per kg in adult recipients of renal transplants, but results differ by age and patient populations. For example, clearance is slower in cardiac transplant patients and more rapid in children. Thus, the intersubject variability is so large that individual monitoring is required (Faulds et al., 1993; Noble and Markham, 1995).

After oral administration of cyclosporine (as NEORAL), the time to peak blood concentrations is 1.5 to 2 hours (Faulds et al., 1993; Noble and Markham, 1995). Administration with food delays and decreases absorption. High- and low-fat meals consumed within 30 minutes of administration decrease the AUC by approximately 13% and the maximum concentration by 33%. This makes it imperative to individualize dosage regimens for outpatients.

Cyclosporine is distributed extensively outside the vascular compartment. After intravenous dosing, the steady-state volume of distribution is reportedly as high as 3 to 5 L/kg in solid-organ transplant recipients.

Only 0.1% of cyclosporine is excreted unchanged in urine (Faulds et al., 1993). Cyclosporine is extensively metabolized in the liver by CYP3A and to a lesser degree by the gastrointestinal tract and kidneys (Fahr, 1993). At least 25 metabolites have been identified in human bile, feces, blood, and urine (Christians and Sewing, 1993). Although the cyclic peptide structure of cyclosporine is relatively resistant to metabolism, the side chains are extensively metabolized. All of the metabolites have reduced biological activity and toxicity compared to the parent drug. Cyclosporine and its metabolites are excreted principally through the bile into the feces, with only about 6% being excreted in the urine. Cyclosporine also is excreted in human milk. In the presence of hepatic dysfunction, dosage adjustments are required. No adjustments generally are necessary for dialysis or renal failure patients.

**Therapeutic Uses.** Clinical indications for cyclosporine are kidney, liver, heart, and other organ transplantation; rheumatoid arthritis; and psoriasis (Faulds et al., 1993). Its use in dermatology is discussed in Chapter 62. Cyclosporine generally is recognized as the agent that ushered in the modern era of organ transplantation, increasing the rates of early engraftment, extending kidney graft survival, and making cardiac and liver transplantation possible. Cyclosporine usually is combined with other agents, especially glucocorticoids and either azathioprine or mycophenolate mofetil, and most recently, sirolimus. The dose of cyclosporine varies, depending on the organ transplanted and the other drugs used in the specific treatment protocol(s). The initial dose generally is not given before the transplant because of the concern about nephrotoxicity. Especially for renal transplant patients, therapeutic algorithms have been developed to delay cyclosporine introduction until a threshold renal function has been attained. The amount of the initial dose and reduction to maintenance dosing is sufficiently variable that no specific recommendation is provided here. Dosage is guided by signs of rejection (too low a dose), renal or other toxicity (too high a dose), and close monitoring of blood levels. Great care must be taken to differentiate renal toxicity from rejection in kidney transplant patients. Ultrasound-guided allograft biopsy is the best way to assess the reason for renal dysfunction. Because adverse reactions have been ascribed more frequently to the intravenous formulation, this route of administration is discontinued as soon as the patient is able to take the drug orally.

In rheumatoid arthritis, cyclosporine is used in severe cases that have not responded to methotrexate. Cyclosporine can be combined with methotrexate, but the levels of both drugs must be monitored closely (Baraldo et al., 1999). In psoriasis, cyclosporine is indicated for treatment of adult immunocompetent patients with severe and disabling disease for whom other systemic therapies have failed (Linden and Weinstein, 1999). Because of its mechanism of action, there is a theoretical basis for the use of cyclosporine in a variety of other T-cell–mediated diseases (Faulds et al., 1993). Cyclosporine reportedly is effective in Behçet’s acute ocular syndrome, endogenous uveitis, atopic dermatitis, inflammatory bowel disease, and nephrotic syndrome, even when standard therapies have failed.

**Toxicity.** The principal adverse reactions to cyclosporine therapy are renal dysfunction, tremor, hirsutism, hypertension, hyperlipidemia, and gum hyperplasia (Burke et al., 1994). Hyperuricemia may lead to worsening of gout, increased P-glycoprotein activity, and hypercholesterolemia. Nephrotoxicity occurs in the majority of patients treated and is the major indication for cessation or modification of therapy. Hypertension occurs in approximately 50% of renal transplant and almost all cardiac transplant patients. Combined use of calcineurin inhibitors and glucocorticoids is particularly diabetogenic, although this apparently is more problematic in patients treated with tacrolimus (see below). Especially at risk are obese patients, African-American or Hispanic recipients, or
those with family history of type II diabetes or obesity. Cyclosporine, as opposed to tacrolimus, is more likely to produce elevations in LDL cholesterol (Artz et al., 2003; Kramer et al., 2003; Tanabe, 2003).

**Drug Interactions.** Cyclosporine interacts with a wide variety of commonly used drugs, and close attention must be paid to drug interactions. Any drug that affects microsomal enzymes, especially the CYP3A system, may impact cyclosporine blood concentrations (Faulds et al., 1993). Substances that inhibit this enzyme can decrease cyclosporine metabolism and increase blood concentrations. These include Ca²⁺ channel blockers (e.g., verapamil, nicardipine), antifungal agents (e.g., fluconazole, ketoconazole), antibiotics (e.g., erythromycin), glucocorticoids (e.g., methylprednisolone), HIV-protease inhibitors (e.g., indinavir), and other drugs (e.g., allopurinol, metoclopramide). Grapefruit and grapefruit juice block CYP3A and the multidrug efflux pump and should be avoided by patients taking cyclosporine; these effects can increase cyclosporine blood concentrations. In contrast, drugs that induce CYP3A activity can increase cyclosporine metabolism and decrease blood concentrations. Such drugs include antibiotics (e.g., nafcillin, rifampin), anticonvulsants (e.g., phenobarbital, phenytoin), and other drugs (e.g., octreotide, ticlopidine). In general, close monitoring of cyclosporine blood levels and the levels of other drugs is required when such combinations are used.

Interactions between cyclosporine and sirolimus (see below) have led to the recommendation that administration of the two drugs be separated by time. Sirolimus aggravates cyclosporine-induced renal dysfunction, while cyclosporine increases sirolimus-induced hyperlipidemia and myelosuppression. Other drug interactions of concern include additive nephrotoxicity when cyclosporine is coadministered with nonsteroidal antiinflammatory drugs and other drugs that cause renal dysfunction; elevation of methotrexate levels when the two drugs are coadministered; and reduced clearance of other drugs, including prednisolone, digoxin, and statins.

**Tacrolimus.** Tacrolimus (PROGRAF, FK506) is a macrolide antibiotic produced by Streptomyces tsukubaensis (Goto et al., 1987). Its formula is shown in Figure 52–1.

**Mechanism of Action.** Like cyclosporine, tacrolimus inhibits T-cell activation by inhibiting calcineurin (Schreiber and Crabtree, 1992). Tacrolimus binds to an intracellular protein, FK506-binding protein–12 (FKBP-12), an immunophilin structurally related to cyclophilin. A complex of tacrolimus-FKBP-12, Ca²⁺, calmodulin, and calcineurin then forms, and calcineurin phosphatase activity is inhibited. As described for cyclosporine and depicted in Figure 52–2, the inhibition of phosphatase activity prevents dephosphorylation and nuclear translocation of NFAT and inhibits T-cell activation. Thus, although the intracellular receptors differ, cyclosporine and tacrolimus target the same pathway for immunosuppression (Plosker and Foster, 2000).

**Disposition and Pharmacokinetics.** Tacrolimus is available for oral administration as capsules (0.5, 1, and 5 mg) and as a sterile solution for injection (5 mg/ml). Immunosuppressive activity resides primarily in the parent drug. Because of intersubject variability in pharmacokinetics, individualized dosing is required for optimal therapy (Fung and Starzl, 1995). Whole blood, rather than plasma, is the most appropriate sampling compartment to describe tacrolimus pharmacokinetics. For tacrolimus, the C₀ level seems to correlate better with clinical events than it does for cyclosporine. Target concentrations in many centers are 200 to 400 ng/ml in the early preoperative period and 100 to 200 ng/ml 3 months after transplantation. Unlike cyclosporine, more frequent tacrolimus dosing has not been formally evaluated. Gastrointestinal absorption is incomplete and variable. Food decreases the rate and extent of absorption. Plasma protein binding of tacrolimus is 75% to 99%, involving primarily albumin and α₁-acid glycoprotein. Its half-life is about 12 hours. Tacrolimus is extensively metabolized in the liver by CYP3A, with a half-life of ~12 hours; at least some of the metabolites are active. The bulk of excretion of the parent drug and metabolites is in the feces. Less than 1% of administered tacrolimus is excreted unchanged in the urine.

**Therapeutic Uses.** Tacrolimus is indicated for the prophylaxis of solid-organ allograft rejection in a manner similar to cyclosporine and as rescue therapy in patients with rejection episodes despite “therapeutic” levels of cyclosporine (Mayer et al., 1997; The U.S. Multicenter FK506 Liver Study Group, 1994). The recommended starting dose for tacrolimus injection is 0.03 to 0.05 mg/kg per day as a continuous infusion. Recommended initial oral doses are 0.15 to 0.2 mg/kg per day for adult kidney transplant patients, 0.1 to 0.15 mg/kg per day for adult liver transplant patients, and 0.15 to 0.2 mg/kg per day for pediatric liver transplant patients in two divided doses 12 hours apart. These dosages are intended to achieve typical blood trough levels in the 5- to 15-ng/ml range. Pediatric patients generally require higher doses than do adults (Shapiro, 1998).

**Toxicity.** Nephrotoxicity, neurotoxicity (tremor, headache, motor disturbances, seizures), GI complaints, hypertension, hyperkalemia, hyperglycemia, and diabetes are all associated with tacrolimus use (Plosker and Foster, 2000). As with cyclosporine, nephrotoxicity is limiting (Mihatsch et al., 1998; Henry, 1999). Tacrolimus has a negative effect on pancreatic islet beta cells, and glucose intolerance and diabetes mellitus are well-recognized complications of tacrolimus-based immunosuppression. As with other immunosuppressive agents, there is an increased risk of secondary tumors and opportunistic infections. Notably, tacrolimus does not adversely affect uric acid or LDL cholesterol.

**Drug Interactions.** Because of its potential for nephrotoxicity, tacrolimus blood levels and renal function should be monitored closely, especially when tacrolimus is used with other potentially nephrotoxic drugs. Coadministration with cyclosporine results in additive or synergistic nephrotoxicity; therefore a delay of at least 24 hours is required when switching a patient from cyclosporine to tacrolimus. Since tacrolimus is metabolized mainly by CYP3A, the potential interactions described above for cyclosporine also apply for tacrolimus (Venkataramanan et al., 1995; Yoshimura et al., 1999).
Antiproliferative and Antimetabolic Drugs

**Sirolimus.** Sirolimus (rapamycin; RAPAMUNE) is a macrolactone produced by *Streptomyces hygroscopicus* (Vezina et al., 1975). Its structure is shown in Figure 52–1.

**Mechanism of Action.** Sirolimus inhibits T-lymphocyte activation and proliferation downstream of the IL-2 and other T-cell growth factor receptors (Figure 52–2) (Kuo et al., 1992). Like cyclosporine and tacrolimus, therapeutic action of sirolimus requires formation of a complex with an immunophilin, in this case FKBP-12. However, the sirolimus–FKBP-12 complex does not affect calcineurin activity. It binds to and inhibits a protein kinase, designated mammalian target of rapamycin (mTOR), which is a key enzyme in cell-cycle progression (Brown et al., 1994). Inhibition of mTOR blocks cell-cycle progression at the G1 → S phase transition. In animal models, sirolimus not only inhibits transplant rejection, graft-versus-host disease, and a variety of autoimmune diseases, but its effect also lasts several months after discontinuing therapy, suggesting a tolerizing effect (see Tolerance, below; Groth et al., 1999). A newer indication for sirolimus is the avoidance of calcineurin inhibitors, even when patients are stable, to protect kidney function (Stegall et al., 2003).

**Disposition and Pharmacokinetics.** After oral administration, sirolimus is absorbed rapidly and reaches a peak blood concentration within about 1 hour after a single dose in healthy subjects and within about 2 hours after multiple oral doses in renal transplant patients (Napoli and Kahan, 1996; Zimmerman and Kahan, 1997). Systemic availability is approximately 15%, and blood concentrations are proportional to doses between 3 and 12 mg/m². A high-fat meal decreases peak blood concentration by 34%; sirolimus therefore should be taken consistently either with or without food, and blood levels should be monitored closely. About 40% of sirolimus in plasma is protein bound, especially to albumin. The drug partitions into formed elements of blood, with a blood-to-plasma ratio of 38 in renal transplant patients. Sirolimus is extensively metabolized by CYP3A4 and is transported by P-glycoprotein. Seven major metabolites have been identified in whole blood (Salm et al., 1999). Metabolites also are detectable in feces and urine, with the bulk of total excretion being in feces. Although some of its metabolites are active, sirolimus itself is the major active component in whole blood and contributes more than 90% of the immunosuppressive effect. The blood half-life after multiple doses in stable renal transplant patients is 62 hours (Napoli and Kahan, 1996; Zimmerman and Kahan, 1997). A loading dose of three times the maintenance dose will provide nearly steady-state concentrations within 1 day in most patients.

**Therapeutic Uses.** Sirolimus is indicated for prophylaxis of organ transplant rejection in combination with a calcineurin inhibitor and glucocorticoids (Kahan et al., 1999a). In patients experiencing or at high risk for calcineurin inhibitor–associated nephrotoxicity, sirolimus has been used with glucocorticoids and mycophenolate mofetil to avoid permanent renal damage. The initial dosage in patients 13 years or older who weigh less than 40 kg should be adjusted based on body surface area (1 mg/m² per day) with a loading dose of 3 mg/m². Data regarding doses for pediatric and geriatric patients are lacking at this time (Kahan, 1999). It is recommended that the maintenance dose be reduced by approximately one-third in patients with hepatic impairment (Watson et al., 1999). Sirolimus also has been incorporated into stents to inhibit local cell proliferation and blood vessel occlusion.

**Toxicity.** The use of sirolimus in renal transplant patients is associated with a dose-dependent increase in serum cholesterol and triglycerides that may require treatment (Murgia et al., 1996). While immunotherapy with sirolimus per se is not nephrotoxic, patients treated with cyclosporine plus sirolimus have impaired renal function compared to patients treated with cyclosporine and either azathioprine or placebo. Sirolimus also may prolong delayed graft function in deceased donor kidney transplants, presumably because of its antiproliferative action (Smith et al., 2003; McTaggart et al., 2003). Renal function therefore must be monitored closely in such patients. Lymphocele, a known surgical complication associated with renal transplantation, is increased in a dose-dependent fashion by sirolimus, requiring close postoperative follow-up. Other adverse effects include anemia, leukopenia, thrombocytopenia (Hong and Kahan, 2000b), hypokalemia or hyperkalemia, fever, and gastrointestinal effects. Delayed wound healing may occur with sirolimus use. As with other immunosuppressive agents, there is an increased risk of neoplasms, especially lymphomas, and infections. Prophylaxis for *Pneumocystis carinii* pneumonia and cytomegalovirus is recommended (Groth et al., 1999).

**Drug Interactions.** Since sirolimus is a substrate for CYP3A4 and is transported by P-glycoprotein, close attention to interactions with other drugs that are metabolized or transported by these proteins is required (Yoshimura et al., 1999). As noted above, cyclosporine and sirolimus interact, and their administration should be separated by time. Dose adjustment may be required when sirolimus is coadministered with diltiazem or rifampin. The combination of sirolimus plus tacrolimus probably is more nephrotoxic than cyclosporine plus sirolimus. Dose adjustment apparently is not required when sirolimus is coadministered with acyclovir, digoxin, glyburide, nifedipine, norgestrel/ethinyl estradiol, prednisolone, or trimethoprim-sulfamethoxazole. This list is incomplete, and blood
levels and potential drug interactions must be monitored closely.

**Everolimus.** Everolimus (40-0-[2-hydroxy] ethyl-rapamycin) is closely related chemically and clinically to sirolimus but has distinct pharmacokinetics. The main difference is a shorter half-life and thus a shorter time to achieve steady-state concentrations of the drug. Dosage on a milligram per kilogram basis is similar to sirolimus. Aside from the shorter half-life, no studies have compared everolimus with sirolimus in standard immunosuppressive regimens (Eisen et al., 2003). As with sirolimus, the combination of a calcineurin inhibitor and an mTOR inhibitor produces worse renal function at 1 year than does calcineurin inhibitor therapy alone, suggesting a drug interaction between the mTOR inhibitors and the calcineurin inhibitors to enhance toxicity and to reduce rejection. The toxicity of everolimus and the drug interactions reported to date seem to be the same as with sirolimus.

**Azathioprine.** Azathioprine (IMuran) is a purine antimetabolite. It is an imidazolyl derivative of 6-mercaptopurine (Figure 52–1).

**Mechanism of Action.** Following exposure to nucleophiles such as glutathione, azathioprine is cleaved to 6-mercaptopurine, which in turn is converted to additional metabolites that inhibit de novo purine synthesis (see Chapter 51). 6-Thio-IMP, a fraudulent nucleotide, is converted to 6-thio-GMP and finally to 6-thio-GTP, which is incorporated into DNA. Cell proliferation is thereby inhibited, impairing a variety of lymphocyte functions. Azathioprine appears to be a more potent immunosuppressive agent than 6-mercaptopurine, which may reflect differences in drug uptake or pharmacokinetic differences in the resulting metabolites.

**Disposition and Pharmacokinetics.** Azathioprine is well absorbed orally and reaches maximum blood levels within 1 to 2 hours after administration. The half-life of azathioprine is about 10 minutes, while that of its metabolite 6-mercaptopurine is about an hour. Other metabolites have half-lives of up to 5 hours. Blood levels have limited predictive value because of extensive metabolism, significant activity of many different metabolites, and high tissue levels attained. Azathioprine and mercaptopurine are moderately bound to plasma proteins and are partially dialyzable. Both are rapidly removed from the blood by oxidation or methyl-ation in the liver and/or erythrocytes. Renal clearance has little impact on biological effectiveness or toxicity, but the dose should be reduced in patients with renal failure.

**Therapeutic Uses.** Azathioprine was first introduced as an immunosuppressive agent in 1961, helping to make allogeneic kidney transplantation possible. It is indicated as an adjunct for prevention of organ transplant rejection and in severe rheumatoid arthritis (Hong and Kahan, 2000a; Gaffney and Scott, 1998). Although the dose of azathioprine required to prevent organ rejection and minimize toxicity varies, 3 to 5 mg/kg per day is the usual starting dose. Lower initial doses (1 mg/kg per day) are used in treating rheumatoid arthritis. Complete blood count and liver function tests should be monitored.

**Toxicity.** The major side effect of azathioprine is bone marrow suppression, including leukopenia (common), thrombocytopenia (less common), and/or anemia (uncommon). Other important adverse effects include increased susceptibility to infections (especially varicella and herpes simplex viruses), hepatotoxicity, alopecia, GI toxicity, pancreatitis, and increased risk of neoplasia.

**Drug Interactions.** Xanthine oxidase, an enzyme of major importance in the catabolism of azathioprine metabolites, is blocked by allopurinol. If azathioprine and allopurinol are used concurrently, the azathioprine dose must be decreased to 25% to 33% of the usual dose; it is best not to use these two drugs together. Adverse effects resulting from coadministration of azathioprine with other myelosuppressive agents or angiotensin-converting enzyme inhibitors include leukopenia, thrombocytopenia, and anemia as a result of myelosuppression.

**Mycophenolate Mofetil.** Mycophenolate mofetil (CELLCEPT) is the 2-morpholinoethyl ester of mycophenolic acid (MPA) (Allison and Eugui, 1993). Its structure is shown in Figure 52–1.

**Mechanism of Action.** Mycophenolate mofetil is a prodrug that is rapidly hydrolyzed to the active drug, mycophenolic acid (MPA), a selective, noncompetitive, and reversible inhibitor of inosine monophosphate dehydrogenase (IMPDH) (Natsumeda and Carr, 1993), an important enzyme in the de novo pathway of guanine nucleotide synthesis. B and T lymphocytes are highly dependent on this pathway for cell proliferation, while other cell types can use salvage pathways; MPA therefore selectively inhibits lymphocyte proliferation and functions, including antibody formation, cellular adhesion, and migration.

**Disposition and Pharmacokinetics.** Mycophenolate mofetil undergoes rapid and complete metabolism to MPA after oral or intravenous administration. MPA, in turn, is metabolized to the inactive phenolic glucuronide MPAG. The parent drug is cleared from the blood within a few minutes. The half-life of MPA is about 16 hours. Negligible (<1%) amounts of MPA are excreted in the urine (Bardsley-Elliot et al., 1999). Most (87%) is excreted in the urine as MPAG. Plasma concentrations of MPA and MPAG are increased in patients with renal insufficiency. In early renal transplant patients (<40 days posttransplant), plasma concentrations of MPA after a single dose of mycophenolate mofetil are about half of those found in healthy volunteers or stable renal transplant patients. Studies in children are...
limited, and safety and effectiveness have not been established (Butani et al., 1999).

**Therapeutic Uses.** Mycophenolate mofetil is indicated for prophylaxis of transplant rejection, and it typically is used in combination with glucocorticoids and a calcineurin inhibitor, but not with azathioprine (Kimball et al., 1995; Ahsan et al., 1999; Kreis et al., 2000). Combined treatment with sirolimus is possible, although potential drug interactions necessitate careful monitoring of drug levels. For renal transplants, 1 g is administered orally or intravenously (over 2 hours) twice daily (2 g per day). A higher dose, 1.5 g twice daily (3 g per day), is recommended for African-American renal transplant patients and all cardiac transplant patients. Use of mycophenolate mofetil in other clinical settings is under investigation.

**Toxicity.** The principal toxicities of mycophenolate mofetil are gastrointestinal and hematologic (Fulton and Markham, 1996; Bardsley-Elliot et al., 1999). These include leukopenia, diarrhea, and vomiting. There is also an increased incidence of some infections, especially sepsis associated with cytomegalovirus. Tacrolimus in combination with mycophenolate mofetil has been associated with devastating viral infections including polyoma nephritis (Zavos et al., 2004; Elli et al., 2002).

**Drug Interactions.** Potential drug interactions between mycophenolate mofetil and several other drugs commonly used by transplant patients have been studied (Bardsley-Elliot et al., 1999). There appear to be no untoward effects produced by combination therapy with cyclosporine, trimethoprim-sulfamethoxazole, or oral contraceptives. Unlike cyclosporine, tacrolimus delays elimination of mycophenolate mofetil by impairing the conversion of MPA to MPAG. This may enhance GI toxicity. Mycophenolate mofetil has not been tested with azathioprine. Coadministration with antacids containing aluminum or magnesium hydroxide leads to decreased absorption of mycophenolate mofetil; thus, these drugs should not be administered simultaneously. Mycophenolate mofetil should not be administered with cholestyramine or other drugs that affect enterohepatic circulation. Such agents decrease plasma MPA concentrations, probably by binding free MPA in the intestines. Aciyclovir and ganciclovir may compete with MPAG for tubular secretion, possibly resulting in increased concentrations of both MPAG and the antiviral agents in the blood, an effect that may be compounded in patients with renal insufficiency.

**Other Antiproliferative and Cytotoxic Agents.** Many of the cytotoxic and antimetabolic agents used in cancer chemotherapy (see Chapter 51) are immunosuppressive due to their action on lymphocytes and other cells of the immune system. Other cytotoxic drugs that have been used as immunosuppressive agents include methotrexate, cyclophosphamide (CYTOXAN), thalidomide, and chlorambucil (LEUKERAN). Methotrexate is used for treatment of graft-versus-host disease, rheumatoid arthritis, and psoriasis, as well as in anticancer therapy (see Chapter 51) (Grosflam and Weinblatt, 1991). Cyclophosphamide and chlorambucil are used in treating childhood nephrotic syndrome (Neuhaus et al., 1994) and a variety of malignancies (see Chapter 51). Cyclophosphamide also is used widely for treatment of severe systemic lupus erythematosus (Valeri et al., 1994) and other vasculitides such as Wegener’s granulomatosis. Leflunomide (ARAVA) is a pyrimidine-synthesis inhibitor indicated for the treatment of adults with rheumatoid arthritis (Prakash and Jarvis, 1999). This drug has found utility in the treatment of polyomavirus nephropathy seen in immunosuppressed renal transplant recipients and is increasingly being used for that purpose. There are no studies showing efficacy, however, compared with control patients treated with withdrawal or reduction of immunosuppression alone in BK virus nephropathy. The drug inhibits dihydroorotate dehydrogenase in the de novo pathway of pyrimidine synthesis. It is hepatotoxic and can cause fetal injury when administered to pregnant women.

**FTY720**

FTY720 (see Figure 52-1), an S1P receptor prodrug, is the first agent in a new class of small molecules, sphingosine 1-phosphate receptor (S1P-R) agonists, which reduce recirculation of lymphocytes from the lymphatic system to the blood and peripheral tissues, including inflammatory lesions and organ grafts.

**Therapeutic Uses.** FTY720 may have an important role in combination immunosuppression therapy in the prevention of acute rejection. FTY720 is not effective as monotherapy; it has demonstrated efficacy in clinical trials with cyclosporine and prednisone or in combination with the mTOR inhibitor everolimus and steroids. In Phase II trials with cyclosporine, FTY720 at daily doses of 2.5 and 5 mg showed comparable efficacy in the prevention of acute rejection in de novo renal transplant patients when compared to immunosuppression with cyclosporine, mycophenolate mofetil, and prednisone. FTY720 now is in Phase III trials.

**Mechanism of Action.** Unlike other immunosuppressive agents, FTY720 acts via “lymphocyte homing.” It specifically and reversibly sequesters host lymphocytes into the lymph nodes and Peyer’s patches, and thus away from the circulation. This protects the graft from T-cell–mediated attack. FTY720 sequesters lymphocytes but does not impair either T or B cell functions. FTY720 is phosphorylated by sphingosine kinase-2 and the FTY720-phosphate product is
a potent agonist of S1P receptors. Altered lymphocyte traffic induced by FTY720 clearly results from its effect on S1P receptors.

Toxicity. Lymphopenia, the most common side effect of FTY720, is predicted from its pharmacologic effect and is fully reversible upon drug discontinuation. Of greater concern is the negative chronotropic effect of FTY720 on the heart, which has been observed with the first dose of FTY720 in up to 30% of patients. In most patients, the heart rate returns to baseline within 48 hours after the administration of the first dose of FTY720, with the remainder returning to baseline thereafter. The negative chronotropic effect of FTY720 likely is related to the presence of S1P-R on human atrial myocytes, thus affecting S1P signaling pathways. This effect can be functionally antagonized by $\beta_1$-receptor agonists or by the muscarinic receptor antagonist atropine. Importantly, cardiac rhythm was not affected in patients treated chronically with FTY720; however, the safety of the first-dose response of FTY720 on the heart rate in patients with underlying coronary artery disease remains to be determined.

Antibodies

Both polyclonal and monoclonal antibodies against lymphocyte cell-surface antigens are widely used for prevention and treatment of organ transplant rejection. Polyclonal antisera are generated by repeated injections of human thymocytes (antithymocyte globulin, ATG) or lymphocytes (antilymphocyte globulin, ALG) into animals such as horses, rabbits, sheep, or goats, and then purifying the serum immunoglobin fraction. Although highly effective immunosuppressive agents, these preparations vary in efficacy and toxicity from batch to batch. The advent of hybridoma technology to produce monoclonal antibodies was a major advance in immunology (Kohler and Milstein, 1975). It is now possible to make essentially unlimited amounts of a single antibody of a defined specificity (Figure 52–3). These monoclonal reagents have overcome the problems of variability in efficacy and toxicity seen with the polyclonal products, but they are more limited in their target specificity. The first-generation murine monoclonal antibodies have been replaced by newer chimeric or humanized monoclonal antibodies that lack antigenicity, have prolonged half-lives, and can be mutagenized to alter their affinity to Fc receptors. Thus, both polyclonal and monoclonal products have a place in immunosuppressive therapy.

Antithymocyte Globulin. Antithymocyte globulin is a purified gamma globulin from the serum of rabbits immu-

---

**Figure 52–3. Generation of monoclonal antibodies.** Mice are immunized with the selected antigen, and spleen or lymph node is harvested and B cells separated. These B cells are fused to a suitable B-cell myeloma that has been selected for its inability to grow in medium supplemented with hypoxanthine, aminopterin, and thymidine (HAT). Only myelomas that fuse with B cells can survive in HAT-supplemented medium. The hybridomas expand in culture. Those of interest based upon a specific screening technique are then selected and cloned by limiting dilution. Monoclonal antibodies can be used directly as supernatants or ascites fluid experimentally but are purified for clinical use. HPRT, hypoxanthine-guanine phosphoribosyl transferase. (From Krensky, 1999, with permission.)
Mechanism of Action. Antithymocyte globulin contains cytotoxic antibodies that bind to CD2, CD3, CD4, CD8, CD11a, CD18, CD25, CD44, CD45, and HLA class I and II molecules on the surface of human T lymphocytes (Bourdage and Hamlin, 1995). The antibodies deplete circulating lymphocytes by direct cytotoxicity (both complement and cell-mediated) and block lymphocyte function by binding to cell surface molecules involved in the regulation of cell function.

Therapeutic Uses. Antithymocyte globulin is used for induction immunosuppression, although the only approved indication is in the treatment of acute renal transplant rejection in combination with other immunosuppressive agents (Mariat et al., 1998). Antilymphocyte-depleting agents (THYMOGLOBULIN, ATGAM, and OKT3) have been neither rigorously tested in clinical trials nor registered for use as induction immunosuppression. However, a meta-analysis (Szczez et al., 1997) showed that antilymphocyte induction improves graft survival. A course of antithymocyte-globulin treatment often is given to renal transplant patients with delayed graft function to avoid early treatment with the nephrotoxic calcineurin inhibitors and thereby aid in recovery from ischemic reperfusion injury. The recommended dose for acute rejection of renal grafts is 1.5 mg/kg per day (over 4 to 6 hours) for 7 to 14 days. Mean T-cell counts fall by day 2 of therapy. Antithymocyte globulin also is used for acute rejection of other types of organ transplants and for prophylaxis of rejection (Wall, 1999).

Toxicity. Polyclonal antibodies are xenogeneic proteins that can elicit major side effects, including fever and chills with the potential for hypotension. Premedication with corticosteroids, acetaminophen, and/or an antihistamine and administration of the antiserum by slow infusion (over 4 to 6 hours) into a large-diameter vessel minimize such reactions. Serum sickness and glomerulonephritis can occur; anaphylaxis is a rare event. Hematologic complications include leukopenia and thrombocytopenia. As with other immunosuppressive agents, there is an increased risk of infection and malignancy, especially when multiple immunosuppressive agents are combined. No drug interactions have been described; anti-ATG antibodies develop, although they do not limit repeated use.

Monoclonal Antibodies. Anti-CD3 Monoclonal Antibodies. Antibodies directed at the ε chain of CD3, a trimeric molecule adjacent to the T-cell receptor on the surface of human T lymphocytes, have been used with considerable efficacy since the early 1980s in human transplantation. The original mouse IgG2a antihuman CD3 monoclonal antibody, muromonab-CD3 (OKT3, ORTHO-CLONE OKT3), still is used to reverse glucocorticoid-resistant rejection episodes (Cosimi, et al., 1981).

Mechanism of Action. Muromonab-CD3 binds to the ε chain of CD3, a monomorphic component of the T-cell receptor complex involved in antigen recognition, cell signaling, and proliferation (Hooks et al., 1991). Antibody treatment induces rapid internalization of the T-cell receptor, thereby preventing subsequent antigen recognition. Administration of the antibody is followed rapidly by depletion and extravasation of a majority of T cells from the bloodstream and peripheral lymphoid organs such as lymph nodes and spleen. This absence of detectable T cells from the usual lymphoid regions is secondary both to cell death following complement activation and activation-induced cell death and to margination of T cells onto vascular endothelial walls and redistribution of T cells to nonlymphoid organs such as the lungs. Muromonab-CD3 also reduces function of the remaining T cells, as defined by lack of IL-2 production and great reduction in the production of multiple cytokines, perhaps with the exception of IL-4 and IL-10.

Therapeutic Uses. Muromonab-CD3 is indicated for treatment of acute organ transplant rejection (Ortho Multicenter Transplant Study Group, 1985; Woodle et al., 1999; Rostaing et al., 1999). Muromonab-CD3 is provided as a sterile solution containing 5 mg per ampule. The recommended dose is 5 mg/day (in adults; less for children) in a single intravenous bolus (less than 1 minute) for 10 to 14 days. Antibody levels increase over the first 3 days and then plateau. Circulating T cells disappear from the blood within minutes of administration and return within approximately 1 week after termination of therapy. Repeated use of muromonab-CD3 results in the immunization of the patient against the mouse determinants of the antibody, which can neutralize and prevent its immunosuppressive efficacy (Jaffers et al., 1983). Thus, repeated treatment with the muromonab-CD3 or other mouse monoclonal antibodies generally is contraindicated. The use of muromonab-CD3 for induction and rejection therapy has diminished substantially in the past 5 years because of its toxicity and the availability of antithymocyte globulin.

Toxicity. The major side effect of anti-CD3 therapy is the “cytokine release syndrome” (Wilde and Goa, 1996; Ortho Multicenter Transplant Study Group, 1985). The syndrome typically begins 30 minutes after infusion of the antibody (but can occur later) and may persist for hours. Antibody binding to the T-cell receptor complex combined with Fc receptor (FcR)—mediated crosslinking is the basis for the initial activating properties of this agent. The syndrome is associated with and attributed to increased serum levels of cytokines (including tumor necrosis factor [TNF]-α, IL-2, IL-6, and interferon-γ,
which are released by activated T cells and/or monocytes. In several studies, the production of TNF-α has been shown to be the major cause of the toxicity (Herbelin et al., 1995). The symptoms usually are worst with the first dose; frequency and severity decrease with subsequent doses. Common clinical manifestations include high fever, chills/rigor, headache, tremor, nausea/vomiting, diarrhea, abdominal pain, malaise, myalgias, arthralgias, and generalized weakness. Less common complaints include skin reactions and cardiorespiratory and CNS disorders, including aseptic meningitis. Potentially fatal severe pulmonary edema, acute respiratory distress syndrome, cardiovascular collapse, cardiac arrest, and arrhythmias have been described.

Administration of glucocorticoids before the injection of muromonab-CD3 prevents the release of cytokines and reduces first-dose reactions considerably and is now a standard procedure. Volume status of patients also must be monitored carefully before therapy; steroids and other premedications should be given, and a fully competent resuscitation facility must be immediately available for patients receiving their first several doses of this therapy.

Other toxicities associated with anti-CD3 therapy include anaphylaxis and the usual infections and neoplasms associated with immunosuppressive therapy. “Rebound” rejection has been observed when muromonab-CD3 treatment is stopped (Wilde and Goa, 1996). Anti-CD3 therapies may be limited by anti-idiotypic or anti-murine antibodies in the recipient.

**New-Generation Anti-CD3 Antibodies.** Recently, genetically altered anti-CD3 monoclonal antibodies have been developed that are “humanized” to minimize the occurrence of antiantibody responses and mutated to prevent binding to FcRs (Friend et al., 1999). The rationale for developing this new generation of anti-CD3 monoclonal antibodies is that they could induce selective immunomodulation in the absence of toxicity associated with conventional anti-CD3 monoclonal antibody therapy. In initial clinical trials, a humanized anti-CD3 monoclonal antibody that does not bind to FcRs reversed acute renal allograft rejection without causing the first-dose cytokine-release syndrome (Woodle et al., 1999). Clinical efficacy of these agents in autoimmune diseases is being evaluated (Herold et al., 2002).

**Anti-IL-2 Receptor (Anti-CD25) Antibodies.** Daclizumab (ZENAPAX), a humanized murine complementarity-determining region (CDR)/human IgG1, chimeric monoclonal antibody, and basiliximab (SIMULECT), a murine-human chimeric monoclonal antibody, have been produced by recombinant DNA technology (Wiseman and Faulds, 1999). The composite daclizumab antibody consists of human (90%) constant domains of IgG1 and variable framework regions of the Eu myeloma antibody and murine (10%) CDR of the anti-Tac antibody.

**Mechanism of Action.** Daclizumab has a somewhat lower affinity than does basiliximab, but a longer half-life (20 days). The exact mechanism of action of the anti-CD25 mAbs is not completely understood, but likely results from the binding of the anti-CD25 mAbs to the IL-2 receptor on the surface of activated, but not resting, T cells (Vincenti et al., 1998; Amlot et al., 1995). Significant depletion of T cells does not appear to play a major role in the mechanism of action of these mAbs. However, other mechanisms of action may mediate the effect of these antibodies. In a study of daclizumab-treated patients, there was a moderate decrease in circulating lymphocytes staining with 7G7, a fluorescein-conjugated antibody that binds a different α-chain epitope than that recognized and bound by daclizumab (Vincenti et al., 1998). Similar results were obtained in studies with basiliximab (Amlot et al., 1995). These findings indicate that therapy with the anti IL-2R mAbs results in a relative decrease of the expression of the α-chain, either from depletion of coated lymphocytes or modulation of the α-chain secondary to decreased expression or increased shedding. There is also recent evidence that the β chain may be down-regulated by the anti-CD25 antibody.

**Therapeutic Uses.** Anti-IL-2-receptor monoclonal antibodies are used for prophylaxis of acute organ rejection in adult patients. There are two anti–IL-2R preparations for use in clinical transplantation: daclizumab and basiliximab (Vincenti et al., 1998; Nashan et al., 1999). In Phase III trials, daclizumab was administered in five doses (1 mg/kg given intravenously over 15 minutes in 50 ml to 100 ml of normal saline) starting immediately preoperatively, and subsequently at biweekly intervals. The half-life of daclizumab was 20 days, resulting in saturation of the IL-2Rα on circulating lymphocytes for up to 120 days after transplantation. In these trials, daclizumab was used with maintenance immunosuppression regimens (cyclosporine, azathioprine, and steroids; cyclosporine and steroids). Subsequently, daclizumab was successfully used with a maintenance triple-therapy regimen—either with cyclosporine or tacrolimus, steroids, and mycophenolate mofetil (MMF) substituting for azathioprine (Ciancio et al., 2003; Pescovitz et al., 2003). In Phase III trials, basiliximab was administered in a fixed dose of 20 mg preoperatively and on days 0 and 4 after transplantation (Nashan et al., 1997; Kahan et al., 1999a). This regimen of basiliximab resulted in a concentration of ≥0.2 μg/mL, sufficient to saturate IL-2R on circulating lymphocytes for 25 to 35 days after transplantation. The half-life of basiliximab was 7 days. In the Phase III trials, basiliximab was used with a maintenance regimen consisting of cyclosporine and prednisone. In one randomized trial, basiliximab was safe and effective when used in a maintenance regimen consisting of cyclosporine, MMF, and prednisone (Lawen et al., 2000).
There presently is no marker or test to monitor the effectiveness of anti–IL-2R therapy. Saturation of α chain on circulating lymphocytes during anti–IL-2R mAb therapy does not predict rejection. The duration of IL-2R blockade by basiliximab was similar in patients with or without acute rejection episodes (34 ± 14 days vs. 37 ± 14 days, mean ± SD) (Kovarik et al., 1999). In another daclizumab trial, patients with acute rejection were found to have circulating and intragraft lymphocytes with saturated IL-2R (Vincenti et al., 2001). A possible explanation is that those patients who reject despite anti–IL-2R blockade do so through a mechanism that bypasses the IL-2 pathway due to cytokine-cytokine receptor redundancy (i.e., IL-7, IL-15).

Toxicity. No cytokine-release syndrome has been observed with these antibodies, but anaphylactic reactions can occur. Although lymphoproliferative disorders and opportunistic infections may occur, as with the depleting antilymphocyte agents, the incidence ascribed to anti–CD25 treatment appears remarkably low. No significant drug interactions with anti–IL-2–receptor antibodies have been described (Hong and Kahan, 1999).

**Campath-1H.** Campath-1H (ALEMTUZUMAB) is a humanized mAb that has been approved for use in chronic lymphocytic leukemia. The antibody targets CD52, a glycoprotein expressed on lymphocytes, monocytes, macrophages, and natural killer cells; thus, the drug causes extensive lympholysis by inducing apoptosis of targeted cells. It has achieved some use in renal transplantation because it produces prolonged T- and B-cell depletion and allows drug minimization. Large controlled studies of efficacy or safety are not available. Although short-term results are promising, further clinical experience is needed before Campath-1H is accepted into the clinical armamentarium for transplantation.

**Anti-TNF Reagents.** **Infliximab.** Infliximab (REMICADE) is a chimeric anti–TNF-α monoclonal antibody containing a human constant region and a murine variable region. It binds with high affinity to TNF-α and prevents the cytokine from binding to its receptors.

Patients with rheumatoid arthritis have elevated levels of TNF-α in their joints, while patients with Crohn’s disease have elevated levels of TNF-α in their stools. In one trial, infliximab plus methotrexate improved the signs and symptoms of rheumatoid arthritis more than methotrexate alone. Patients with active Crohn’s disease who had not responded to other immunosuppressive therapies also improved when treated with infliximab, including those with Crohn’s-related fistulae. Infliximab is approved in the United States for treating the symptoms of rheumatoid arthritis, and is used in combination with methotrexate in patients who do not respond to methotrexate alone. Infliximab also is approved for treatment of symptoms of moderate to severe Crohn’s disease in patients who have failed to respond to conventional therapy, and in treatment to reduce the number of draining fistulae in Crohn’s disease patients (see Chapter 38). About 1 of 6 patients receiving infliximab experiences an infusion reaction characterized by fever, urticaria, hypotension, and dyspnea within 1 to 2 hours after antibody administration. Serious infections also have occurred in infliximab-treated patients, most frequently in the upper respiratory and urinary tracts. The development of antinuclear antibodies, and rarely a lupuslike syndrome, have been reported after treatment with infliximab.

Although not a monoclonal antibody, etanercept (ENBREL) is mechanistically related to infliximab because it also targets TNF-α. Etanercept contains the ligand-binding portion of a human TNF-α receptor fused to the Fc portion of human IgG1, and binds to TNF-α and prevents it from interacting with its receptors. It is approved in the United States for treatment of the symptoms of rheumatoid arthritis in patients who have not responded to other treatments. Etanercept can be used in combination with methotrexate in patients who have not responded adequately to methotrexate alone. As with infliximab, serious infections have occurred after treatment with etanercept. Injection-site reactions (erythema, itching, pain, or swelling) have occurred in more than one-third of etanercept-treated patients.

**Adalimumab** (HUMIRA) is another anti-TNF product for intravenous use. This recombinant human IgG1 monoclonal antibody was created by phage display technology and is approved for use in rheumatoid arthritis.

**LFA-1 Inhibition.** Efalizumab is a humanized IgG1 mAb targeting the CD11a chain of LFA-1 (lymphocyte function associated antigen). Efalizumab binds to LFA-1 and prevents the LFA-1–ICAM (intercellular adhesion molecule) interaction to block T-cell adhesion, trafficking, and activation (Arnaout, 1990). Pretransplant therapy with anti–CD11a prolonged survival of murine skin and heart allografts and monkey heart allografts (Nakakura et al., 1996). In a randomized, multicenter trial, a murine anti–ICAM-1 mAb (ENLIMOMAB) failed to reduce the rate of acute rejection or to improve delayed graft function of cadaveric renal transplants (Salmela et al., 1999). This may have been due to either the murine nature of the mAb or the redundancy of the ICAMs. Efalizumab also is approved for use in patients with psoriasis. In a Phase I/II open-label, dose-ranging, multidose, multicenter trial, efalizumab (dose 0.5 mg/kg or 2 mg/kg) was administered subcutaneously for 12 weeks after renal transplantation (Vincenti et al., 2001). Both doses of efalizumab decreased the incidence of...
Immunosuppression has concomitant risks of opportunistic infections and secondary tumors. Therefore, the ultimate goal of research on organ transplantation and autoimmune diseases is to induce and maintain immunologic tolerance, the active state of antigen-specific nonresponsiveness (Krensky and Clayberger, 1994; Hackett and Dickler, 1999). Tolerance, if attainable, would represent a true cure for conditions discussed above without the side effects of the various immunosuppressive therapies. The calcineurin inhibitors prevent tolerance induction in some, but not all, preclinical models (Wood, 1991; Van Parijs and Abbas, 1998). In these same model systems, sirolimus does not prevent tolerance and may even promote tolerance induction (Li et al., 1998). Several other promising approaches are being evaluated in clinical trials. Because they remain experimental, they are discussed only briefly here.

**Costimulatory Blockade**

Induction of specific immune responses by T lymphocytes requires two signals: an antigen-specific signal via the T-cell receptor and a costimulatory signal provided by the interaction of molecules such as CD28 on the T lymphocyte and CD80 and CD86 on the antigen-presenting cell (Figure 52–4; Khoury et al., 1999). In preclinical studies, inhibition of the costimulatory signal can induce tolerance (Larsen et al., 1996; Kirk et al., 1997). Experimental approaches to inhibit costimulation include a recombinant fusion protein molecule, CTLA4Ig, and anti-CD80 and/or anti-CD86 mAbs. The antibodies h1F1 and h3D1 are humanized anti-CD80 and anti-CD-86 mAbs, respectively. In vitro, h1F1 and h3D1 were shown to block CD28-dependent T-cell proliferation and decrease mixed lymphocyte reactions. These mAbs must be used in tandem since either CD80 or CD86 is sufficient to stimulate T cells via CD28. In nonhuman primates, anti CD80 and CD86 mAbs were proven effective in renal transplantation, either as monotherapy or in combination with steroids or cyclosporine (Kirk et al., 2001; Ossevoort et al., 1999), but did not induce durable tolerance. A Phase I study of h1F1 and h3D1 in renal transplant recipients was performed in patients receiving maintenance therapy consisting of cyclosporine, mycophenolate mofetil, and steroids (Vincenti, 2002). While the results of this study are as yet unpublished, the preliminary results appear to show that these mAbs are safe and possibly effective.

Figure 52–4. Costimulation. A. Two signals are required for T-cell activation. Signal 1 is via the T-cell receptor (TCR) and signal 2 is via a costimulatory receptor-ligand pair. Both signals are required for T-cell activation. Signal 1 in the absence of signal 2 results in an inactivated T cell. B. One important costimulatory pathway involves CD28 on the T cell and B7-1 (CD80) and B7-2 (CD86) on the antigen-presenting cell (APC). After a T cell is activated, it expresses additional costimulatory molecules. CD152 is CD40 ligand, which interacts with CD40 as a costimulatory pair. CD154 (CTLA4) interacts with CD80 and CD86 to dampen or down-regulate an immune response. Antibodies against CD80, CD86, and CD152 are being evaluated as potential therapeutic agents. CTLA4-Ig, a chimeric protein consisting of part of an immunoglobulin molecule and part of CD154, also has been tested as a therapeutic agent. (From Clayberger and Krensky, 2001, with permission.)
renal transplant studies in nonhuman primates showed that LEA29Y did not induce tolerance but did prolong graft survival. LEA29Y (administered intravenously every 4 or 8 weeks) is undergoing clinical trials in calcineurin inhibitor–free immunosuppression regimens.

A second costimulatory pathway involves the interaction of CD40 on activated T cells with CD40 ligand (CD154) on B cells, endothelium, and/or antigen-presenting cells (Figure 52–4). Among the purported activities of anti-CD154 antibody treatment is its blockade of B7 expression induced by immune activation. Two humanized anti-CD154 monoclonal antibodies have been used in clinical trials in renal transplantation and autoimmune diseases. The development of these antibodies, however, is on hold because of associated thromboembolic events. An alternative approach to block the CD154-CD40 pathway is to target CD40 with monoclonal antibodies.

**Donor Cell Chimerism**

Another promising approach is induction of chimerism (coexistence of cells from two genetic lineages in a single individual) by any of a variety of protocols that first dampen or eliminate immune function in the recipient with ionizing radiation, drugs such as cyclophosphamide, and/or antibody treatment, and then provide a new source of immune function by adoptive transfer (transfusion) of bone marrow or hematopoietic stem cells (Starzl et al., 1997; Fuchimoto et al., 1999; Spitzer et al., 1999; Hale et al., 2000). Upon reconstitution of immune function, the recipient no longer recognizes new antigens provided during a critical period as “nonself.” Such tolerance is long-lived and is less likely to be complicated by the use of calcineurin inhibitors. Although the most promising approaches in this arena have been therapies that promote the development of mixed or macrochimerism, in which substantial numbers of donor cells are present in the circulation, some microchimerization approaches also have shown promise in the development of long-term unresponsiveness.

**Soluble HLA**

In the precyclosporine era, blood transfusions were shown to be associated with improved outcomes in renal transplant patients (Opelz and Terasaki, 1978). These findings gave rise to donor-specific transfusion protocols that improved outcomes (Opelz et al., 1997). After the introduction of cyclosporine, however, these effects of blood transfusions disappeared, presumably due to the efficacy of this drug in blocking T-cell activation. Nevertheless, the existence of tolerance-promoting effects of transfusions is irrefutable. It is possible that this effect is due to HLA molecules on the surface of cells or in soluble forms. Recently, soluble HLA and peptides corresponding to linear sequences of HLA molecules have been shown to induce immunologic tolerance in animal models via a variety of mechanisms (Murphy and Krenskey, 1999).

**Antigens**

Specific antigens provided in a variety of forms (generally as peptides) induce immunologic tolerance in preclinical models of diabetes mellitus, arthritis, and multiple sclerosis. Clinical trials of such approaches are under way. The past decade has witnessed a revolution in our understanding of the basis for immune tolerance. It is now well established that antigen/MHC complex binding to the T-cell receptor/CD3 complex coupled with soluble and membrane-bound costimulatory signals initiates a cascade of signaling events that lead to productive immunity. In addition, the immune response is regulated by a number of negative signaling events that control cell survival and expansion. For the first time, in vitro and preclinical in vivo studies have demonstrated that one can selectively inhibit immune responses to specific antigens without the associated toxicity of established immunosuppressive therapies (Van Paruijs and Abbas, 1998). With these new insights comes the enormous promise of specific immune therapies to treat the vast array of immune disorders from autoimmunity to transplant rejection. These new therapies will take advantage of a combination of drugs that target the primary T-cell receptor–mediated signal, either by blocking cell-surface receptor interactions or inhibiting early signal transduction events. The drugs will be combined with therapies that effectively block costimulation to prevent cell expansion and differentiation of those cells that have engaged antigen while maintaining a noninflammatory milieu.
**Immunostimulants**

**Levamisole.** Levamisole (ERGAMISOL) was synthesized originally as an anthelmintic but appears to “restore” depressed immune function of B lymphocytes, T lymphocytes, monocytes, and macrophages. Its only clinical indication is as adjuvant therapy with 5-fluorouracil after surgical resection in patients with Dukes’ stage C colon cancer (Moertel et al., 1990; Figueredo et al., 1997), where it occasionally has been associated with fatal agranulocytosis.

**Thalidomide.** Thalidomide (THALOMID) is best known for the severe, life-threatening birth defects it caused when administered to pregnant women (Smithells and Newman, 1992; Lary et al., 1999). For this reason, it is available only under a restricted distribution program and can be prescribed only by specially licensed physicians who understand the risk of teratogenicity if thalidomide is used during pregnancy. Thalidomide should never be taken by women who are pregnant or who could become pregnant while taking the drug. Nevertheless, it is indicated for the treatment of patients with erythema nodosum leprosum (Sampaio et al., 1993; see Chapter 47) and also is used in conditions such as multiple myeloma. Its mechanism of action is unclear (Tseng et al., 1996). Reported immunologic effects vary substantially under different conditions. For example, thalidomide has been reported to decrease circulating TNF-α in patients with erythema nodosum leprosum, but to increase it in patients who are HIV-seropositive (Jacobson et al., 1997). Alternatively, it has been suggested that the drug affects angiogenesis (Miller and Stromland, 1999). The anti-TNF-α effect has led to its evaluation as a treatment for severe, refractory rheumatoid arthritis (Keessal et al., 1999).

**Bacillus Calmette-Guérin (BCG).** Live bacillus Calmette-Guérin (BCG; TICE BCG, THERACYS) is an attenuated, live culture of the bacillus of Calmette and Guérin strain of Mycobacterium bovis, that induces a granulomatous reaction at the site of administration. By unclear mechanisms, this preparation is active against tumors and is indicated for treatment and prophylaxis of carcinoma in situ of the urinary bladder and for prophylaxis of primary and recurrent stage Ta and/or T1 papillary tumors after transurethral resection (Morales et al., 1981; Paterson and Patel, 1998; Patard et al., 1998). Adverse effects include hypersensitivity, shock, chills, fever, malaise, and immune complex disease.

**Recombinant Cytokines. Interferons.** Although interferons (alpha, beta, and gamma) initially were identified by their antiviral activity, these agents also have important immunomodulatory activities (Johnson et al., 1994; Tilg and Kaser, 1999; Ransohoff, 1998). The interferons bind to specific cell-surface receptors that initiate a series of intracellular events: induction of certain enzymes, inhibition of cell proliferation, and enhancement of immune activities, including increased phagocytosis by macrophages and augmentation of specific cytotoxicity by T lymphocytes (Tompkins, 1999). Recombinant interferon alfa-2b (IFN-alpha 2, INTRON A) is obtained from Escherichia coli by recombinant expression. It is a member of a family of naturally occurring small proteins with molecular weights of 15,000 to 27,600 daltons, produced and secreted by cells in response to viral infections and other inducers. Interferon alfa-2b is indicated in the treatment of a variety of tumors, including hairy cell leukemia, malignant melanoma, follicular lymphoma, and AIDS-related Kaposi’s sarcoma (Punt, 1998; Bukowski, 1999; Sinkovics and Horvath, 2000). It also is indicated for infectious diseases, chronic hepatitis B, and condylomata acuminata. In addition, it is supplied in combination with ribavirin (REBETRON) for treatment of chronic hepatitis C in patients with compensated liver function not treated previously with interferon alfa-2b or who have relapsed after interferon alfa-2b therapy (Lo Iacono et al., 2000). Flu-like symptoms, including fever, chills, and headache, are the most common adverse effects after interferon alfa-2b administration. Adverse experiences involving the cardiovascular system (hypotension, arrhythmias, and rarely cardiomyopathy and myocardial infarction) and CNS (depression, confusion) are less-frequent side effects.

**Interferon gamma-1b (ACTIMMUNE)** is a recombinant polypeptide that activates phagocytes and induces their generation of oxygen metabolites that are toxic to a number of microorganisms. It is indicated to reduce the frequency and severity of serious infections associated with chronic granulomatous disease. Adverse reactions include fever, headache, rash, fatigue, GI distress, anorexia, weight loss, myalgia, and depression.

**Interferon beta-1a (AVONEX, REBIF), a 166–amino acid recombinant glycoprotein, and interferon beta-1b (BETASERON), a 165–amino acid recombinant protein, have antiviral and immunomodulatory properties. They are FDA approved for the treatment of relapsing and relapsing-remitting multiple sclerosis to reduce the frequency of clinical exacerbations (see below). The mechanism of their action in multiple sclerosis is unclear. Flu-like symptoms (fever, chills, myalgia) and injection-site reactions have been common adverse effects.

Further discussion of the use of these and other interferons in the treatment of viral diseases can be found in Chapter 49.

**Interleukin-2.** Human recombinant interleukin-2 (aldesleukin, PROLEUKIN; des-alamyl-1, serine-125 human IL-2) is produced by recombinant DNA technology in E. coli (Taniguchi and Minami, 1993). This recombinant form differs from native IL-2 in that it is not glycosylated, has no amino terminal alanine, and has a serine substituted for the cysteine at amino acid 125 (Doyle et al., 1985). The potency of the preparation is represented in International Units in a lymphocyte proliferation assay such that 1.1 mg of recombinant IL-2 protein equals 18 million International Units. Aldesleukin has the following in vitro biologic activities of native IL-2: enhancement of lymphocyte proliferation and growth of IL-2–dependent cell lines; enhancement
of lymphocyte-mediated cytotoxicity and killer cell activity; and induction of interferon-γ activity (Winkelhake et al., 1990; Whittington and Faulds, 1993). In vivo administration of aldesleukin in animals produces multiple immunologic effects in a dose-dependent manner. Cellular immunity is profoundly activated with lymphocytosis, eosinophilia, thrombocytopenia, and release of multiple cytokines (e.g., TNF, IL-1, interferon-γ). Aldesleukin is indicated for the treatment of adults with metastatic renal cell carcinoma and melanoma. Administration of aldesleukin has been associated with serious cardiovascular toxicity resulting from capillary leak syndrome, which involves loss of vascular tone and leak of plasma proteins and fluid into the extravascular space. Hypotension, reduced organ perfusion, and death may occur. An increased risk of disseminated infection due to impaired neutrophil function also has been associated with aldesleukin treatment.

**Immunization**

Immunization may be active or passive. Active immunization involves stimulation with an antigen to develop immunologic defenses against a future exposure. Passive immunization involves administration of preformed antibodies to an individual who is already exposed or is about to be exposed to an antigen.

**Vaccines.** Active immunization, vaccination, involves administration of an antigen as a whole, killed organism, attenuated (live) organism, or a specific protein or peptide constituent of an organism. Booster doses often are required, especially when killed (inactivated) organisms are used as the immunogen. In the United States, vaccination has sharply curtailed or practically eliminated a variety of major infections, including diphtheria, measles, mumps, pertussis, rubella, tetanus, *Haemophilus influenzae* type b, and pneumococcus (Dorner and Barrett, 1999; The National Vaccine Advisory Committee, 1999).

Although most vaccines have targeted infectious diseases, a new generation of vaccines may provide complete or limited protection from specific cancers or autoimmune diseases (Lee et al., 1998; Del Vecchio and Parmiani, 1999; Simone et al., 1999). Because T cells optimally are activated by peptides and costimulatory ligands that both are present on antigen-presenting cells (APCs), one approach for vaccination has consisted of immunizing patients with APCs expressing a tumor antigen. The first generation of anticancer vaccines used whole cancer cells or tumor-cell lysates as a source of antigen in combination with various adjuvants, relying on host APCs to process and present tumor-specific antigens (Sinkovics and Horvath, 2000). These anticancer vaccines resulted in occasional clinical responses and are being tested in prospective clinical trials. Second generation anticancer vaccines utilized specific APCs incubated *ex vivo* with antigen or transduced to express antigen and subsequently reinfused into patients. In laboratory animals, immunization with dendritic cells previously pulsed with MHC class I–restricted peptides derived from tumor-specific antigens led to pronounced antitumor cytotoxic T-lymphocyte responses and protective tumor immunity (Tarte and Klein, 1999). Finally, multiple studies have demonstrated the efficacy of DNA vaccines in small- and large-animal models of infectious diseases and cancer (Lewis and Babik, 1999; Liljeqvist and Stahl, 1999). The advantage of DNA vaccination over peptide immunization is that it permits generation of entire proteins, enabling determinant selection to occur in the host without having to restrict immunization to patients bearing specific HLA alleles. However, a safety concern about this technique is the potential for integration of the plasmid DNA into the host genome, possibly disrupting important genes and thereby leading to phenotypic mutations or carcinogenicity. A final approach to generate or enhance immune responses against specific antigens consists of infecting cells with recombinant viruses that encode the protein antigen of interest. Different types of viral vectors that can infect mammalian cells, such as vaccinia, avipox, lentivirus, adenovirus or adeno-virus-associated virus, have been used.

**Immune Globulin.** Passive immunization is indicated when an individual is deficient in antibodies because of a congenital or acquired immunodeficiency, when an individual with a high degree of risk is exposed to an agent and there is inadequate time for active immunization (e.g., measles, rabies, hepatitis B), or when a disease is already present but can be ameliorated by passive antibodies (e.g., botulism, diphtheria, tetanus). Passive immunization may be provided by several different products (Table 52–2). Nonspecific immunoglobulins or highly specific immunoglobulins may be provided based upon the indication. The protection provided usually lasts from 1 to 3 months. Immune globulin is derived from pooled plasma of adults by an alcohol-fractionation procedure. It contains largely IgG (95%) and is indicated for antibody-deficiency disorders, exposure to infections such as hepatitis A and measles, and specific immunologic diseases such as immune thrombocytopenic purpura and Guillain-Barré syndrome (Ballow, 1997; Jordan et al., 1998a; Jordan et al., 1998b).

In contrast, specific immune globulins (“hyperimmune”) differ from other immune globulin preparations in that donors are selected for high titers of the desired antibodies. Specific immune globulin preparations are available...
Section X  /  Immunomodulators

for hepatitis B, rabies, varicella-zoster, cytomegalovirus, and respiratory syncytial virus. Rho(D) immune globulin is a specific hyperimmune globulin for prophylaxis against hemolytic disease of the newborn due to Rh incompatibility between mother and fetus. All such plasma-derived products carry the theoretical risk of transmission of infectious disease.

Rho(D) Immune Globulin. The commercial forms of Rho(D) immune globulin (Table 52–2) consist of IgG containing a high titer of antibodies against the Rh(D) antigen on the surface of red blood cells. All donors are carefully screened to reduce the risk of transmitting infectious diseases. Fractionation of the plasma is performed by precipitation with cold alcohol followed by passage through a viral clearance system (Bowman, 1998; Contreras, 1998; Lee, 1998).

Mechanism of Action. Rho(D) immune globulin binds Rh antigens, thereby preventing sensitization (Peterec, 1995). Rh-negative women may be sensitized to the “foreign” Rh antigen on red blood cells via the fetus at the time of birth, miscarriage, ectopic pregnancy, or any transplacental hemorrhage. If the women go on to have a primary immune response, they will make antibodies to Rh antigen that can cross the placenta and damage subsequent fetuses by lysing red blood cells. This syndrome, called hemolytic disease of the newborn, is life-threatening. The form due to Rh incompatibility is largely preventable by Rho(D) immune globulin.

Therapeutic Use. Rho(D) immune globulin is indicated whenever fetal red blood cells are known or suspected to have entered the circulation of an Rh-negative mother unless the fetus is known also to be Rh-negative. The drug is given intramuscularly. The half-life of circulating immunoglobulin is approximately 21 to 29 days.

Toxicity. Injection site discomfort and low-grade fever have been reported. Systemic reactions are extremely rare, but myalgia, lethargy, and anaphylactic shock have been reported. As with all plasma-derived products, there is a theoretical risk of transmission of infectious diseases.

Intravenous Immunoglobulin (IVIG). In recent years, indications for the use of intravenous immunoglobulin (IVIG) have expanded beyond replacement therapy for agammaglobulinemia and other immunodeficiencies to include a variety of bacterial and viral infections, and an array of autoimmune and inflammatory diseases as diverse as thrombocytopenic purpura, Kawasaki’s disease, and autoimmune skin, neuromuscular, and neurologic diseases (Dalakas, 2004). Although the mechanism of action of IVIG in immune modulation remains largely unknown, proposed mechanisms include modulation of expression and function of Fc receptors on leukocytes and endothelial cells, interference with complement activation and cytokine production, provision of anti-idiotypic antibodies (Jerne network theory), and effects on the activation and effector function of T and B lymphocytes (Larroche et al., 2002; Rutter and Luger, 2002). Although IVIG is effective in many autoimmune diseases, its spectrum of efficacy and appropriate dosing (especially duration of therapy) are unknown. Additional controlled studies of IVIG are needed to identify proper dosing, cost-benefit, and quality-of-life parameters.

A CASE STUDY: IMMUNOTHERAPY FOR MULTIPLE SCLEROSIS

Clinical Features and Pathology. Multiple sclerosis (MS) is a demyelinating inflammatory disease of the CNS white matter that displays a triad of pathogenic symptoms: mononuclear cell infiltration, demyelination, and scarring (gliosis). The peripheral nervous system is uninolved. The disease, which may be episodic or progressive, occurs in early to middle adulthood with prevalence increasing from late adolescence to 35 years and then declining. MS is roughly twice as common in females as in males and occurs mainly

in higher latitudes of the temperate climates. Epidemiologic studies suggest a role for environmental factors in the pathogenesis of MS; despite many suggestions, associations with infectious agents have proven inconclusive, even though several viruses can cause similar demyelinating diseases in laboratory animals and humans. A stronger linkage is the genetic one: people of Northern European origin have a higher susceptibility to MS, and studies in twins and siblings suggest a genetic component of susceptibility to MS. The genetic linkage in the pathogenesis of MS is complex. Several studies indicate that one determinant of MS may be the class II (or HLA-DR) domain of the major histocompatibility complex (MHC) on chromosome 6 that encodes the histocompatibility antigens. Other loci under study include polymorphisms for GSH transferase and CD45. There is also substantial evidence of an autoimmune component to MS: in MS patients, there are activated T cells that are reactive to different myelin antigens including myelin basic protein (MBP); in addition, there is evidence for the presence of autoantibodies to myelin oligodendrocyte glycoprotein (MOG) and to MBP that can be eluted from the CNS plaque tissue, though it appears unlikely that high-affinity autoantibodies are present in the circulation. These antibodies may act with pathogenic T cells to produce some of the cellular pathology of MS. The neurophysiological result is altered conduction (both positive and negative) in myelinated fibers within the CNS (cerebral white matter, brain stem, cerebellar tracts, optic nerves, spinal cord); some alterations appear to result from exposure of voltage-dependent K+ channels that are normally covered by myelin.

Attacks are classified by type and severity and likely correspond to specific degrees of CNS damage and pathologic processes. Thus, physicians refer to acute MS (an acute attack), relapsing-remitting MS (the form in 85% of younger patients), secondary progressive MS (progressive neurologic deterioration following a long period of relapsing-remitting disease), and primary progressive MS (about 15% of patients, wherein deterioration with relatively little inflammation is apparent at onset). Keegan and Noseworthy (2002) have recently reviewed current concepts of the etiology, natural history, and current therapy of MS.

**Pharmacotherapy for MS.** Specific therapies are aimed at resolving acute attacks, reducing recurrences and exacerbations, and slowing the progression of disability (Table 52–3). Nonspecific therapies focus on maintaining function and quality of life. For acute attacks, pulse glucocorticoids are often employed (typically, 1 g/day of methylprednisolone administered intravenously for 3 to 5 days). There is no evidence that tapered doses of oral prednisone are useful or even desirable.

For relapsing-remitting attacks, immunomodulatory therapies are approved: beta-1 interferons (interferon beta-1a, interferon beta-1b, and glatiramer acetate [COPAXONE]). The interferons suppress the proliferation of T lymphocytes, inhibit their movement into the CNS from the periphery, and shift the cytokine profile from pro- to anti-inflammatory types.

Random polymers that contain amino acids commonly used as MHC anchors and T-cell receptor contact residues have been proposed as possible “universal APLs (altered peptide ligands).” Glatiramer acetate (GA) is a random sequence polypeptide consisting of four amino acids (alanine [A], lysine [K], glutamate [E], and tyrosine [Y]) at a molar ratio of A:K:E:Y of 4.5:3.6:1.5:1) with an average length of 40 to 100 amino acids. Directly labeled GA binds efficiently to different murine H2 I-A molecules, as well as to their human counterparts, the MHC class II DR molecules, but does not bind MHC class II DQ or MHC class I molecules in vitro. In Phase III clinical trials, GA, administered subcutaneously to patients with relapsing-remitting MS, decreased the rate of exacerbations by about 30% (Steinman, 2004; Hafler, 2004). In vivo administration of GA induces highly cross-reactive CD4+ T cells that are immune-deviated to secrete Th2 cytokines and prevents the appearance of new lesions detectable by MRI. This represents one of the first successful uses of an agent that ameliorates autoimmune disease by altering signals through the T-cell receptor complex (Steinman, 2004; Hafler, 2004).

For relapsing-remitting attacks and for secondary progressive MS, the alkylating agent cyclophosphamide (reviewed in Weiner, 2004) and the anthracenedionene-derivative mitoxantrone (NOVATRONE) are currently used in patients refractory to other immunomodulators. These agents, used primarily for cancer chemotherapy, have significant toxicities (see Chapter 51 for structures and pharmacology). While cyclophosphamide in patients with MS may not be limited by an accumulated dose exposure, mitoxantrone can be tolerated only up to an accumulated dose of 100 to 140 mg/m² (Crossey, 1984). The utility of interferon therapy in patients with secondary progressive MS is unclear. In primary progressive MS, with no discrete attacks and less observed inflammation, suppression of inflammation seems to be less helpful. A minority of patients at this stage will respond to high doses of glucocorticoids. Table 52–3 summarizes current immunomodulatory therapies for MS.

Each of the agents mentioned above has side effects and contraindications that may be limiting: infections (for glucocorticoids); hypersensitivity and pregnancy (for immunomodulators); and prior anthracycline/anthracenedione use, mediastinal irradiation, or cardiac disease (mitoxantrone). With all of these agents, it is clear that the
earlier they are used, the more effective they are in pre-
venting disease relapses. What is not clear is whether any
of these agents will prevent or diminish the later onset of
secondary progressive disease, which causes the more
severe form of disability. Given the fluctuating nature of
this disease, only long-term studies lasting decades will
answer this question.

A number of other new immunomodulatory therapies
are completing Phase III trials. One is a monoclonal anti-
body, natalizumab (ANTEGREN), directed against
the adhesion molecule \( \alpha_4 \beta_1 \) integrin; natalizumab binds to \( \alpha_4 \beta_1 \)
integrin and antagonizes interactions with integrin het-
erodimers containing \( \alpha_4 \) integrin, such as \( \alpha_4 \beta_1 \) integrin
that is expressed on the surface of activated lymphocytes
and monocytes. Preclinical data suggest that an interac-
tion of \( \alpha_4 \beta_1 \) integrin with VCAM-1 (vascular cellular-
adhesion molecule 1) is critical for T-cell trafficking from
the periphery into the CNS (Steinman, 2004); thus, block-
ing this interaction would hypothetically inhibit disease
exacerbations. In fact, Phase II clinical trials have demon-
strated a significant decrease in the number of new lesions
as determined by magnetic resonance imaging and clini-
cal attacks in MS patients receiving natalizumab (Miller
et al., 2003). Monoclonal antibodies directed against the
IL-2 receptor are also entering Phase III clinical trials.

IFN, interferon; IM, intramuscularly; RRMS, relapsing-remitting MS; SC, subcutaneously; SPMS, secondary progressive MS; IV, intravenously. Gd, gadolinium, used in Gd-enhanced MRI to assess number and size of inflammatory brain lesions; EDSS, Expanded Disability Status Scale, a neurologic assessment scale for MS pathology (see Ravnborg et al., 2005); MMP, matrix metalloprotease.
CLINICAL SUMMARY

Most transplant centers employ some combination of immunosuppressive drugs with antilymphocyte induction therapy with either a monoclonal or polyclonal antibody agent. Maintenance immunosuppression consists of a calcineurin inhibitor (cyclosporine or tacrolimus), glucocorticoids, and an antimetabolite (azathioprine or mycophenolate mofetil). Mycophenolate mofetil has largely replaced azathioprine as part of the standard immunosuppressive regimen after transplantation. At present, a number of centers are conducting trials with new drug combinations including either cyclosporine or tacrolimus in combination with glucocorticoids and mycophenolate mofetil, with or without antibody-induction therapy or FTY70 with cyclosporine. Sirolimus is being used to limit the number of different organs, including kidney, liver, pancreas, and heart. The apparent effectiveness of new drug combinations has resulted in a resurgence of interest in glucocorticoid withdrawal.

BIBLIOGRAPHY

**MONOGRAPHS AND REVIEWS**

This page intentionally left blank
The finite life span of most mature blood cells requires their continuous replacement, a process termed hematopoiesis. New cell production must respond to basal needs and states of increased demand. Red blood cell production can increase more than twentyfold in response to anemia or hypoxemia, white blood cell production increases dramatically in response to a systemic infection, and platelet production can increase ten- to twentyfold when platelet consumption results in thrombocytopenia.

The regulation of blood cell production is complex. Hematopoietic stem cells are rare marrow cells that manifest self-renewal and lineage commitment, resulting in cells destined to differentiate into the nine distinct blood-cell lineages. For the most part, this process occurs in the marrow cavities of the skull, vertebral bodies, pelvis, and proximal long bones; it involves interactions among hematopoietic stem and progenitor cells and the cells and complex macromolecules of the marrow stroma, and is influenced by a number of soluble and membrane-bound hematopoietic growth factors. A number of these hormones and cytokines have been identified and cloned, permitting their production in quantities sufficient for therapeutic use. Clinical applications range from the treatment of primary hematological diseases to use as adjuncts in the treatment of severe infections and in the management of patients who are undergoing cancer chemotherapy or marrow transplantation.

Hematopoiesis also requires an adequate supply of minerals (e.g., iron, cobalt, and copper) and vitamins (e.g., folic acid, vitamin B₁₂, pyridoxine, ascorbic acid, and riboflavin), and deficiencies generally result in characteristic anemias, or, less frequently, a general failure of hematopoiesis (Hoffbrand and Herbert, 1999). Therapeutic correction of a specific deficiency state depends on the accurate diagnosis of the anemic state and knowledge about the correct dose, the use of these agents in various combinations, and the expected response. This chapter deals with the growth factors, vitamins, minerals, and drugs that affect the blood and blood-forming organs.

I. HEMATOPOIETIC GROWTH FACTORS

History. Modern concepts of hematopoietic cell growth and differentiation arose in the 1950s, when cells from the spleen and marrow were shown to play an important role in the restoration of hematopoietic tissue in irradiated animals. In 1961, Till and McCulloch demonstrated that individual hematopoietic cells could form macroscopic hematopoietic colonies in the spleens of irradiated mice.
Their work established the concept that there exist discrete hematopoietic stem cells, which can be experimentally identified, albeit in retrospect (i.e., the presence of a multilineage clonal splenic colony appearing 11 days after transplantation implied that a single cell lodged and expanded into several cell lineages). This concept now has been expanded to include normal human marrow cells. Moreover, such cells now can be prospectively identified.

The basis for identifying soluble growth factors was provided by Sachs and independently by Metcalf, who developed clonal, in vitro assays for hematopoietic progenitor cells. Initially, such hematopoietic colonies developed only in the presence of conditioned culture medium from leukocytes or tumor cell lines. Individual growth factors then were isolated based on their activities in such assays. Many of these same assays were instrumental in purifying a hierarchy of progenitor cells committed to individual and combinations of mature blood cells (Kondo et al., 1997; Akashi et al., 2000; Sawada et al., 1990; Nakorn et al., 2003).

The existence of a circulating growth factor that controls red blood cell development was first suggested by the experiments of Paul Carnot in 1906. He observed an increase in the red cell count in rabbits injected with serum obtained from anemic animals and postulated the existence of a factor that he called hemapoietine. However, it was not until the 1950s that Reissmann, Erslev, and Jacobsen and coworkers defined the origin and actions of the hormone, now called erythropoietin. Subsequently, extensive studies of erythropoietin were carried out in patients with anemia and polycythemia, leading to the purification of erythropoietin from urine and the subsequent cloning of the erythropoietin gene. The high-level expression of erythropoietin in and purification from cell lines has allowed for its use in humans with anemia.

Similarly, the existence of specific leukocyte growth factors was suggested by the capacity of different conditioned culture media to induce the in vitro growth of colonies containing different combinations of granulocytes and monocytes. Using a multipstep purification process beginning with conditioned culture medium from fibroblasts, macrophage colony-stimulating factor (M-CSF) was purified and the corresponding gene identified (Wong et al., 1987). An activity that stimulated the production of both granulocytes and monocytes was purified from murine lung-conditioned medium, leading to cloning of its cDNA (Gough et al., 1984), as was an activity that stimulated the exclusive production of neutrophils, permitting the cloning of granulocyte colony-stimulating factor (G-CSF) (Welte et al., 1985). Most recently, a megakaryocyte colony-stimulating factor termed thrombopoietin was purified and cloned (Kaushansky, 1998).

The growth factors that support lymphocyte growth were not identified using in vitro colony-forming assays, but rather using assays that measured the capacity of the cytokine to promote lymphocyte proliferation in vitro. This permitted the identification of the growth-promoting properties of interleukin-7, interleukin-4, or interleukin-15 for all lymphocytes, B cells, or NK cells, respectively (Goodwin et al., 1989; Yokota et al., 1986; Grabstein et al., 1994). Again, recombinant expression of these cDNAs permitted production of sufficient quantities of biologically active growth factors for clinical investigations, allowing for the demonstration of the potential clinical utility of such factors.

**Growth Factor Physiology.** Steady-state hematopoiesis encompasses the production of more than 400 billion blood cells each day. This production is tightly regulated and can be increased severalfold with increased demand. The hematopoietic organ also is unique in adult physiology in that several mature cell types are derived from a much smaller number of multipotent progenitors, which develop from a more limited number of pluripotent hematopoietic stem cells. Such cells are capable of maintaining their own number and differentiating under the influence of cellular and humoral factors to produce the large and diverse number of mature blood cells.

Stem cell differentiation can be described as a series of steps that produce so-called burst-forming units (BFU) and colony-forming units (CFU) for each of the major cell lines (Quesenberry and Levitt, 1979). These early progenitors (BFU and CFU) are capable of further proliferation and differentiation, increasing their number by some thirtyfold. Subsequently, colonies of morphologically distinct cells form under the control of an overlapping set of additional growth factors (G-CSF, M-CSF, erythropoietin, and thrombopoietin). Proliferation and maturation of the CFU for each cell line can amplify the resulting mature cell product by another thirtyfold or more, generating more than 1000 mature cells from each committed stem cell.

Hematopoietic and lymphopoietic growth factors are glycoproteins produced by a number of marrow cells and peripheral tissues. They are active at very low concentrations and typically affect more than one committed cell lineage. Most interact synergistically with other factors and also stimulate production of additional growth factors, a process called networking. Growth factors generally exert actions at several points in the processes of cell proliferation and differentiation and in mature cell function (Metcalf, 1985). However, the network of growth factors that contributes to any given cell lineage depends absolutely on a nonredundant, lineage-specific factor, such that absence of factors that stimulate developmentally early progenitors is compensated for by redundant cytokines, but loss of the lineage-specific factor leads to a specific cytopenia. Some of the overlapping and nonredundant effects of the more important hematopoietic growth factors are illustrated in Figure 53–1 and listed in Table 53–1.

**ERYTHROPOIETINS**

While erythropoietin is not the sole growth factor responsible for erythropoiesis, it is the most important regulator of the proliferation of committed progenitors (CFU-E) and their immediate progeny. In its absence, severe anemia is invariably present. Erythropoiesis is controlled by a highly responsive feedback system in which a sensor in the kidney detects changes in oxygen delivery to modu-
The sensor mechanism is now understood at the molecular level (Maxwell et al., 2001). Hypoxia-inducible factor (HIF-1) is a heterodimeric (HIF-1α and HIF-1β) transcription factor that enhances expression of multiple hypoxia-inducible genes, such as vascular endothelial growth factor and erythropoietin. HIF-1α is labile due to its prolyl hydroxylation and subsequent polyubiquitination and degradation, aided by the von Hippel-Lindau (VHL) protein. During states of hypoxia, the prolyl hydroxylase is inactive, allowing the accumulation of HIF-1α and activating erythropoietin expression, which in turn stimulates a rapid expansion of erythroid progenitors. Specific alteration of VHL leads to an oxygen-sensing defect, characterized by constitutively elevated levels of HIF-1α and erythropoietin, with a resultant polycythemia (Gordeuk et al., 2004).

Erythropoietin is encoded by a gene on human chromosome 7 that is expressed primarily in peritubular interstitial cells of the kidney. Erythropoietin contains 193 amino acids, of which the first 27 are cleaved during secretion. The final hormone is heavily glycosylated and has a molecular mass of approximately 30,000 daltons.

After secretion, erythropoietin binds to a receptor on the surface of committed erythroid progenitors in the marrow and is internalized. With anemia or hypoxemia, synthesis rapidly increases by one hundredfold or more, serum erythropoietin levels rise, and marrow progenitor cell survival, proliferation, and maturation are dramati-

| **INTERLEUKINS**                     | *IL-1, IL-3, IL-5, IL-6, IL-9, and IL-11*  
  - Act synergistically with each other and SCF, GM-CSF, G-CSF, and EPO to stimulate BFU-E, CFU-GEMM, CFU-GM, CFU-E, and CFU-Meg growth.  
  - Numerous immunologic roles, including stimulation of B cell and T cell growth.  
  - IL-6 stimulates human myeloma cells to proliferate.  
  - IL-6 and IL-11 stimulate BFU-Meg to increase platelet production. |
| **IL-5**                             | Controls eosinophil survival and differentiation.  
  *IL-1, IL-2, IL-4, IL-7, and IL-12*  
  - Stimulate growth and function of T cells, B cells, NK cells, and monocytes.  
  - Co-stimulate B, T, and LAK cells. |
| **IL-8 and IL-10**                   | Numerous immunological activities involving B and T cell functions.  
  - IL-8 acts as a chemoattractant factor for basophils and neutrophils.  
  - Acts synergistically with SCF, IL-1, IL-3, and IL-6 to stimulate CFU-GM, and CFU-Meg to increase neutrophil and monocyte production.  
  - With EPO may promote BFU-E formation.  
  - Enhances migration, phagocytosis, superoxide production, and antibody-dependent cell-mediated toxicity of neutrophils, monocytes, and eosinophils.  
  - Prevents alveolar proteinosis. |
| **GRANULOCYTE-MACROPHAGE COLONY–STIMULATING FACTOR (GM-CSF)** | Acts synergistically with SCF, IL-1, IL-3, and IL-6 to stimulate CFU-GM, and CFU-Meg to increase neutrophil and monocyte production. With EPO may promote BFU-E formation. Enhances migration, phagocytosis, superoxide production, and antibody-dependent cell-mediated toxicity of neutrophils, monocytes, and eosinophils. Prevents alveolar proteinosis. |
| **GRANULOCYTE COLONY–STIMULATING FACTOR (G-CSF)** | Stimulates CFU-G to increase neutrophil production. Enhances phagocytic and cytotoxic activities of neutrophils. |
| **MONOCYTE/MACROPHAGE COLONY–STIMULATING FACTOR (M-CSF, CSF-1)** | Stimulates CFU-M to increase monocyte precursors. Activates and enhances function of monocyte/macrophages. |
| **MACROPHAGE COLONY–STIMULATING FACTOR (M-CSF)** | Stimulates CFU-M to increase monocyte/macrophage precursors. Acts in concert with tissues and other growth factors to determine the proliferation, differentiation, and survival of a range of cells of the mononuclear phagocyte system. |
| **THROMBOPOIETIN (TPO, Mpl ligand)** | Stimulates the self-renewal and expansion of hematopoietic stem cells. Stimulates stem cell differentiation into megakaryocyte progenitors. Selectively stimulates megakaryocytopenesis to increase platelet production. Acts synergistically with other growth factors, especially IL-6 and IL-11. |

**ABBREVIATIONS:** BFU, burst-forming unit; CFU, colony-forming unit; E, erythrocyte; G, granulocyte; M, macrophage; Meg, megakaryocyte; NK cells, natural killer cells; LAK cells, lymphokine-activated killer cells.
cally stimulated. This finely tuned feedback loop can be disrupted by kidney disease, marrow damage, or a deficiency in iron or an essential vitamin. With an infection or an inflammatory state, erythropoietin secretion, iron delivery, and progenitor proliferation all are suppressed by inflammatory cytokines, but this accounts for only part of the resultant anemia; interference with iron metabolism also is an effect of inflammatory mediator effects on the hepatic protein hepcidin (Nemeth et al., 2004).

Recombinant human erythropoietin (epoetin alfa), produced using engineered Chinese hamster ovary cells, is nearly identical to the endogenous hormone except for two subtle differences. First, the carbohydrate modification pattern of epoetin alfa differs slightly from the native protein, but this difference apparently does not alter kinetics, potency, or immunoreactivity of the drug. However, modern assays can detect these differences (Skibeli et al., 2001), which is of significance for detecting athletes who use the recombinant product for “blood doping.” The second difference probably is related to the manufacturing process, as one commercially available form of the drug was recently associated with the development of anti-recombinant erythropoietin antibodies that cross-react with the patient’s own erythropoietin, potentially causing pure red cell aplasia (MacDougal, 2004). Most of these cases were caused by one preparation of the drug shortly after albumin was removed from the formulation (Casadevall, 2003).

Available preparations of epoetin alfa include EPOGEN, PROCRIT, and EXPREX, supplied in single-use vials of from 2000 to 40,000 units/ml for intravenous or subcutaneous administration. When injected intravenously, epoetin alfa is cleared from plasma with a half-life of 4 to 8 hours. However, the effect on marrow progenitors is sufficiently sustained that it need only be given three times a week to achieve an adequate response. Combination of the weekly dose into a single injection also can achieve virtually identical results. No significant allergic reactions have been associated with the intravenous or subcutaneous administration of epoetin alfa, and—except as noted above—antibodies have not been detected even after prolonged administration.

More recently, novel erythropoiesis-stimulating protein (NESP) or darbepoetin alfa (ARANESP) has been approved for clinical use in patients with indications similar to those for epoetin alfa. It is a genetically modified form of erythropoietin in which four amino acids have been mutated such that additional carbohydrate side chains are added during its synthesis, prolonging the circulatory survival of the drug to 24 to 26 hours (Jelkmann, 2002).

Therapeutic Uses, Monitoring, and Adverse Effects. Recombinant erythropoietin therapy, in conjunction with adequate iron intake, can be highly effective in a number of anemias, especially those associated with a poor erythropoietic response. There is a clear dose-response relationship between the epoetin alfa dose and the rise in hematocrit in anephric patients, with eradication of their anemia at higher doses (Eschbach et al., 1987). Epoetin alfa also is effective in the treatment of anemias associated with surgery, AIDS, cancer chemotherapy, prematurity, and certain chronic inflammatory conditions. Darbepoetin alfa also has been approved for use in patients with anemia associated with chronic kidney disease and is under review for several other indications.

During erythropoietin therapy, absolute or functional iron deficiency may develop. Functional iron deficiency (i.e., normal ferritin levels but low transferrin saturation) presumably results from the inability to mobilize iron stores rapidly enough to support the increased erythropoiesis. Virtually all patients eventually will require supplemental iron to increase or maintain transferrin saturation to levels that will adequately support stimulated erythropoiesis. Supplemental iron therapy is recommended for all patients whose serum ferritin is below 100 µg/L or whose serum transferrin saturation is less than 20% (see below).

During initial therapy and after any dosage adjustment, the hematocrit is determined once a week (HIV-infected and cancer patients) or twice a week (renal failure patients) until it has stabilized in the target range and the maintenance dose has been established; the hematocrit then is monitored at regular intervals. If the hematocrit increases by more than 4 points in any 2-week period, the dose should be decreased. Due to the time required for erythropoiesis and the erythrocyte half-life, hematocrit changes lag behind dosage adjustments by 2 to 6 weeks. The dose of darbepoetin should be decreased if the hemoglobin increase exceeds 1 g/dl in any two-week period because of the association of excessive rate of rise of hemoglobin with adverse cardiovascular events.

During hemodialysis, patients receiving epoetin alfa or darbepoetin may require increased anticoagulation. Serious thromboembolic events have been reported, including migratory thrombophlebitis, microvascular thrombosis, pulmonary embolism, and thrombosis of the retinal artery and temporal and renal veins. The risk of thrombotic events, including vascular access thromboses, was higher in adults with ischemic heart disease or congestive heart failure receiving epoetin alfa therapy with the goal of reaching a normal hematocrit (42%) than in those with a lower target hematocrit of 30%. The higher risk of cardiovascular events from erythropoietic therapies may be associated with higher hemoglobin or higher rates of rise of hemoglobin. The hemoglobin level should be managed to avoid exceeding a target level of 12 g/dl. Although epoetin alfa is not associated with direct pressor effects, blood pressure may rise, especially during the early phases of therapy when the hematocrit is increasing. Erythropoietins should be withheld in patients with pre-existing uncontrolled hypertension. Patients may require initiation of, or increases in, antihypertensive therapy. Hypertensive encephalopathy and seizures have occurred in chronic renal failure patients treated with epoetin alfa. The incidence of seizures appears to be higher during the first 90 days of therapy with epoetin alfa in patients on dialysis (occurring in about 2.5% of patients) when compared with subsequent 90-day periods. Headache, tachycardia, edema, shortness of breath, nausea, vomiting, diarrhea, injection site stinging, and flu-like symptoms (e.g., arthralgias and myalgias) also have been reported in conjunction with epoetin alfa therapy. Pure red cell
Anemia in association with neutralizing antibodies to native erythropoietin has been observed in patients treated with recombinant erythropoietins (see above); underlying infectious, inflammatory, or malignant processes; occult blood loss; underlying hematologic diseases (e.g., thalassemia, refractory anemia, or other myelodysplastic disorders); folic acid or vitamin B₁₂ deficiency; hemolysis; aluminum intoxication; bone marrow fibrosis; and osteitis fibrosa cystica.

Anemia of Chronic Renal Failure. Patients with anemia secondary to chronic kidney disease are ideal candidates for epoetin alfa therapy. The response in predialysis, peritoneal dialysis, and hemo-dialysis patients is dependent on severity of the renal failure, the erythropoietin dose and route of administration, and iron availability (Eschbach et al., 1989; Kaufman et al., 1998; Besarab et al., 1999). The subcutaneous route of administration is preferred over the intravenous route because absorption is slower and the amount of drug required is reduced by 20% to 40%.

The dose of epoetin alfa should be adjusted to obtain a gradual rise in the hematocrit over a 2- to 4-month period to a final hematocrit of 33% to 36%. Treatment to hematocrit levels greater than 36% is not recommended, as patients treated to a hematocrit above 40% showed a higher incidence of myocardial infarction and death (Besarab et al., 1998). The drug should not be used to replace emergency transfusion in patients who need immediate correction of a life-threatening anemia.

Patients are started on doses of 80 to 120 units/kg of epoetin alfa, given subcutaneously, three times a week. It can be given on a once-a-week schedule, but somewhat more drug is required for an equivalent effect. If the response is poor, the dose should be progressively increased. The final maintenance dose of epoetin alfa can vary from as little as 10 units/kg to more than 300 units/kg, with an average dose of 75 units/kg, three times a week. Children younger than 5 years generally require a higher dose. Resistance to therapy is common in patients who develop an inflammatory illness or become iron deficient, so close monitoring of general health and iron status is essential. Less common causes of resistance include occult blood loss, folic acid deficiency, carnitine deficiency, inadequate dialysis, aluminum toxicity, and osteitis fibrosa cystica secondary to hyperparathyroidism.

The most common side effect of epoetin alfa therapy is aggravation of hypertension, which occurs in 20% to 30% of patients and most often is associated with a rapid rise in hematocrit. Blood pressure usually can be controlled either by increasing antihypertensive therapy or ultrafiltration in dialysis patients or by reducing the epoetin alfa dose to slow the hematocrit response.

Darbepoetin alfa also is approved for use in patients who are anemic secondary to chronic kidney disease. The recommended starting dose is 0.45 μg/kg administered intravenously or subcutaneously once weekly, with dose adjustments depending on the response. Like epoetin alfa, side effects tend to occur when patients experience a rapid rise in hemoglobin concentration; a rise of less than 1 g/dl every 2 weeks generally has been considered safe.

Anemia in AIDS Patients. Epoetin alfa therapy has been approved for the treatment of HIV-infected patients, especially those on zidovudine therapy (Fischl et al., 1999). Excellent responses to doses of 100 to 300 units/kg, given subcutaneously three times a week, generally are seen in patients with zidovudine-induced anemia. In the face of advanced disease, marrow damage, and elevated serum erythropoietin levels (greater than 500 IU/L), therapy is less effective.

Cancer-Related Anemias. Epoetin alfa therapy, 150 units/kg three times a week or 450 to 600 units/kg once a week, can reduce the transfusion requirement in cancer patients undergoing chemotherapy. Evidence-based guidelines for the therapeutic use of recombinant erythropoietin in patients with cancer have been published (Rizzo et al., 2002). Briefly, the guidelines recommend the use of epoetin alfa in patients with chemotherapy-associated anemia when hemoglobin levels fall below 10 g/dl, basing the decision to treat less severe anemia (hemoglobin between 10 and 12 g/dl) on clinical circumstances. For anemia associated with hematologic malignancies, the guidelines support the use of recombinant erythropoietin in patients with low-grade myelodysplastic syndrome, although the evidence that the drug is effective in anemic patients with multiple myeloma, non-Hodgkin’s lymphoma, or chronic lymphocytic leukemia not receiving chemotherapy is less robust. A baseline serum erythropoietin level may help to predict the response; most patients with blood levels of more than 500 IU/L are unlikely to respond to any dose of the drug. Most patients treated with epoetin alfa experienced an improvement in their anemia, sense of well being, and quality of life (Demetri et al., 1998; Littlewood et al., 2003). This improved sense of well being, particularly in cancer patients, may not be solely due to the rise in the hematocrit. Erythropoietin receptors have been demonstrated in cells of the CNS, and erythropoietin has been found to act as a cytoprotectant in several models of CNS ischemia (Juul, 2002; Prass et al., 2003; Martinez-Estrada et al., 2003). Thus, high levels of the hormone may directly affect cancer patients’ sense of well-being.

Darbepoetin alfa also has been tested in cancer patients undergoing chemotherapy (Bloomfield et al., 2003; Hesketh et al., 2004), and preliminary studies appear promising. However, recent case reports have suggested a direct effect of both epoetin alfa and darbepoetin alfa in stimulation of tumor cells. For example, patients with cancer of the head and neck randomized to receive recombinant erythropoietin had a statistically significant increase in likelihood of tumor progression during the duration of the study (Henke et al., 2003). This finding is being evaluated by the FDA and warrants serious attention.

Surgery and Autologous Blood Donation. Epoetin alfa has been used perioperatively to treat anemia and reduce the need for transfusion. Patients undergoing elective orthopedic and cardiac procedures have been treated with 150 to 300 units/kg of epoetin alfa once daily for the 10 days preceding surgery, on the day of surgery, and for 4 days after surgery. As an alternative, 600 units/kg can be given on days −2, −1, and −7 before surgery, with an additional dose on the day of surgery. This can correct a moderately severe preoperative anemia (i.e., hematocrit 30% to 36%) and reduce the need for transfusion. Epoetin alfa also has been used to improve autologous blood donation (Goodnough et al., 1989). However, the potential benefit generally is small, and the expense is considerable. Patients treated for 3 to 4 weeks with epoetin alfa (300 to 600 units/kg twice a week) are able to donate only one or two more units than untreated patients, and most of the time this goes unused. Still, the ability to stimulate erythropoiesis for blood storage can be invaluable in the patient with multiple alloantibodies to red blood cells.

Other Uses. Epoetin alfa has received orphan drug status from the FDA for the treatment of the anemia of prematurity, HIV infection, and myelodysplasia. In the latter case, even very high doses of more than 1000 units/kg two to three times a week have had limited success. The utility of very high-dose therapy in other hematologic disorders, such as sickle cell anemia, still is under study. Highly competitive athletes have used epoetin alfa to increase their hemoglobin levels (“blood doping”) and improve performance. Unfortu-
nately, this misuse of the drug has been implicated in the deaths of several athletes and is strongly discouraged.

**MYELOID GROWTH FACTORS**

The myeloid growth factors are glycoproteins that stimulate the proliferation and differentiation of one or more myeloid cell lines. They also enhance the function of mature granulocytes and monocytes. Recombinant forms of several growth factors have been produced, including GM-CSF (Wong et al., 1985), G-CSF (Welte et al., 1985), IL-3 (Yang et al., 1986), M-CSF or CSF-1 (Kawasaki et al., 1985), and SCF (Huang et al., 1990) (Table 53–1).

The myeloid growth factors are produced naturally by a number of different cells, including fibroblasts, endothelial cells, macrophages, and T cells (Figure 53–2). They are active at extremely low concentrations and act via membrane receptors of the cytokine receptor superfamily to activate the JAK/STAT signal transduction pathway. GM-CSF is capable of stimulating the proliferation, differentiation, and function of a number of the myeloid cell lineages (Figure 53–1). It acts synergistically with other growth factors, including erythropoietin, at the level of the BFU. GM-CSF stimulates the CFU-GEMM, CFU-GM, CFU-M, CFU-E, and CFU-Meg to increase cell production. It also enhances the migration, phagocytosis, superoxide production, and antibody-dependent cell-mediated toxicity of neutrophils, monocytes, and eosinophils (Weisbart et al., 1987).

The activity of G-CSF is restricted to neutrophils and their progenitors, stimulating their proliferation, differentiation, and function. It acts primarily on the CFU-G, although it also can play a synergistic role with IL-3 and GM-CSF in stimulating other cell lines. G-CSF enhances phagocytic and cytotoxic activities of neutrophils. Unlike GM-CSF, G-CSF has little effect on monocytes, macrophages, and eosinophils and reduces inflammation by inhibiting IL-1, tumor necrosis factor, and interferon gamma. G-CSF also mobilizes primitive hematopoietic cells, including hematopoietic stem cells, from the marrow into the peripheral blood (Sheridan et al., 1992). This observation has virtually transformed the practice of stem cell transplantation, such that more than 90% of all such procedures today use G-CSF–mobilized peripheral blood stem cells as the donor product.

**Granulocyte-Macrophage Colony-Stimulating Factor (GM-CSF).** Recombinant human GM-CSF (sargramostim) is a 127–amino acid glycoprotein produced in yeast. Except for the substitution of a leucine in position 23 and variable levels of glycosylation, it is identical to endogenous human GM-CSF. While sargramostim, like natural GM-CSF, has a wide range of effects on cells in culture, its primary therapeutic effect is to stimulate myelopoiesis. The initial clinical application of sargramostim was in patients undergoing autologous bone marrow transplantation. By shortening the duration of neutropenia, transplant morbidity was significantly reduced without a change in long-term survival or risk of inducing an early relapse of the malignant process (Brandt et al., 1988; Rabinowe et al., 1993).

The role of GM-CSF therapy in allogeneic transplantation is less clear. Its effect on neutrophil recovery is less pronounced in patients receiving prophylactic treatment for graft-versus-host disease (GVHD), and studies have failed to show a significant effect on transplant mortality, long-term survival, the appearance of GVHD, or disease relapse. However, it may improve survival in transplant patients who exhibit early graft failure (Nemunaitis et al., 1990). It also has been used to mobilize CD34-positive progenitor cells for peripheral blood stem cell collection for transplantation after myeloablative chemotherapy (Haas et al., 1990). Sargramostim has been used to shorten the period of neutropenia and reduce morbidity in patients receiving intensive cancer chemotherapy (Gehartz et al., 1993). It also stimulates myelopoiesis in some patients with cyclic neutropenia, myelodysplasia, aplastic anemia, or AIDS-associated neutropenia (Groopman et al., 1987).

![Figure 53–2. Cytokine–cell interactions.](image-url) Macrophages, T cells, B cells, and marrow stem cells interact via several cytokines (IL-1, IL-2, IL-3, IL-4, IFN [interferon]-γ, GM-CSF, and G-CSF) in response to a bacterial or a foreign antigen challenge. See Table 53–1 for the functional activities of these various cytokines.
Sargramostim (LEUKINE) is administered by subcutaneous injection or slow intravenous infusion at doses of 125 to 500 \( \mu g/ \) m\(^2\) per day. Plasma levels of GM-CSF rise rapidly after subcutaneous injection and then decline with a half-life of 2 to 3 hours. When given intravenously, infusions should be maintained over 3 to 6 hours. With the initiation of therapy, there is a transient decrease in the absolute leukocyte count secondary to margination and sequestration in the lungs. This is followed by a dose-dependent, biphasic increase in leukocyte counts over the next 7 to 10 days. Once the drug is discontinued, the leukocyte count returns to baseline within 2 to 10 days. When GM-CSF is given in lower doses, the response is primarily neutrophilic, while monocytoplasia and eosinophilia are observed at larger doses. After hematopoietic stem cell transplantation or intensive chemotherapy, sargramostim is given daily during the period of maximum neutropenia until a sustained rise in the granulocyte count is observed. Frequent blood counts are essential to avoid an excessive rise in the granulocyte count. The dose may be increased if the patient fails to respond after 7 to 14 days of therapy. However, higher doses are associated with more pronounced side effects, including bone pain, malaise, flu-like symptoms, fever, diarrhea, dyspnea, and rash. An acute reaction to the first dose, characterized by flushing, hypotension, nausea, vomiting, and dyspnea, with a fall in arterial oxygen saturation due to granulocyte sequestration in the pulmonary circulation occurs in sensitive patients. With prolonged administration, a few patients may develop a capillary leak syndrome, with peripheral edema and pleural and pericardial effusions. Other serious side effects have included transient supraventricular arrhythmia, dyspnea, and elevation of serum creatinine, bilirubin, and hepatic enzymes.

**Granulocyte Colony-Stimulating Factor (G-CSF).**

Recombinant human G-CSF filgrastim (NEUPOGEN) is a 175–amino acid glycoprotein produced in *E. coli*. Unlike natural G-CSF, it is not glycosylated and carries an extra N-terminal methionine. The principal action of filgrastim is the stimulation of CFU-G to increase neutrophil production (Figure 53–1). It also enhances the phagocytic and cytotoxic functions of neutrophils.

Filgrastim is effective in the treatment of severe neutropenia after autologous hematopoietic stem cell transplantation and high-dose cancer chemotherapy (Lieschke and Burgess, 1992). Like GM-CSF, filgrastim shortens the period of severe neutropenia and reduces morbidity secondary to bacterial and fungal infections. When used as a part of an intensive chemotherapy regimen, it can decrease the frequency of hospitalization for febrile neutropenia and interruptions in the chemotherapy protocol; a positive impact on patient survival has not been demonstrated. G-CSF also is effective in the treatment of severe congenital neutropenias. In patients with cyclic neutropenia, G-CSF therapy will increase the level of neutrophils and shorten the length of the cycle sufficiently to prevent recurrent bacterial infections (Hammond *et al.*, 1989). Filgrastim therapy can improve neutrophil counts in some patients with myelodysplasia or marrow damage (moderately severe aplastic anemia or tumor infiltration of the marrow). The neutropenia of AIDS patients receiving zidovudine also can be partially or completely reversed.

Filgrastim is routinely used in patients undergoing peripheral blood stem cell (PBSC) collection for stem cell transplantation. It promotes the release of CD34+ progenitor cells from the marrow, reducing the number of collections necessary for transplant. Moreover, filgrastim-mobilized PBSCs appear more capable of rapid engraftment. PBSC-transplanted patients require fewer days of platelet and red blood cell transfusions and a shorter duration of hospitalization than do patients receiving autologous bone marrow transplants.

Filgrastim is administered by subcutaneous injection or intravenous infusion over at least 30 minutes at doses of 1 to 20 \( \mu g/kg \) per day. The usual starting dose in a patient receiving myelosuppressive chemotherapy is 5 \( \mu g/kg \) per day. The distribution and clearance rate from plasma (half-life of 3.5 hours) are similar for both routes of administration. As with GM-CSF therapy, filgrastim given daily after hematopoietic stem cell transplantation or intensive cancer chemotherapy will increase granulocyte production and shorten the period of severe neutropenia. Frequent blood counts should be obtained to determine the effectiveness of the treatment and guide dosage adjustment. In patients who received intensive myelosuppressive cancer chemotherapy, daily administration of G-CSF for 14 to 21 days or longer may be necessary to correct the neutropenia. With less intensive chemotherapy, fewer than 7 days of treatment may suffice. In AIDS patients on zidovudine or patients with cyclic neutropenia, chronic G-CSF therapy often is required.

One indication for G-CSF presently under investigation is its use to increase the number of peripheral blood neutrophils in leukocyte donors. For many years it had been hoped that, like platelet transfusions for the bleeding associated with severe thrombocytopenia, neutrophil transfusion could diminish the infectious complications of neutropenia. However, given the short circulatory half-life of neutrophils (~6 hours) and the need for large numbers of cells, the practical collection of sufficient cell numbers has eluded hematologists. With few complications of therapy in more than 15 years of clinical experience, G-CSF now has been used to increase peripheral neutrophil counts in prospective donors and neutrophil transfusions (Hubel *et al.*, 2002). While initial results were modest, the therapy is likely to be optimized and greater efficacy is anticipated.

Adverse reactions to filgrastim include mild to moderate bone pain in patients receiving high doses over a protracted period, local skin reactions following subcutaneous injection, and rare cutaneous necrotizing vasculitis. Patients with a history of hypersensitivity to proteins produced by *E. coli* should not receive the drug. Marked granulocytosis, with counts greater than 100,000/\( \mu l \), can occur in patients receiving filgrastim over a prolonged period of time. However, this is not associated with any reported clinical morbidity or mortality and rapidly resolves once therapy is discontinued. Mild to moderate splenomegaly has been observed in patients on long-term therapy.
Pegylated recombinant human G-CSF pegfilgrastim (NEULASTA) is generated through conjugation of a 20,000-dalton polyethylene glycol moiety to the N-terminal methionyl residue of the 175–amino acid G-CSF glycoprotein produced in E. coli. The clearance of pegfilgrastim by glomerular filtration is minimized, thus making neutrophil-mediated clearance the primary route of elimination. Consequently the circulating half-life of pegfilgrastim is longer than that of filgrastim, allowing for more sustained duration of action and less frequent dosing (Waladkhani, 2004). Clinical studies suggest that neutrophil-mediated clearance of pegfilgrastim may be self-regulating and therefore specific to each patient’s hematopoietic recovery (Crawford, 2002). As such, the recommended dose for pegfilgrastim is fixed at 6 mg administered subcutaneously.

The therapeutic roles of other growth factors still need to be defined, although IL-3 and IL-6 have been removed from testing due to poor efficacy and/or significant toxicity. M-CSF may play a role in stimulating monocyte and macrophage production, although with significant side effects, including splenomegaly and thrombocytopenia. Stem cell factor (SCF) has been shown to augment peripheral blood mobilization of primitive hematopoietic progenitor cells (Molineux et al., 1991; Moskowitz et al., 1997).

**THROMBOPOIETIC GROWTH FACTORS**

**Interleukin-11.** Interleukin-11 was cloned based on its activity to promote proliferation of an IL-6–dependent myeloma cell line (Du et al., 1994). The 23,000-dalton cytokine contains 178 amino acids and stimulates hematopoiesis, intestinal epithelial cell growth, and osteoclastogenesis and inhibits adipogenesis. IL-11 enhances megakaryocyte maturation in vitro (Teramura et al., 1992; Debili et al., 1993), and its in vivo administration to animals modestly increases peripheral blood platelet counts (Neben et al., 1993; Farese et al., 1994). Clinical trials in patients who previously demonstrated significant chemotherapy-induced thrombocytopenia demonstrated that administration of the recombinant cytokine was associated with less severe thrombocytopenia and reduced use of platelet transfusion (Tepler et al., 1996; Isaacs et al., 1997) leading to its approval for clinical use by the FDA.

Recombinant human interleukin-11 oprelvekin (NEUMEGA) is a bacterially derived, 19,000-dalton polypeptide of 177 amino acids that differs from the native protein only because it lacks the amino terminal proline residue and is not glycosylated. The recombinant protein has a 7-hour half-life after subcutaneous injection. In normal subjects, daily administration of oprelvekin leads to a thrombopoietic response in 5 to 9 days.

The drug is available in single-use vials containing 5 mg and is administered to patients at 25 to 50 µg/kg per day subcutaneously. Oprelvekin is approved for use in patients undergoing chemotherapy for nonmyeloid malignancies that displayed severe thrombocytopenia (platelet count <20,000/µl) on a prior cycle of the same chemotherapy, and is administered until the platelet count returns to more than 100,000/µl. The major complications of therapy are fluid retention and other associated cardiac symptoms, such as tachycardia, palpitation, edema, and shortness of breath; this is a significant concern in elderly patients and often requires concomitant therapy with diuretics. Fluid retention reverses upon drug discontinuation, but volume status should be carefully monitored in elderly patients, those with a history of heart failure, or those with preexisting fluid collections in the pleura, pericardium, or peritoneal cavity. Also reported are blurred vision, injection-site rash or erythema, and paresthesias.

**Thrombopoietin.** The cloning and expression of recombinant thrombopoietin, a cytokine that predominantly stimulates megakaryopoiesis, is potentially another milestone in the development of hematopoietic growth factors as therapeutic agents (Lok et al., 1994; de Sauvage et al., 1994; Kaushansky et al., 1994) (Table 53–1). Thrombopoietin is a 45,000- to 75,000-dalton glycoprotein containing 332 amino acids that is produced by the liver, marrow stromal cells, and many other organs. In both humans and mice, genetic elimination of thrombopoietin or its receptor reduces the platelet counts to 10% of normal values. Moreover, blood levels of the hormone are inversely related to the blood platelet count, together indicating that the hormone is the primary regulator of platelet production.

Administration of recombinant thrombopoietin leads to a log-linear increase in the platelet count in mice, rats, dogs, and nonhuman primates (Harker, 1999) that begins on the third day of administration. In a number of human preclinical trials in several models of chemotherapy- and radiation-induced myelosuppression, thrombopoietin accelerated the recovery of platelet counts and other hematologic parameters (Kaushansky, 1998). Of note, however, the agent failed to substantially affect hematopoietic recovery when administered after myeloablative therapy and stem cell transplantation, unless given to the stem cell donor (Fibbe et al., 1995).
Two forms of recombinant thrombopoietin have been developed for clinical use. One is a truncated version of the native polypeptide, termed recombinant human megakaryocyte growth and development factor (rHuMGDF), which is produced in bacteria and then covalently modified with polyethylene glycol to increase the circulatory half-life. The second is the full-length polypeptide termed recombinant human thrombopoietin (rHuTPO), which is produced in mammalian cells. In vitro, both drugs are equally potent in stimulating megakaryocyte growth.

In clinical trials, both drugs are safe in the patient populations selected for study (Basser et al., 1996; Fanucchi et al., 1997; Vadhan-Raj et al., 1997). However, efficacy results using these agents have been mixed. In a small number of patients with gynecological cancers who were receiving carboplatin (Vadhan-Raj et al., 2000), recombinant human thrombopoietin therapy reduced the duration of severe thrombocytopenia and the need for platelet transfusions. In a similar study of patients treated with carboplatin plus cyclophosphamide, patients receiving a cycle of chemotherapy supplemented with G-CSF plus thrombopoietin had higher platelet counts at nadir and a shorter median duration of severe thrombocytopenia than they did after cycles of therapy supplemented only with G-CSF (Basser et al., 2000). When used to augment peripheral blood counts in preparation for platelet donation, a single dose of thrombopoietin in the platelet donors tripled their platelet counts, allowed for a threefold increase in the number of platelets that could be collected in a single apheresis, and led to a fourfold increase in the mean platelet count increase noted in transfusion recipients (Kuter et al., 2001). However, this particular regimen was associated with several instances of anti–recombinant thrombopoietin antibodies that cross-reacted with the native hormone, resulting in subsequent thrombocytopenia (Li et al., 2001).

In several studies, although the drug was safe, rHuMGDF was not effective. In two studies of patients treated for 7 days with standard, aggressive therapy for acute leukemia, the addition of recombinant thrombopoietin failed to accelerate platelet recovery (Archimbaud et al., 1999; Schiffer et al., 2000). A similar lack of efficacy was seen when the drug was used following autologous peripheral blood stem cell transplantation (Bolwell et al., 2000). Failure to improve hematopoiesis in some of these trials may have resulted from the dosing regimen employed; the optimal dose and schedule of administration in various clinical settings need to be established. After a single bolus injection, platelet counts showed a detectable increase by day 4, peaked by 12 to 14 days, and then returned to normal over the next 4 weeks. The peak platelet response follows a log-linear dose response. Platelet activation and aggregation are not affected, and patients are not at increased risk of thromboembolic disease, unless the platelet count is allowed to rise to very high levels. These kinetics need to be taken into account when planning therapy in cancer chemotherapy patients.

Due to concerns over the immunogenicity of these agents, and to other considerations, efforts now are under way to develop small molecular mimics of recombinant thrombopoietin, discovered either through screening of phage display peptide libraries (Broudy et al., 2004) or of small organic molecules (Kimura et al., 1998). Several of these agents are in clinical trials.

## II. DRUGS EFFECTIVE IN IRON DEFICIENCY AND OTHER HYPOCHROMIC ANEMIAS

### IRON AND IRON SALTS

Iron deficiency is the most common nutritional cause of anemia in humans. It can result from inadequate iron intake, malabsorption, blood loss, or an increased requirement, as with pregnancy. When severe, it results in a characteristic microcytic, hypochromic anemia. The impact of iron deficiency is not limited to the erythron (Dallman, 1982). Iron also is an essential component of myoglobin; heme enzymes such as the cytochromes, catalase, and peroxidase; and the metalloflavoprotein enzymes, including xanthine oxidase and the mitochondrial enzyme α-glycerophosphate oxidase. Iron deficiency can affect metabolism in muscle independently of the effect of anemia on oxygen delivery. This may reflect a reduction in the activity of iron-dependent mitochondrial enzymes. Iron deficiency also has been associated with behavioral and learning problems in children, abnormalities in catecholamine metabolism, and possibly, impaired heat production. Awareness of the ubiquitous role of iron has stimulated considerable interest in the early and accurate detection of iron deficiency and in its prevention.

**History.** The modern understanding of iron metabolism began in 1937 with the work of McCance and Widdowson on iron absorption and excretion and Heilmeyer and Plotner’s measurement of iron in plasma (Beutler, 2002). In 1947, Laurell described a plas-
Iron and the Environment. Iron exists in the environment largely as ferric oxide or hydroxide or as polymers. In this state, its biological availability is limited unless solubilized by acid or chelating agents. For example, bacteria and some plants produce high-affinity chelating agents that extract iron from the surrounding environment. Most mammals have little difficulty in acquiring iron; this is explained by an ample iron intake and perhaps also by a greater efficiency in absorbing iron. Humans, however, appear to be an exception. Although total dietary intake of elemental iron in human beings usually exceeds requirements, the bioavailability of the iron in the diet is limited.

Metabolism of Iron. The body store of iron is divided between essential iron-containing compounds and excess iron, which is held in storage. Quantitatively, hemoglobin dominates the essential fraction (Table 53–2). This protein, with a molecular weight of 64,500, contains four atoms of iron per molecule, amounting to 1.1 mg of iron per milliliter of red blood cells (20 mmol). Other forms of essential iron include myoglobin and a variety of heme and nonheme iron-dependent enzymes. Ferritin is a protein-iron storage complex that exists as individual molecules or as aggregates. Apoferritin has a molecular weight of about 450,000 and is composed of 24 polypeptide subunits that form an outer shell, within which resides a storage cavity for polynuclear hydrous ferric oxide phosphate. More than 30% of the weight of ferritin may be iron (4000 atoms of iron per ferritin molecule). Ferritin aggregates, referred to as hemosiderin and visible by light microscopy, constitute about one-third of normal stores, a fraction that increases as stores enlarge. The two predominant sites of iron storage are the reticuloendothelial system and the hepatocytes, although some storage also occurs in muscle.

Internal exchange of iron is accomplished by the plasma protein transferrin. This 76-kd \( \beta_t \)-glycoprotein has two binding sites for ferric iron. Iron is delivered from transferrin to intracellular sites by means of specific transferrin receptors in the plasma membrane. The iron–transferrin complex binds to the receptor, and the ternary complex is taken up by receptor-mediated endocytosis. Iron subsequently dissociates in the acidic, intracellular vesicular compartment (the endosomes), and the receptor returns the apotransferrin to the cell surface, where it is released into the extracellular environment (Klausner et al., 1983).

Cells regulate their expression of transferrin receptors and intracellular ferritin in response to the iron supply. When iron is plentiful, the synthesis of transferrin receptors is reduced and ferritin production is increased (Rouault, 2002). Conversely, with iron deficiency, cells express a greater number of transferrin receptors and reduce ferritin concentrations to maximize uptake and prevent diversion of iron to storage forms. Apoferritin synthesis is regulated posttranscriptionally by two cytoplasmic binding proteins (IRP-1 and IRP-2) and an iron-regulating element on mRNA (IRE). When iron is in short supply, IRP binds to mRNA IRE and inhibits apoferritin translation. Conversely, when iron is abundant, binding is blocked and apoferritin synthesis increases (Klausner et al., 1993).

The flow of iron through the plasma amounts to a total of 30 to 40 mg per day in the adult (about 0.46 mg/kg of body weight) (Finch and Huebers, 1982). The major internal circulation of iron involves the erythron and reticuloendothelial cells (Figure 53–3). About 80% of the iron in plasma goes to the erythroid marrow to be packaged into new erythrocytes; these normally circulate for about 120 days before being catabolized by the reticuloendothelial system. At that time, a portion of the iron is immediately returned to the plasma bound to transferrin, while another portion is incorporated into the ferritin stores of reticuloendothelial cells and returned to the circulation more gradually. Isotopic studies indicate some degree of iron wastage in this process, where-in defective cells or unused portions of their iron are transferred to the reticuloendothelial cell during matura-

idiologically localized in the reticuloendothelial cells as defective red cell precursors are broken down; this is termed ineffective erythropoiesis. The rate of iron turnover in plasma may be reduced by one-half or more with red cell aplasia, with all the iron directed to the hepatocytes for storage.

The most remarkable feature of iron metabolism is the degree to which body stores are conserved. Only 10% of the total is lost per year by normal men, i.e., about 1 mg per day. Two-thirds of this iron is excreted from the gastrointestinal tract as extravasated red cells, iron in bile, and iron in exfoliated mucosal cells. The other third is accounted for by small amounts of iron in desquamated skin and in the urine. Physiological losses of iron in men vary over a narrow range, from 0.5 mg in the iron-deficient individual to 1.5 to 2 mg per day when excessive iron is consumed. Additional losses of iron occur in women due to menstruation. While the average loss in menstruating women is about 0.5 mg per day, 10% of menstruating women lose more than 2 mg per day. Pregnancy and lactation impose an even greater requirement for iron (Table 53–3). Other causes of iron loss include blood donation, the use of antiinflammatory drugs that cause bleeding from the gastric mucosa, and gastrointestinal disease with associated bleeding. Two much rarer causes are the hemosiderinuria that follows intravascular hemolysis, and pulmonary siderosis, where iron deposited in the lungs becomes unavailable to the rest of the body.

The limited physiological losses of iron point to the primary importance of absorption in determining the body’s iron content. Unfortunately, this process is understood only in general terms (Roy and Enns, 2000; Morgan and Oates, 2002). After acidification and partial digestion of food in the stomach, iron is presented to the intestinal mucosa as either inorganic iron or heme iron. These fractions are taken up by the absorptive cells of the duodenum and upper small intestine, and the iron is transported either directly into the plasma or stored as mucosal ferritin. Absorption appears to be regulated by two transporters: DCT1, which controls uptake from the intestinal lumen, and a second transporter that governs movement of mucosal cell iron across the basolateral membrane to bind to plasma protein. Mucosal cell iron transport and the delivery of iron to transferrin from reticuloendothelial stores both are determined by the HFE gene, a major histocompatibility complex class 1 molecule localized to chromosome 6 (Peters et al., 1993; Beutler, 2003). Regulation is finely tuned to prevent iron overload in times of iron excess while allowing for increased absorption and mobilization of iron stores with iron deficiency (Roy and Andrews, 2001; Sheth and Brittenham, 2000). A predominant negative regulator of iron absorption in the small intestine is hepcidin, a 25-amino acid peptide made by hepatocytes (Ganz, 2003). The synthesis of hepcidin is greatly stimulated by inflammation or by iron overload. A deficient hepcidin response to iron

loading can contribute to iron overload and one type of hemochromatosis. In anemia of chronic disease, hepcidin production can be increased up to one hundredfold, potentially accounting for characteristic features of this condition, namely poor gastrointestinal uptake and enhanced sequestration of iron in the reticuloendothelial system.

Normal iron absorption is about 1 mg per day in adult men and 1.4 mg per day in adult women; 3 to 4 mg of dietary iron is the most that normally can be absorbed. Increased iron absorption is seen whenever iron stores are depleted or when erythropoiesis is increased or ineffective. Patients with hereditary hemochromatosis due to HFE mutations demonstrate increased iron absorption and loss of the normal regulation of iron delivery to transferrin by reticuloendothelial cells (Beutler, 2003; Ajioka and Kushner, 2003). The resulting increased saturation of transferrin permits abnormal iron deposition in nonhematopoietic tissues.

Iron Requirements and the Availability of Dietary Iron. Iron requirements are determined by obligatory physiological losses and the needs imposed by growth. Thus, adult men require only 13 μg/kg per day (about 1 mg), whereas menstruating women require about 21 μg/kg per day (about 1.4 mg). In the last two trimesters of pregnancy, requirements increase to about 80 μg/kg per day (5 to 6 mg), and infants have similar requirements due to their rapid growth. These requirements (Table 53–4) must be considered in the context of the amount of dietary iron available for absorption.

In developed countries, the normal adult diet contains about 6 mg of iron per 1000 calories, providing an average daily intake for adult men of between 12 and 20 mg and for adult women of between 8 and 15 mg. Foods high in iron (>5 mg/100 g) include organ meats such as liver and heart, brewer’s yeast, wheat germ, egg yolks, oysters, and certain dried beans and fruits; foods low in iron (<1 mg/100 g) include milk and milk products and most non-green vegetables. The content of iron in food is affected further by the manner of its preparation, since iron may be added from cooking in iron pots.

Although the iron content of the diet obviously is important, of greater nutritional significance is the bioavailability of iron in food. Heme iron, which constitutes only 6% of dietary iron, is far more available and is absorbed independent of the diet composition; it therefore represents 30% of iron absorbed (Conrad and Umbreit, 2002).

The nonheme fraction nonetheless represents by far the largest amount of dietary iron ingested by the economically underprivileged. In a vegetarian diet, nonheme iron is absorbed very poorly because of the inhibitory action of a variety of dietary components, particularly phosphates. Ascorbic acid and meat facilitate the absorption of iron by forming complexes with and/or reduces ferric to ferrous iron. Meat facilitates the absorption of iron by stimulating production of gastric acid; other effects also may be involved. Either of these substances can increase availability severalfold. Thus, assessment of available dietary iron should include both the amount of iron ingested and an estimate of its availability (Figure 53–4) (Monsen et al., 1978).

A comparison of iron requirements with available dietary iron is seen in Table 53–4. Obviously, pregnancy and infancy represent periods of negative balance. Menstruating women also are at risk, whereas iron balance in adult men and nonmenstruating women is reasonably secure. The difference between dietary supply and require-
Iron Deficiency. Iron deficiency is the most common nutritional disorder (World Health Organization, 2003; Hoffbrand and Herbert, 1999). The prevalence of iron-deficiency anemia in the United States is on the order of 1% to 4% (Anonymous, 2002) and depends on the economic status of the population. In developing countries, up to 20% to 40% of infants and pregnant women may be affected. Better iron balance has resulted from the practice of fortifying flour, the use of iron-fortified formulas for infants, and the prescription of medicinal iron supplements during pregnancy.

Iron-deficiency anemia results from dietary intake of iron that is inadequate to meet normal requirements (nutritional iron deficiency), blood loss, or interference with iron absorption. Most nutritional iron deficiency in the United States is mild. More severe iron deficiency is usually the result of blood loss, either from the gastrointestinal tract, or in women, from the uterus. Impaired absorption of iron from food results most often from partial gastrectomy or malabsorption in the small intestine. Finally, treatment of patients with erythropoietin can result in a functional iron deficiency (Beutler, 2003).

Iron deficiency in infants and young children can lead to behavioral disturbances and can impair development, which may not be fully reversible. Iron deficiency in children also can lead to an increased risk of lead toxicity secondary to pica and an increased absorption of heavy metals. Premature and low-birth-weight infants are at greatest risk for developing iron deficiency, especially if they are not breast-fed and/or do not receive iron-fortified formula. After age 2 to 3, the requirement for iron declines until adolescence, when rapid growth combined with irregular dietary habits again increase the risk of iron deficiency. Adolescent girls are at greatest risk; the dietary iron intake of most girls ages 11 to 18 is insufficient to meet their requirements.

The recognition of iron deficiency rests on an appreciation of the sequence of events that lead to depletion of iron stores (Hillman and Finch, 1997; Beutler, 2003). A negative balance first results in a reduction of iron stores, and eventually a parallel decrease in red-cell iron and iron-related enzymes (Figure 53–5). In adults, depletion of iron stores may be recognized by a plasma ferritin of less than 12 μg/L and the absence of reticuloendothelial hemosiderin in the marrow aspirate. Iron-deficient erythropoiesis is identified by a decreased saturation of transferrin to less than 16% and/or by an increase above normal in red-cell protoporphyrin. Iron-deficiency anemia is associated with a recognizable decrease in the concentration of hemoglobin in blood. However, the physiological variation in hemoglobin levels is so great that only about half the individuals with iron-deficient erythropoiesis are identified from their anemia. Moreover, “normal” hemoglobin and iron values in infancy and childhood are lower because of the more restricted supply of iron in young children (Dallman et al., 1980).

In mild iron deficiency, identifying the underlying cause is more important than any symptoms related to the deficiency state. Because of the frequency of iron deficiency in infants and in menstruating or pregnant women, the need for exhaustive evaluation of such individuals usually is determined by the severity of the anemia. However, iron deficiency in men or postmenopausal women necessitates a search for a site of bleeding.

Although the presence of microcytic anemia is the most common indicator of iron deficiency, laboratory tests—such as quantitation of transferrin saturation, red cell protoporphyrin, and plasma ferritin—are required to distinguish iron deficiency from other causes of microcytosis. Such measurements are particularly useful when circulating red cells are not yet microcytic because of the recent nature of blood loss, but iron supply nonetheless limits erythropoiesis. More difficult is the differentiation of true iron deficiency from iron-deficient erythropoiesis due to inflammation. In the latter condition, iron stores actually are increased, but the release of iron from reticuloendothelial cells is blocked; the concentration of iron in plasma is decreased, and the supply of iron to the erythroid marrow becomes inadequate. The increased stores of iron in this condition may be demonstrated directly by examination of an aspirate of marrow or may be inferred from determination of an elevated plasma concentration of ferritin.
**Treatment of Iron Deficiency**

**General Therapeutic Principles.** The response of iron-deficiency anemia to iron therapy is influenced by several factors, including the severity of anemia, the ability of the patient to tolerate and absorb medicinal iron, and the presence of other complicating illnesses. Therapeutic effectiveness is best measured by the resulting increase in the rate of production of red cells. The magnitude of the marrow response to iron therapy is proportional to the severity of the anemia (level of erythropoietin stimulation) and the amount of iron delivered to marrow precursors.

The patient’s ability to tolerate and absorb medicinal iron is a key factor in determining the rate of response to therapy. The small intestine regulates absorption, and with increasing doses of oral iron, limits the entry of iron into the bloodstream. This provides a natural ceiling on how much iron can be supplied by oral therapy. In the patient with a moderately severe iron-deficiency anemia, tolerable doses of oral iron will deliver, at most, 40 to 60 mg of iron per day to the erythroid marrow. This is an amount sufficient for production rates of two to three times normal.

Complicating illness also can interfere with the response of an iron-deficiency anemia to iron therapy. By decreasing the number of red cell precursors, intrinsic disease of the marrow can blunt the response. Inflammatory illnesses suppress the rate of red cell production, both by reducing iron absorption and reticuloendothelial release and by direct inhibition of erythropoietin and erythroid precursors. Continued blood loss can mask the response as measured by recovery of the hemoglobin or hematocrit.

Clinically, the effectiveness of iron therapy is best evaluated by tracking the reticulocyte response and the rise in the hemoglobin or the hematocrit. An increase in the reticulocyte count is not observed for at least 4 to 7 days after beginning therapy. A measurable increase in the hemoglobin level takes even longer. A decision as to the effectiveness of treatment should not be made for 3 to 4 weeks after the start of treatment. An increase of 20 g per liter or more in the concentration of hemoglobin by that time should be considered a positive response, assuming that no other change in the patient’s clinical status can account for the improvement and that the patient has not been transfused.

If the response to oral iron is inadequate, the diagnosis must be reconsidered. A full laboratory evaluation should be conducted, and poor compliance by the patient or the presence of a concurrent inflammatory disease must be explored. A source of continued bleeding obviously should be sought. If no other explanation can be found, an evaluation of the patient’s ability to absorb oral iron should be considered. There is no justification for merely continuing oral iron therapy beyond 3 to 4 weeks if a favorable response has not occurred.
Once a response to oral iron is demonstrated, therapy should be continued until the hemoglobin returns to normal. Treatment may be extended if it is desirable to replenish iron stores. This may require a considerable period of time, since the rate of absorption of iron by the intestine will decrease markedly as iron stores are reconstituted. The prophylactic use of oral iron should be reserved for patients at high risk, including pregnant women, women with excessive menstrual blood loss, and infants. Iron supplements also may be of value for rapidly growing infants who are consuming substandard diets and for adults with a recognized cause of chronic blood loss. Except for infants, in whom the use of supplemented formulas is routine, the use of over-the-counter mixtures of vitamins and minerals to prevent iron deficiency should be discouraged.

**Therapy with Oral Iron.** Orally administered **ferrous sulfate** is the treatment of choice for iron deficiency. Ferrous salts are absorbed about three times as well as ferric salts, and the discrepancy becomes even greater at high dosages. Variations in the particular ferrous salt have relatively little effect on bioavailability, and the sulfate, fumarate, succinate, gluconate, and other ferrous salts are absorbed to approximately the same extent.

Ferrous sulfate (FEOSOL, others) is the hydrated salt, FeSO₄·7H₂O, which contains 20% iron. Dried ferrous sulfate (32% elemental iron) is also available. **Ferrous fumarate** (FEOSTAT, others) contains 33% iron and is moderately soluble in water, stable, and almost tasteless. **Ferrous gluconate** (FERGON, others) also has been successfully used in the therapy of iron-deficiency anemia. The gluconate contains 12% iron. **Polysaccharide–iron complex** (NIFEREX, others), a compound of ferrhydrite and carbohydrate, is another preparation with comparable absorption. The effective dose of all of these preparations is based on iron content.

Other iron compounds have utility in fortification of foods. Reduced iron (metallic iron, elemental iron) is as effective as ferrous sulfate, provided that the material employed has a small particle size. Large-particle **ferrum reductum** and iron phosphate salts have a much lower bioavailability, and their use for the fortification of foods is undoubtedly responsible for some of the confusion concerning effectiveness. **Ferric edetate** has been shown to have good bioavailability and to have advantages for maintenance of the normal appearance and taste of food. The amount of iron, rather than the mass of the total salt in iron tablets, is important. It also is essential that the coating of the tablet dissolve rapidly in the stomach. Surprisingly, since iron usually is absorbed in the upper small intestine, certain delayed-release preparations have been reported to be effective and have been said to be even more effective than ferrous sulfate when taken with meals. However, reports of absorption from such preparations vary. Because a number of forms of delayed-release preparations are on the market, and information on their bioavailability is limited, the effectiveness of most such preparations must be considered questionable.

A variety of substances designed to enhance the absorption of iron has been marketed, including surface-acting agents, carbohydrates, inorganic salts, amino acids, and vitamins. When present in an amount of 200 mg or more, ascorbic acid increases the absorption of medicinal iron by at least 30%. However, the increased uptake is associated with a significant increase in the incidence of side effects; therefore, the addition of ascorbic acid seems to have little advantage over increasing the amount of iron administered. It is inadvisable to use preparations that contain other compounds with therapeutic actions of their own, such as vitamin B₁₂, folate, or cobalt, because the patient’s response to the combination cannot easily be interpreted.

The average dose for the treatment of iron-deficiency anemia is about 200 mg of iron per day (2 to 3 mg/kg), given in three equal doses of 65 mg. Children weighing 15 to 30 kg can take half the average adult dose, while small children and infants can tolerate relatively large doses of iron—for example, 5 mg/kg. The dose used is a compromise between the desired therapeutic action and the toxic effects. Prophylaxis and mild nutritional iron deficiency may be managed with modest doses. When the object is the prevention of iron deficiency in pregnant women, for example, doses of 15 to 30 mg of iron per day are adequate to meet the 3- to 6-mg daily requirement of the last two trimesters. When the purpose is to treat iron-deficiency anemia, but the circumstances do not demand haste, a total dose of about 100 mg (35 mg three times daily) may be used.

The responses expected for different dosage regimens of oral iron are given in Table 53–5. These effects are modified by the severity of the iron-deficiency anemia and by the time of ingestion of iron relative to meals. Bioavailability of iron ingested with food is probably one-half or one-third of that seen in the fasting subject (Grebe et al., 1975). Antacids also reduce iron absorption if given concurrently. It is always preferable to administer iron in the fasting state, even if the dose must be reduced because of gastrointestinal side effects. For patients who require maximal therapy to encourage a rapid response or to counteract continued bleeding, as much as 120 mg of iron may be administered four times a day. Sustained high rates of red cell production require an uninterrupted supply of iron, and oral doses should be spaced equally to maintain a continuous high concentration of iron in plasma.

The duration of treatment is governed by the rate of recovery of hemoglobin and the desire to create iron stores. The former depends on the severity of the anemia. With a daily rate of repair of 2 g of hemoglobin per liter of whole blood, the red cell mass usually is reconstituted within 1 to 2 months. Thus, an individual with a hemoglobin of 50 g per liter may achieve a normal complement of 150 g per liter in about 50 days, whereas an individual

with a hemoglobin of 100 g per liter may take only half that time. The creation of stores of iron requires many months of oral iron administration. The rate of absorption decreases rapidly after recovery from anemia, and after 3 to 4 months of treatment, stores may increase at a rate of not much more than 100 mg per month. Much of the strategy of continued therapy depends on the estimated future iron balance. Patients with an inadequate diet may require continued therapy with low doses of iron. If the bleeding has stopped, no further therapy is required after the hemoglobin has returned to normal. With continued bleeding, long-term, high-dose therapy clearly is indicated.

Untoward Effects of Oral Preparations of Iron. Intolerance to oral preparations of iron primarily is a function of the amount of soluble iron in the upper GI tract and of psychological factors. Side effects include heartburn, nausea, upper gastric discomfort, and diarrhea or constipation. A good policy is to initiate therapy at a small dosage, to demonstrate freedom from symptoms at that level, and then gradually to increase the dosage to that desired. With a dose of 200 mg of iron per day divided into three equal portions, symptoms occur in approximately 25% of treated individuals versus 13% among those receiving placebo; this increases to approximately 40% when the dosage of iron is doubled. Nausea and upper abdominal pain are increasingly common at high dosage. Constipation and diarrhea, perhaps related to iron-induced changes in the intestinal bacterial flora, are not more prevalent at higher dosage, nor is heartburn. If a liquid is given, one can place the iron solution on the back of the tongue with a dropper to prevent transient staining of teeth.

The normal individual apparently is able to control absorption of iron despite high intake, and it is only individuals with underlying disorders that augment the absorption of iron who run the hazard of developing iron overload (hemochromatosis). However, hemochromatosis is a relatively common genetic disorder, present in 0.5% of the population.

Iron Poisoning. Large amounts of ferrous salts are toxic, but fatalities are rare in children, particularly between the ages of 12 and 24 months. As little as 1 to 2 g of iron may cause death, but 2 to 10 g usually is ingested in fatal cases. The frequency of iron poisoning relates to its availability in the household, particularly the supply that remains after a pregnancy. The colored sugar coating of many of the commercially available tablets gives them the appearance of candy. All iron preparations should be kept in childproof bottles.

Signs and symptoms of severe poisoning may occur within 30 minutes after ingestion or may be delayed for several hours. They include abdominal pain, diarrhea, or vomiting of brown or bloody stomach contents containing pills. Of particular concern are pallor or cyanosis, lassitude, drowsiness, hyperventilation due to acido-sis, and cardiovascular collapse. If death does not occur within 6 hours, there may be a transient period of apparent recovery, followed by death in 12 to 24 hours. The corrosive injury to the stomach may result in pyloric stenosis or gastric scarring. Hemorrhagic gastroenteritis and hepatic damage are prominent findings at autopsy. In the evaluation of a child thought to have ingested iron, a color test for iron in the gastric contents and an emergency determination of the concentration of iron in plasma can be performed. If the latter is less than 63 μmol (3.5 mg per liter), the child is not in immediate danger. However, vomiting should be induced when there is iron in the stomach, and an x-ray should be taken to evaluate the number of pills remaining in the small bowel (iron tablets are radiopaque). Iron in the upper GI tract can be precipitated by lavage with sodium bicarbonate or phosphate solution, although the clinical benefit is questionable. When the plasma concentration of iron is greater than the total iron-binding capacity (63 μmol; 3.5 mg per liter), deferoxamine should be administered; dosage and routes of administration are detailed in Chapter 65. Shock, dehydration, and acid-base abnormalities should be treated in the conventional manner. Most important is the speed of diagnosis and therapy. With early effective treatment, the mortality from iron poisoning can be reduced from as high as 45% to about 1%.

Therapy with Parenteral Iron. When oral iron therapy fails, parenteral iron administration may be an effective alternative (Silverstein and Rodgers, 2004). The rate of response to parenteral therapy is similar to that which follows usual oral doses. Common indications are iron malabsorption (e.g., sprue, short bowel syndrome), severe oral iron intolerance, as a routine supplement to total parenteral nutrition, and in patients who are receiving erythropoietin (Eschbach et al., 1987). Parenteral iron also has been given to iron-deficient patients and pregnant women to create iron stores, something that would take months to achieve by the oral route. Parenteral iron therapy should be used only when clearly indicated, since acute hypersensitivity, including anaphylactic and anaphylactoid reactions, can occur in 0.2% to 3% of patients. The belief that the response to parenteral iron, especially iron dextran, is faster than oral iron is open to debate. In otherwise healthy individuals, the rate of hemoglobin response is determined by the balance between the severity of the anemia (the level of erythropoietin stimulus) and the delivery of iron to the marrow from iron absorption and iron stores. When a large intravenous dose of iron dextran is given to a severely anemic patient, the hematologic response can exceed that seen with oral iron for 1 to 3 weeks. Subsequently, however, the response is no better than that seen with oral iron.

Three preparations of iron are FDA-approved for parenteral therapy, sodium ferric gluconate complex in sucrose (FERR-LECIT), iron sucrose (SACCHARATE), and iron dextran (INFED, DEXFERRUM). Unlike iron dextran, which requires processing by
macrophages that may require several weeks, approximately 80% of sodium ferric gluconate is delivered to transferrin with 24 hours. Sodium ferric gluconate also has a much lower risk of inducing serious anaphylactic reactions than iron dextran (Michael et al., 2002). No deaths were reported with 25 million infusions of sodium ferric gluconate, whereas there were 31 infusion-related deaths reported from approximately half the number of patients treated with iron dextran (Faich and Strohos, 1999). Thus, sodium ferric gluconate is the preferred agent for parenteral iron therapy. Currently, iron dextran is reserved for noncompliant patients or for those who are seriously inconvenienced by the multiple infusions that may be required for treatment with sodium ferric gluconate (Beutler, 2003). Sodium ferric gluconate complex in sucrose (FERRLECIT) was approved by the FDA for the treatment of iron deficiency in patients undergoing chronic hemodialysis who are receiving supplemental erythropoietin therapy (Eichbaum et al., 2003).

Iron sucrose (SACCHARATE) also is approved for use in the United States, providing yet another form of parenteral iron for treatment of patients with iron deficiency intractable to therapy with oral iron. Like sodium ferric gluconate, iron sucrose appears to be better tolerated than iron dextran (Fishbane and Kowalski, 2000; Michaud, et al., 2002). However, the experience with iron sucrose is much more limited than that with either iron dextran or sodium ferric gluconate.

Iron dextran injection (INFED, DEXFERRUM) is a colloidal solution of ferric oxyhydroxide complexed with polymerized dextran (molecular weight approximately 180,000) that contains 50 mg/ml of elemental iron. It can be administered by either intravenous (preferred) or intramuscular injection. When given by deep intramuscular injection, it is gradually mobilized via the lymphatics and transported to reticuloendothelial cells; the iron then is released from the dextran complex. Intravenous administration gives a more reliable response. Given intravenously in a dose of less than 500 mg, the iron dextran complex is cleared exponentially with a plasma half-life of 6 hours. When 1 g or more is administered intravenously as total dose therapy, reticuloendothelial cell clearance is constant at 10 to 20 mg/hour. This slow rate of clearance results in a brownish discoloration of the plasma for several days and an elevation of the serum iron for 1 to 2 weeks.

Once the iron is released from the dextran within the reticuloendothelial cells, it is either incorporated into stores or transported via transferrin to the erythroid marrow. While a portion of the processed iron is rapidly made available to the marrow, a significant fraction is only gradually converted to usable iron stores. All of the iron eventually is released, although many months are required before the process is complete. During this time, the iron dextran stores in reticuloendothelial cells can confuse the clinician who attempts to evaluate the iron status of the patient.

Intramuscular injection of iron dextran should only be initiated after a test dose of 0.5 ml (25 mg of iron). If no adverse reactions are observed, the injections can proceed. The daily dose ordinarily should not exceed 0.5 ml (25 mg of iron) for infants weighing less than 4.5 kg (10 lb), 1 ml (50 mg of iron) for children weighing less than 9 kg (20 lb), and 2 ml (100 mg of iron) for other patients. Iron dextran should be injected only into the muscle mass of the upper outer quadrant of the buttock using a z-track technique (displacement of the skin laterally before injection). However, local reactions and the concern about malignant change at the site of injection (Weinbren et al., 1978) make intramuscular administration inappropriate except when the intravenous route is inaccessible.

A test injection of 0.5 ml of undiluted iron dextran or an equivalent amount (25 mg of iron) diluted in saline also should precede intravenous administration of a therapeutic dose of iron dextran. The patient should be observed for signs of immediate anaphylaxis, and for an hour after injection for any signs of vascular instability or hypersensitivity, including respiratory distress, hypotension, tachycardia, or back or chest pain. When widely spaced, total-dose infusion therapy is given, a test dose injection should be given before each infusion because hypersensitivity can appear at any time. Furthermore, the patient should be monitored closely throughout the infusion for signs of cardiovascular instability. Delayed hypersensitivity reactions also are observed, especially in patients with rheumatoid arthritis or a history of allergies. Fever, malaise, lymphadenopathy, arthralgias, and urticaria can develop days or weeks following injection and last for prolonged periods of time. Therefore, iron dextran should be used with extreme caution in patients with rheumatoid arthritis or other connective tissue diseases, and during the acute phase of an inflammatory illness. Once hypersensitivity is documented, iron dextran therapy must be abandoned.

Before initiating iron dextran therapy, the total dose of iron required to repair the patient’s iron-deficient state should be calculated. Relevant factors are the hemoglobin deficit, the need to reconstitute iron stores, and continued excess losses of iron, as seen with hemodialysis and chronic GI bleeding. Iron dextran solution (50 mg/ml of elemental iron) can be administered undiluted in daily doses of 2 ml until the total dose is reached or given as a single total-dose infusion. In the latter case, the iron dextran should be diluted in 250 to 1000 ml of 0.9% saline and infused over an hour or more.

When hemodialysis patients are started on erythropoietin, oral iron therapy alone generally is insufficient to guarantee an optimal hemoglobin response. It therefore is recommended that sufficient parenteral iron be given to maintain a plasma ferritin level between 100 and 800 μg/L and a transferrin saturation of between 20% and 50% (Goodnough et al., 2000). One approach is to administer an initial intravenous dose of 200 to 500 mg, followed by weekly or every-other-week injections of 25 to 100 mg of iron dextran to replace ongoing blood loss (Besarab et al., 1999). With repeated doses of iron dextran—especially multiple, total-dose infusions such as those sometimes used in the treatment of chronic GI blood loss—accumulations of slowly metabolized iron dextran stores in reticuloendothelial cells can be impressive. The plasma ferritin level also can rise to levels associated with iron overload. While disease-related hemochromatosis has been associated with an increased risk of infections and cardiovascular disease, this has not been shown to be true in hemodialysis patients treated with iron dextran (Owen, 1999). It seems prudent, however, to withhold the drug whenever the plasma ferritin rises above 800 μg/L.

Reactions to intravenous iron include headache, malaise, fever, generalized lymphadenopathy, arthralgias, urticaria, and in some patients with rheumatoid arthritis, exacerbation of the disease. Phlebitis may occur with prolonged infusions of a concentrated solution or when an intramuscular preparation containing 0.5% phenol is used in error. Of greatest concern is the rare anaphylactic reaction, which may be fatal despite treatment (Faich and Strohos, 1999).
COPPER

Copper deficiency is extremely rare because the amount present in food is more than adequate to provide the needed body complement of slightly more than 100 mg. There is no evidence that copper ever needs to be added to a normal diet, either prophylactically or therapeutically. Even in clinical states associated with hypocupremia (sprue, celiac disease, and nephrotic syndrome), effects of copper deficiency usually are not demonstrable. Anemia due to copper deficiency has been described in individuals who have undergone intestinal bypass surgery (Zidar et al., 1974), in those who are receiving parenteral nutrition (Dunlap et al., 1974), in malnourished infants (Graham et al., 1978), and in patients ingesting excessive amounts of zinc (Hoffman et al., 1988). While an inherited disorder affecting the transport of copper in human beings (Menkes’ disease; steely hair syndrome) is associated with reduced activity of several copper-dependent enzymes, this disease is not associated with hematological abnormalities.

Copper deficiency in experimental animals interferes with the absorption of iron and its release from reticuloendothelial cells (Lee et al., 1976). The associated microcytic anemia is related to a decrease in the availability of iron to the normoblasts, and perhaps even more importantly, to decreased mitochondrial production of heme. It may be that the specific defect in the latter case is a decrease in the activity of cytochrome oxidase. Other pathological effects involving the skeletal, cardiovascular, and nervous systems have been observed in copper-deficient experimental animals. In human beings, the outstanding findings have been leukopenia, particularly granulocytopenia, and anemia. Concentrations of iron in plasma are variable, and the anemia is not always microcytic. When a low plasma copper concentration is determined in the presence of leukopenia and anemia, a therapeutic trial with copper is appropriate. Daily doses up to 0.1 mg/kg of cupric sulfate have been given by mouth, or 1 to 2 mg per day may be added to the solution of nutrients for parenteral administration.

PYRIDOXINE

Harris and associates first described pyridoxine-responsive anemia in 1956. Subsequent reports suggested that the vitamin might improve hematopoiesis in up to 50% of patients with either hereditary or acquired sideroblastic anemia. These patients characteristically have impaired hemoglobin synthesis and accumulate iron in the perinuclear mitochondria of erythroid precursor cells, so-called ringed sideroblasts. Hereditary sideroblastic anemia is an X-linked recessive trait with variable penetrance and expression that results from mutations in the erythrocyte form of δ-aminolevulinate synthase. Affected men typically show a dual population of normal red cells and microcytic, hypochromic cells in the circulation. In contrast, idiopathic acquired sideroblastic anemia and the sideroblastic anemias associated with a number of drugs, inflammatory states, neoplastic disorders, and preleukemic syndromes show a variable morphological picture. Moreover, erythrokinetic studies demonstrate a spectrum of abnormalities, from a hypoproliferative defect with little tendency to accumulate iron to marked ineffective erythropoiesis with iron overload of the tissues (Solomon and Hillman, 1979a).

Oral therapy with pyridoxine is of proven benefit in correcting the sideroblastic anemias associated with the antituberculosis drugs isoniazid and pyrazinamide, which act as vitamin B6 antagonists. A daily dose of 50 mg of pyridoxine completely corrects the defect without interfering with treatment, and routine supplementation of pyridoxine often is recommended (see Chapter 47). In contrast, if pyridoxine is given to counteract the sideroblastic abnormality associated with administration of levodopa, the effectiveness of levodopa in controlling Parkinson’s disease is decreased. Pyridoxine therapy does not correct the sideroblastic abnormalities produced by chloramphenicol or lead.

Patients with idiopathic acquired sideroblastic anemia generally fail to respond to oral pyridoxine, and those individuals who appear to have a pyridoxine-responsive anemia require prolonged therapy with large doses of the vitamin, 50 to 500 mg per day. Unfortunately, the early enthusiasm for treatment with pyridoxine was not reinforced by results of later studies (Chillar et al., 1976; Solomon and Hillman, 1979a). Moreover, even when a patient with sideroblastic anemia responds, the improvement is only partial because both the ringed sideroblasts and the red cell defect persist, and the hematocrit rarely returns to normal. Nonetheless, in view of the low toxicity of oral pyridoxine, a therapeutic trial with pyridoxine is appropriate.

As shown in studies of normal subjects, oral pyridoxine in a dosage of 100 mg three times daily produces a maximal increase in red cell pyridoxine kinase and the major pyridoxal phosphate–dependent enzyme glutamic-aspartic aminotransferase (Solomon and Hillman, 1978). For an adequate therapeutic trial, the drug is administered for at least 3 months while the response is monitored by measuring the reticulocyte index and the hemoglobin concentration. The occasional patient who is refractory to oral pyridoxine may respond to parenteral administration of pyridoxal phosphate. However, oral pyridoxine in doses of 200 to 300 mg per day produces intracellular concentrations of pyridoxal phosphate equal to or greater than those generated by therapy with the phosphorylated vitamin (Solomon and Hillman, 1979b).
**RIBOFLAVIN**

Pure red cell aplasia that responded to the administration of riboflavin was reported in patients with protein depletion and complicating infections. Lane and associates induced riboflavin deficiency in human beings and demonstrated that a hypoproliferative anemia resulted within a month. The spontaneous appearance in human beings of red cell aplasia due to riboflavin deficiency undoubtedly is rare, if it occurs at all. It has been described in combination with infection and protein deficiency, both of which are capable of producing a hypoproliferative anemia. However, it seems reasonable to include riboflavin in the nutritional management of patients with gross, generalized malnutrition.

### III. Vitamin B\textsubscript{12}, Folic Acid, and the Treatment of Megaloblastic Anemias

Vitamin B\textsubscript{12} and folic acid are dietary essentials. A deficiency of either vitamin impairs DNA synthesis in any cell in which chromosomal replication and division are taking place. Since tissues with the greatest rate of cell turnover show the most dramatic changes, the hematopoietic system is especially sensitive to deficiencies of these vitamins. An early sign of deficiency is megaloblastic anemia. Abnormal macrocytic red blood cells are produced, and the patient becomes severely anemic. Recognized in the 19th century, this pattern of abnormal hematopoiesis, termed pernicious anemia, spurred investigations that ultimately led to the discovery of vitamin B\textsubscript{12} and folic acid. Even today, the characteristic abnormality in red blood cell morphology is important for diagnosis and as a therapeutic guide following administration of the vitamins.

**History.** The discovery of vitamin B\textsubscript{12} and folic acid is a dramatic story that started more than 180 years ago and includes two Nobel prize–winning discoveries. The first descriptions of what must have been megaloblastic anemias came from the work of Combe and Addison, who published a series of case reports beginning in 1824. It still is common practice to describe megaloblastic anemia as Addsonian pernicious anemia. Although Combe suggested that the disorder might have some relationship to digestion, it was Austin Flint who in 1860 first described the severe gastric atrophy and called attention to its possible relationship to the anemia.

After the observation by Whipple in 1925 that liver is a source of a potent hematopoietic substance for iron-deficient dogs, Minot and Murphy carried out Nobel Prize–winning experiments that demonstrated the effectiveness of the feeding of liver to reverse pernicious anemia. Soon thereafter, Castle defined the need for both intrinsic factor, a substance secreted by the parietal cells of the gastric mucosa, and extrinsic factor, the vitamin-like material provided by crude liver extracts. Nearly 20 years passed before Rickes and coworkers and Smith and Parker isolated and crystallized vitamin B\textsubscript{12}; Dorothy Hodgkin received the Nobel Prize for determining its x-ray crystal structure.

As attempts were being made to purify extrinsic factor, Wills and her associates described a macrocytic anemia in women in India that responded to a factor present in crude liver extracts but not in the purified fractions known to be effective in pernicious anemia. This factor, first called Wills’ factor and later vitamin M, is now known to be folic acid. The term folic acid was coined by Mitchell and coworkers in 1941, after its isolation from leafy vegetables.

More recent work has shown that neither vitamin B\textsubscript{12} nor folic acid as purified from foodstuffs is the active coenzyme for human beings. During extraction, active, labile forms are converted to stable congeners of vitamin B\textsubscript{12} and folic acid, cyanocobalamin and pteroylglutamic acid, respectively. These congeners must then be modified \textit{in vivo} to be effective. While a great deal has been learned about the intracellular metabolic pathways in which these vitamins function as required cofactors, many questions remain. The most important of these is the relationship of vitamin B\textsubscript{12} deficiency to the neurological abnormalities that occur with this disorder (Chananin et al., 1985).

**Relationships Between Vitamin B\textsubscript{12} and Folic Acid.** The major roles of vitamin B\textsubscript{12} and folic acid in intracellular metabolism are summarized in Figure 53–6. Intracellular vitamin B\textsubscript{12} is maintained as two active coenzymes: methylcobalamin and deoxyadenosylcobalamin. Deoxyadenosylcobalamin (deoxyadenosyl B\textsubscript{12}) is a cofactor for the mitochondrial mutase enzyme that catalyzes the isomerization of L-methylmalonyl CoA to succinyl CoA, an important reaction in carbohydrate and lipid metabolism. This reaction has no direct relationship to the metabolic pathways that involve folate. In contrast, methylcobalamin (CH\textsubscript{3}B\textsubscript{12}) supports the methionine synthetase reaction, which is essential for normal metabolism of folate (Weir and Scott, 1983). Methyl groups contributed by methyltetrahydrofolate (CH\textsubscript{3}H\textsubscript{4}PteGlu\textsubscript{1}) are used to form methylcobalamin, which then acts as a methyl group donor for the conversion of homocysteine to methionine. This folate–cobalamin interaction is pivotal for normal synthesis of purines and pyrimidines, and therefore of DNA. The methionine synthetase reaction is largely responsible for the control of the recycling of folate cofactors; the maintenance of intracellular concentrations of folylpolyglutamates; and, through the synthesis of methionine and its product, S-adenosylmethionine, the maintenance of a number of methylation reactions.
Since methyltetrahydrofolate is the principal folate congener supplied to cells, the transfer of the methyl group to cobalamin is essential for the adequate supply of tetrahydrofolate (H₄PteGlu), the substrate for a number of metabolic steps. Tetrahydrofolate is a precursor for the formation of intracellular folylpolyglutamates; it also acts as the acceptor of a one-carbon unit in the conversion of serine to glycine, with the resultant formation of 5,10-methylenetetrahydrofolate (5,10-CH₂H₄PteGlu). The latter derivative donates the methylene group to deoxyuridylate (dUMP) for the synthesis of thymidylate (dTMP)—an extremely important reaction in DNA synthesis. In the process, the 5,10-CH₂H₄PteGlu is converted to dihydrofolate (H₂PteGlu). The cycle then is completed by the reduction of the H₂PteGlu to H₄PteGlu by dihydrofolate reductase, the step that is blocked by folate antagonists such as methotrexate (see Chapter 51). As shown in Figure 53–6, other pathways also lead to the synthesis of 5,10-methylenetetrahydrofolate. These pathways are important in the metabolism of formiminoglutamic acid (FIGLU) and purines and pyrimidines (see reviews by Weir and Scott, 1983; Chanarin et al., 1985).

In the presence of a deficiency of either vitamin B₁₂ or folic acid, the decreased synthesis of methionine and S-adenosylmethionine interferes with protein biosynthesis, a number of methylation reactions, and the synthesis of polyamines. In addition, the cell responds to the deficiency by redirecting folate metabolic pathways to supply increasing amounts of methyltetrahydrofolate; this tends to preserve essential methylation reactions at the expense of nucleic acid synthesis. With vitamin B₁₂ deficiency, methylenetetrahydrofolate reductase activity increases, directing available intracellular folates into the methyltetrahydrofolate pool (not shown in Figure 53–6). The methyltetrahydrofolate then is trapped by the lack of sufficient vitamin B₁₂ to accept and transfer methyl groups, and subsequent steps in folate metabolism that require tetrahydrofolate are deprived of substrate. This process provides a common basis for the development of megaloblastic anemia with deficiency of either vitamin B₁₂ or folic acid.

The mechanisms responsible for the neurological lesions of vitamin B₁₂ deficiency are less well understood (Weir and Scott, 1983). Damage to the myelin sheath is the most obvious lesion in this neuropathy. This observation led to the early suggestion that the deoxyadenosyl B₁₂–dependent methylmalonyl CoA mutase reaction, a step in propionate metabolism, is related to the abnormality. However, other evidence suggests that the deficiency of methionine synthetase and the block of the conversion of methionine to S-adenosylmethionine are more likely to be responsible (Scott et al., 1981).
Nitrous oxide (N₂O), used for anesthesia (see Chapter 13), can cause megaloblastic changes in the marrow and a neuropathy that resemble those of vitamin B₁₂ deficiency (Chanarin et al., 1985). Studies with N₂O have demonstrated a reduction in methionine synthetase and reduced concentrations of methionine and S-adenosylmethionine. The latter is necessary for methylation reactions, including those required for the synthesis of phospholipids and myelin. Significantly, the neuropathy induced with N₂O can be prevented partially by feeding methionine. A neuropathy similar to that occurring with vitamin B₁₂ deficiency has been reported in dentists who are exposed to N₂O used as an anesthetic.

VITAMIN B₁₂

Chemistry. The structural formula of vitamin B₁₂ is shown in Figure 53–7. The three major portions of the molecule are:

A planar group or corrin nucleus—a porphyrin-like ring structure with four reduced pyrrole rings (A to D in Figure 53–7) linked to a central cobalt atom and extensively substituted with methyl, acetamide, and propionamide residues.

A 5,6-dimethylbenzimidazolyl nucleotide, which links almost at right angles to the corrin nucleus with bonds to the cobalt atom and to the propionate side chain of the C pyrrole ring.

A variable R group—the most important of which are found in the stable compounds cyanocobalamin and hydroxocobalamin and the active coenzymes methylcobalamin and 5-deoxyadenosylcobalamin.

The terms vitamin B₁₂ and cyanocobalamin are used interchangeably as generic terms for all of the cobamides active in humans. Preparations of vitamin B₁₂ for therapeutic use contain either cyanocobalamin or hydroxocobalamin, since only these derivatives remain active after storage.

Metabolic Functions. The active coenzymes methylcobalamin and 5-deoxyadenosylcobalamin are essential for cell growth and replication. Methylcobalamin is required for the conversion of homocysteine to methionine and its derivative S-adenosylmethionine. In addition, when concentrations of vitamin B₁₂ are inadequate, folate becomes “trapped” as methyltetrahydrofolate to cause a functional deficiency of other required intracellular forms of folic acid (see Figures 53–6 and 53–7 and discussion above). The hematological abnormalities in vitamin B₁₂-deficient patients result from this process. 5-Deoxyadenosylcobalamin is required for the isomerization of L-methylmalonyl CoA to succinyl CoA (Figure 53–6).

Sources in Nature. Humans depend on exogenous sources of vitamin B₁₂. In nature, the primary sources are certain microorganisms that grow in soil, sewage, water, or the intestinal lumen of animals that synthesize the vitamin. Vegetable products are free of vitamin B₁₂ unless they are contaminated with such microorganisms, so that animals are dependent on synthesis in their own alimentary tract or the ingestion of animal products containing vitamin B₁₂. The daily nutritional requirement of 3 to 5 μg must be obtained from animal by-products in the diet. Despite this, strict vegetarians rarely develop vitamin B₁₂ deficiency. Some vitamin B₁₂ is available from legumes, which are contaminated with bacteria capable of synthesizing vitamin B₁₂, and vegetarians often fortify their diets with a wide range of vitamins and minerals.

Absorption, Distribution, Elimination, and Daily Requirements. In the presence of gastric acid and pancreatic proteases, dietary vitamin B₁₂ is released from
food and salivary binding protein and bound to gastric intrinsic factor. When the vitamin B₁₂–intrinsic factor complex reaches the ileum, it interacts with a receptor on the mucosal cell surface and is actively transported into circulation. Adequate intrinsic factor, bile, and sodium bicarbonate (to provide a suitable pH) all are required for ileal transport of vitamin B₁₂. Vitamin B₁₂ deficiency in adults is rarely the result of a deficient diet per se; rather, it usually reflects a defect in one or another aspect of this complex sequence of absorption (Figure 53–8). Achlorhydria and decreased secretion of intrinsic factor by parietal cells secondary to gastric atrophy or gastric surgery is a common cause of vitamin B₁₂ deficiency in adults. Antibodies to parietal cells or intrinsic factor complex also can play a prominent role in producing a deficiency. A number of intestinal diseases can interfere with absorption, including pancreatic disorders (loss of pancreatic protease secretion), bacterial overgrowth, intestinal parasites, sprue, and localized damage to ileal mucosal cells by disease or as a result of surgery.

Once absorbed, vitamin B₁₂ binds to transcobalamin II, a plasma β-globulin, for transport to tissues. Two other transcobalamins (I and III) also are present in plasma; their concentrations are related to the rate of turnover of granulocytes. They may represent intracellular storage proteins that are released with cell death. Vitamin B₁₂ bound to transcobalamin II is rapidly cleared from plasma and preferentially distributed to hepatic parenchymal cells. The liver is a storage depot for other tissues. In normal adults, as much as 90% of the body’s stores of vitamin B₁₂, from 1 to 10 mg, is in the liver. Vitamin B₁₂ is stored as the active coenzyme with a turnover rate of 0.5 to 8 μg per day, depending on the size of the body stores. The recommended daily intake of the vitamin in adults is 2.4 μg.

Approximately 3 μg of cobalamins is secreted into bile each day, 50% to 60% of which is not destined for reabsorption. This enterohepatic cycle is important because interference with reabsorption by intestinal disease can progressively deplete hepatic stores of the vitamin. This process may help explain why patients can develop vitamin B₁₂ deficiency within 3 to 4 years of major gastric surgery, even though a daily requirement of 1 to 2 μg would not be expected to deplete hepatic stores of more than 2 to 3 mg during this time.

The supply of vitamin B₁₂ available for tissues is directly related to the size of the hepatic storage pool and the amount of vitamin B₁₂ bound to transcobalamin II (Figure 53–8). The plasma concentration of vitamin B₁₂ is the best routine measure of B₁₂ deficiency, and normally ranges from 150 to 660 pmol (about 200 to 900 pg/ml). Deficiency should be suspected whenever the concentration falls below 150 pmol. The correlation is excellent except when the plasma concentrations of transcobalamin I and III are increased, as occurs with hepatic disease or a myeloproliferative disorder. Inasmuch as the vitamin B₁₂ bound to these transport proteins is relatively unavailable to cells, tissues can become deficient when the concentration of vitamin B₁₂ in plasma is normal or even high. In subjects with congenital absence of transcobalamin II, megaloblastic anemia occurs despite normal plasma concentrations of vitamin B₁₂; the anemia will respond to parenteral doses of vitamin B₁₂ that exceed the renal clearance (Hakami et al., 1971).

Defects in intracellular metabolism of vitamin B₁₂ have been reported in children with methylmalonic aciduria and homocystinuria. Potential mechanisms include an incapacity of cells to transport vitamin B₁₂ or accumulate the vitamin because of a failure to synthesize an intracellular acceptor, a defect in the formation of deoxyadenosylcobalamin, or a congenital lack of methylmalonyl CoA isomerase.

**Figure 53–8. The absorption and distribution of vitamin B₁₂.** Deficiency of vitamin B₁₂ can result from a congenital or acquired defect in any one of the following: (1) inadequate dietary supply; (2) inadequate secretion of intrinsic factor (classical pernicious anemia); (3) ileal disease; (4) congenital absence of transcobalamin II (TcII); or (5) rapid depletion of hepatic stores by interference with reabsorption of vitamin B₁₂ excreted in bile. The utility of measurements of the concentration of vitamin B₁₂ in plasma to estimate supply available to tissues can be compromised by liver disease and (6) the appearance of abnormal amounts of transcobalamins I and III (TcI and TcIII) in plasma. Finally, the formation of methylcobalamin requires (7) normal transport into cells and an adequate supply of folic acid as CH₃H₄PteGlu₁.
mucosa and cervical epithelium) also have high requirements for the vitamin.

As a result of an inadequate supply of vitamin $B_{12}$, DNA replication becomes highly abnormal. Once a hematopoietic stem cell is committed to enter a programmed series of cell divisions, the defect in chromosomal replication results in an inability of maturing cells to complete nuclear divisions while cytoplasmic maturation continues at a relatively normal rate. This results in the production of morphologically abnormal cells and death of cells during maturation, a phenomenon referred to as ineffective hematopoiesis. These abnormalities are readily identified by examination of the marrow and peripheral blood. Maturation of red cell precursors is highly abnormal (megaloblastic erythropoiesis). Those cells that do leave the marrow also are abnormal, and many cell fragments, poikilocytes, and macrocytes appear in the peripheral blood. The mean red cell volume increases to values greater than 110 fl. Severe deficiency affects all cell lines, and a pronounced pancytopenia results.

The diagnosis of a vitamin $B_{12}$ deficiency usually can be made using measurements of the serum vitamin $B_{12}$ and/or serum methylmalonic acid. The latter is somewhat more sensitive and has been used to identify metabolic deficiency in patients with normal serum vitamin $B_{12}$ levels. As part of the clinical management of a patient with severe megaloblastic anemia, a therapeutic trial using very small doses of the vitamin can be used to confirm the diagnosis. Serial measurements of the reticulocyte count, serum iron, and hematocrit are performed to define the characteristic recovery of normal red cell production. The Schilling test can be used to quantitate the absorption of the vitamin and delineate the mechanism of the disease. By performing the Schilling test with and without added intrinsic factor, it is possible to discriminate between intrinsic factor deficiency by itself and primary ileal cell disease.

Vitamin $B_{12}$ deficiency can irreversibly damage the nervous system. Progressive swelling of myelinated neurons, demyelination, and neuronal cell death are seen in the spinal column and cerebral cortex. This causes a wide range of neurological signs and symptoms, including paresthesias of the hands and feet, decreased vibration and position senses with resultant unsteadiness, decreased deep tendon reflexes, and in the later stages, confusion, moodiness, loss of memory, and even a loss of central vision. The patient may exhibit delusions, hallucinations, or even overt psychosis. Since the neurological damage can be dissociated from the changes in the hematopoietic system, vitamin $B_{12}$ deficiency must be considered in elderly patients with dementia or psychiatric disorders, even if they are not anemic (Lindenbaum et al., 1988).

**Vitamin $B_{12}$ Therapy.** Vitamin $B_{12}$ is available for injection or oral administration; combinations with other vitamins and minerals also can be given orally or parenterally. The choice of a preparation always depends on the cause of the deficiency. Although oral preparations may be used to supplement deficient diets, they are of limited value in the treatment of patients with deficiency of intrinsic factor or ileal disease. Even though small amounts of vitamin $B_{12}$ may be absorbed by simple diffusion, the oral route of administration cannot be relied upon for effective therapy in the patient with a marked deficiency of vitamin $B_{12}$ and abnormal hematopoiesis or neurological deficits. Therefore, the preparation of choice for treatment of a vitamin $B_{12}$-deficiency state is cyanocobalamin, and it should be administered by intramuscular or subcutaneous injection.

Cyanocobalamin injection is safe when given by the intramuscular or deep subcutaneous route, but it should never be given intravenously. There have been rare reports of transitory exanthema and anaphylaxis after injection. If a patient reports a previous sensitivity to injections of vitamin $B_{12}$, an intradermal skin test should be performed before the full dose is administered.

Cyanocobalamin is administered in doses of 1 to 1000 $\mu$g. Tissue uptake, storage, and utilization depend on the availability of transcobalamin II (see above). Doses in excess of 100 $\mu$g are cleared rapidly from plasma into the urine, and administration of larger amounts of vitamin $B_{12}$ will not result in greater retention of the vitamin. Administration of 1000 $\mu$g is of value in the performance of the Schilling test. After isotopically labeled vitamin $B_{12}$ is administered orally, the compound that is absorbed can be quantitatively recovered in the urine if 1000 $\mu$g of cyanocobalamin is administered intramuscularly. This unlabeled material saturates the transport system and tissue binding sites, so that more than 90% of the labeled and unlabeled vitamin is excreted during the next 24 hours.

A number of multivitamin preparations are marketed either as nutritional supplements or for the treatment of anemia. Many of these contain up to 80 $\mu$g of cyanocobalamin without or with intrinsic factor concentrate prepared from the stomachs of hogs or other domestic animals. One oral unit of intrinsic factor is defined as that amount of material that will bind and transport 15 $\mu$g of cyanocobalamin. Most multivitamin preparations supplemented with intrinsic factor contain 0.5 oral unit per tablet. While the combination of oral vitamin $B_{12}$ and intrinsic factor would appear to be ideal for patients with an intrinsic factor deficiency, such preparations are not reliable. With prolonged therapy, some patients become refractory to oral intrinsic factor, perhaps related to production of an intraluminal antibody against the hog protein. Patients taking such preparations must be reevaluated at periodic intervals for recurrence of pernicious anemia.

Hydroxocobalamin given in doses of 100 $\mu$g intramuscularly has been reported to have a more sustained effect than cyanocobal-
amin, with a single dose maintaining plasma vitamin $B_{12}$ concentrations in the normal range for up to 3 months. However, some patients show reductions of the concentration of vitamin $B_{12}$ in plasma within 30 days, similar to that seen after cyanocobalamin. Furthermore, the administration of hydroxocobalamin has resulted in the formation of antibodies to the transcobalamin II–vitamin $B_{12}$ complex.

Vitamin $B_{12}$ has an undeserved reputation as a health tonic and has been used for a number of disease states. Effective use of the vitamin depends on accurate diagnosis and an understanding of the following general principles of therapy:

1. Vitamin $B_{12}$ should be given prophylactically only when there is a reasonable probability that a deficiency exists or will exist. Dietary deficiency in the strict vegetarian, the predictable malabsorption of vitamin $B_{12}$ in patients who have had a gastrectomy, and certain diseases of the small intestine constitute such indications. When gastrointestinal function is normal, an oral prophylactic supplement of vitamins and minerals, including vitamin $B_{12}$, may be indicated. Otherwise, the patient should receive monthly injections of cyanocobalamin.

2. The relative ease of treatment with vitamin $B_{12}$ should not prevent a full investigation of the etiology of the deficiency. The initial diagnosis usually is suggested by a macrocytic anemia or an unexplained neuropsychiatric disorder. Full understanding of the etiology of vitamin $B_{12}$ deficiency involves studies of dietary supply, gastrointestinal absorption, and transport.

3. Therapy always should be as specific as possible. While a large number of multivitamin preparations are available, the use of “shotgun” vitamin therapy in the treatment of vitamin $B_{12}$ deficiency can be dangerous. With such therapy, there is the danger that sufficient folic acid will be given to result in a hematological recovery. This can mask continued vitamin $B_{12}$ deficiency and permit neurological damage to develop or progress.

4. Although a classical therapeutic trial with small amounts of vitamin $B_{12}$ can help confirm the diagnosis, acutely ill, elderly patients may not be able to tolerate the delay in the correction of a severe anemia. Such patients require supplemental blood transfusions and immediate therapy with folic acid and vitamin $B_{12}$ to guarantee rapid recovery.

5. Long-term therapy with vitamin $B_{12}$ must be evaluated at intervals of 6 to 12 months in patients who are otherwise well. If there is an additional illness or a condition that may increase the requirement for the vitamin (e.g., pregnancy), reassessment should be performed more frequently.

**Treatment of the Acutely Ill Patient.** The therapeutic approach depends on the severity of the patient’s illness. In uncomplicated pernicious anemia, in which the abnormality is restricted to a mild or moderate anemia without leukopenia, thrombocytopenia, or neurological signs or symptoms, the administration of vitamin $B_{12}$ alone will suffice. Moreover, therapy may be delayed until other causes of megaloblastic anemia have been excluded and sufficient studies of gastrointestinal function have been performed to reveal the underlying cause of the disease. In this situation, a therapeutic trial with small amounts of parenteral vitamin $B_{12}$ (1 to 10 $\mu$g per day) can confirm the presence of an uncomplicated vitamin $B_{12}$ deficiency.

In contrast, patients with neurological changes or severe leukopenia or thrombocytopenia associated with infection or bleeding require emergency treatment. The older individual with a severe anemia (hematocrit less than 20%) is likely to have tissue hypoxia, cerebrovascular insufficiency, and congestive heart failure. Effective therapy must not wait for detailed diagnostic tests. Once the megaloblastic erythropoiesis has been confirmed and sufficient blood collected for later measurements of vitamin $B_{12}$ and folic acid, the patient should receive intramuscular injections of 100 $\mu$g of cyanocobalamin and 1 to 5 $\mu$g of folic acid. For the next 1 to 2 weeks the patient should receive daily intramuscular injections of 100 $\mu$g of cyanocobalamin, together with a daily oral supplement of 1 to 2 mg of folic acid. Because an effective increase in red cell mass will not occur for 10 to 20 days, the patient with a markedly depressed hematocrit and tissue hypoxia also should receive a transfusion of 2 to 3 units of packed red blood cells. If congestive heart failure is present, diuretics can be administered to prevent volume overload.

Patients usually report an increased sense of well-being within the first 24 hours of the initiation of therapy. Objectively, memory and orientation can improve dramatically, although full recovery of mental function may take months, or may never occur. In addition, even before an obvious hematological response is apparent, the patient may report an increase in strength, a better appetite, and reduced soreness of the mouth and tongue.

The first objective hematological change is the disappearance of the megaloblastic morphology of the bone marrow. As the ineffective erythropoiesis is corrected, the concentration of iron in plasma falls dramatically as the metal is used in the formation of hemoglobin. This usually occurs within the first 48 hours. Full correction of precursor maturation in marrow with production of an increased number of reticulocytes begins about the second or third day and peaks 3 to 5 days later. When the anemia is moderate to severe, the maximal reticulocyte index will be between three and five times the normal value (i.e., a reticulocyte count of 20% to 40%). The ability of the marrow to sustain a high rate of production determines the rate of recovery of the hematocrit. Patients with complicating iron deficiency, an infection or other inflammatory state, or renal disease may be unable to correct their anemia. Therefore it is important to monitor the reticulocyte index over the first several weeks. If it does not continue at elevated levels while the hematocrit is less than 35%, plasma concentrations of iron and folic acid should again be determined and the patient reevaluated for an illness that could inhibit the response of the marrow.

The degree and rate of improvement of neurological signs and symptoms depend on the severity and the duration of the abnormalities. Those that have been present for only a few months usually disappear relatively rapidly. When a defect has been present for many months or years, full return to normal function may never occur.
**Long-Term Therapy with Vitamin B₁₂.** Once begun, vitamin B₁₂ therapy must be maintained for life. This fact must be impressed upon the patient and family, and a system must be established to guarantee continued monthly injections of cyanocobalamin. Intramuscular injection of 100 μg of cyanocobalamin every 4 weeks is sufficient to maintain a normal concentration of vitamin B₁₂ in plasma and an adequate supply for tissues. Patients with severe neurological symptoms and signs may be treated with larger doses of vitamin B₁₂ in the period immediately after the diagnosis. Doses of 100 μg per day or several times per week may be given for several months with the hope of encouraging faster and more complete recovery. It is important to monitor vitamin B₁₂ concentrations in plasma and to obtain peripheral blood counts at intervals of 3 to 6 months to confirm the adequacy of therapy. Since refractoriness to therapy can develop at any time, evaluation must continue throughout the patient’s life.

**Other Therapeutic Uses of Vitamin B₁₂.** Vitamin B₁₂ has been used in the therapy of a number of conditions, including trigeminal neuralgia, multiple sclerosis and other neuroopathies, various psychiatric disorders, poor growth or nutrition, and as a “tonic” for patients complaining of tiredness or easy fatigue. There is no evidence for the validity of such therapy in any of these conditions. Maintenance therapy with vitamin B₁₂ has been used with some apparent success in the treatment of children with methylmalonic aciduria.

---

**FOLIC ACID**

**Chemistry and Metabolic Functions.** The structural formula of pteroylglutamic acid (PteGlu) is shown in Figure 53–9. Major portions of the molecule include a pteridine ring linked by a methylene bridge to para-aminobenzoic acid, which is joined by an amide linkage to glutamic acid. While pteroylglutamic acid is the common pharmaceutical form of folic acid, it is neither the principal folate congener in food nor the active coenzyme for intracellular metabolism. After absorption, PteGlu is rapidly reduced at the 5, 6, 7, and 8 positions to tetrahydrofolic acid (H₄PteGlu), which then acts as an acceptor of a number of one-carbon units. These are attached at either the 5 or the 10 position of the pteridine ring or may bridge these atoms to form a new five-membered ring. The most important forms of the coenzyme that are synthesized by these reactions are listed in Figure 53–9. Each plays a specific role in intracellular metabolism, summarized as follows (see “Relationships Between Vitamin B₁₂ and Folic Acid,” above, as well as Figure 53–6):

- **Conversion of homocysteine to methionine.** This reaction requires CH₃H₄PteGlu as a methyl donor and utilizes vitamin B₁₂ as a cofactor.
- **Conversion of serine to glycine.** This reaction requires tetrahydrofolate as an acceptor of a methylene group from serine and utilizes pyridoxal phosphate as a cofactor. It results in the formation of 5,10-CH₂H₄PteGlu, an essential coenzyme for the synthesis of thymidylate.
- **Synthesis of thymidylate.** 5,10-CH₂H₄PteGlu donates a methylene group and reducing equivalents to deoxyuridylate for the synthesis of thymidylate—a rate-limiting step in DNA synthesis.
- **Histidine metabolism.** H₄PteGlu also acts as an acceptor of a formimino group in the conversion of formiminoglutaric acid to glutamic acid.
A constant supply of CH₃H₄PteGlu is maintained by food and by an enterohepatic cycle of the vitamin. The liver actively reduces and methylates PteGlu (and H₂ or H₄PteGlu) and then transports the CH₃H₄PteGlu into bile for reabsorption by the gut and subsequent delivery to tissues (Steinberg et al., 1979). This pathway may provide 200 μg or more of folate each day for recirculation to tissues. The importance of the enterohepatic cycle is suggested by animal studies that show a rapid reduction of the plasma folate concentration after either drainage of bile or ingestion of alcohol, which apparently blocks the release of CH₃H₄PteGlu from hepatic parenchymal cells (Hillman et al., 1977).

Following uptake into cells, CH₃H₄PteGlu acts as a methyl donor for the formation of methylcobalamin and as a source of H₄PteGlu and other folate congeners, as described above. Folate is stored within cells as polyglutamates.

**Figure 53–9.** *The structures and nomenclature of pteroylglutamic acid (folic acid) and its congeners.* X represents additional residues of glutamate; polyglutamates are the storage and active forms of the vitamin. The subscript that designates the number of residues of glutamate is frequently omitted because this number is variable.

**Figure 53–10.** *Absorption and distribution of folate derivatives.* Dietary sources of folate polyglutamates are hydrolyzed to the monoglutamate, reduced, and methylated to CH₃H₄PteGlu during gastrointestinal transport. Folate deficiency commonly results from (1) inadequate dietary supply and (2) small intestinal disease. In patients with uremia, alcoholism, or hepatic disease there may be defects in (3) the concentration of folate binding proteins in plasma and (4) the flow of CH₃H₄PteGlu into bile for reabsorption and transport to tissue (the folate enterohepatic cycle). Finally, vitamin B₁₂ deficiency will (5) “trap” folate as CH₃H₄PteGlu, thereby reducing the availability of H₄PteGlu for its essential roles in purine and pyrimidine synthesis.

**Folate Deficiency.** Folate deficiency is a common complication of diseases of the small intestine, which interfere with the absorption of folate from food and the recirculation of folate through the enterohepatic cycle. In acute or chronic alcoholism, daily intake of folate in food may be severely restricted, and the enterohepatic cycle of the vitamin may be impaired by toxic effects of
alcohol on hepatic parenchymal cells; this is the most common cause of folate-deficient megaloblastic erythropoiesis. However, it also is the most amenable to therapy, inasmuch as the reinstitution of a normal diet is sufficient to overcome the effect of alcohol. Disease states characterized by a high rate of cell turnover, such as hemolytic anemias, also may be complicated by folate deficiency. Additionally, drugs that inhibit dihydrofolate reductase (e.g., methotrexate and trimethoprim) or that interfere with the absorption and storage of folate in tissues (e.g., certain anticonvulsants and oral contraceptives) can lower the concentration of folate in plasma and may cause a megaloblastic anemia (Stebbins and Bertino, 1976).

Folate deficiency has been implicated in the incidence of neural tube defects, including spina bifida, encephaloceles, and anencephaly. This is true even in the absence of folate-deficient anemia or alcoholism. A less-than-adequate intake of folate also can result in elevations in plasma homocysteine (Green and Miller, 1999). Since even moderate hyperhomocysteinemia is considered an independent risk factor for coronary artery and peripheral vascular disease and for venous thrombosis, the role of folate as a methyl donor in the homocysteine-to-methionine conversion is getting increased attention. Patients who are heterozygous for one or another enzymatic defect and have high normal to moderate elevations of plasma homocysteine may improve with folic acid therapy.

Folate deficiency is recognized by its impact on the hematopoietic system. As with vitamin B₁₂, this fact reflects the increased requirement associated with high rates of cell turnover. The megaloblastic anemia that results from folate deficiency cannot be distinguished from that caused by vitamin B₁₂ deficiency. This finding is to be expected because of the final common pathway of the major intracellular metabolic roles of the two vitamins. At the same time, folate deficiency is rarely if ever associated with neurological abnormalities. Thus the observation of characteristic abnormalities in vibratory and position sense and in motor and sensory pathways is incompatible with an isolated deficiency of folic acid.

After deprivation of folate, megaloblastic anemia develops much more rapidly than it does following interruption of vitamin B₁₂ absorption (e.g., gastric surgery). This observation reflects the fact that body stores of folate are limited. Although the rate of induction of megaloblastic erythropoiesis may vary, a folate-deficiency state may appear in 1 to 4 weeks, depending on the individual’s dietary habits and stores of the vitamin.

Folate deficiency is best diagnosed from measurements of folate in plasma and in red cells. However, an empiric trial of folate in cases of suspected deficiency has been proposed as more cost effective (Robinson and Mladenovic, 2001). Indeed, the concentration of folate in plasma is extremely sensitive to changes in dietary intake of the vitamin and the influence of inhibitors of folate metabolism or transport, such as alcohol. Normal folate concentrations in plasma range from 9 to 45 nmol (4 to 20 ng/ml); below 9 nmol is considered folate deficient. The plasma folate concentration rapidly falls to values indicative of deficiency within 24 to 48 hours of steady ingestion of alcohol (Eichner and Hillman, 1971; Eichner and Hillman, 1973). The plasma folate concentration will revert quickly to normal once such ingestion is stopped, even while the marrow is still megaloblastic. Such rapid fluctuations detract from the clinical utility of the plasma folate concentration. The amount of folate in red cells or the adequacy of stores in lymphocytes (as measured by the deoxyuridine suppression test) may be used to diagnose a long-standing deficiency of folic acid. A positive result on either test shows that the deficiency must have existed for a sufficient time to allow the production of a population of cells with deficient folate stores.

Folic acid is marketed as oral tablets containing 0.4, 0.8, and 1 mg pteroylglutamic acid, as an aqueous solution for injection (5 mg/ml), and in combination with other vitamins and minerals. Folic acid in large amounts may counteract the antiepileptic effects. Folic acid in cases of suspected deficiency has been proposed as more cost effective (Robinson and Mladenovic, 2001). Indeed, the concentration of folate in plasma is extremely sensitive to changes in dietary intake of the vitamin and the influence of inhibitors of folate metabolism or transport, such as alcohol. Normal folate concentrations in plasma range from 9 to 45 nmol (4 to 20 ng/ml); below 9 nmol is considered folate deficient. The plasma folate concentration rapidly falls to values indicative of deficiency within 24 to 48 hours of steady ingestion of alcohol (Eichner and Hillman, 1971; Eichner and Hillman, 1973). The plasma folate concentration will revert quickly to normal once such ingestion is stopped, even while the marrow is still megaloblastic. Such rapid fluctuations detract from the clinical utility of the plasma folate concentration. The amount of folate in red cells or the adequacy of stores in lymphocytes (as measured by the deoxyuridine suppression test) may be used to diagnose a long-standing deficiency of folic acid. A positive result on either test shows that the deficiency must have existed for a sufficient time to allow the production of a population of cells with deficient folate stores.

Folinic acid (leucovorin calcium, citrovorum factor) is the 5-formyl derivative of tetrahydrofolic acid. The principal therapeutic uses of folic acid are to circumvent the inhibition of dihydrofolate reductase as a part of high-dose methotrexate therapy and to potentiate fluorouracil in the treatment of colorectal cancer (see Chapter 51). It also has been used as an antidote to counteract the toxicity of folate antagonists such as pyrimethamine or trimethoprim. While it can be used to treat any folate-deficient state, folinic acid provides no advantage over folic acid, is more expensive, and therefore is not recommended. A single exception is the megaloblastic anemia associated with congenital dihydrofolate reductase deficiency. Leucovorin should never be used for the treatment of pernicious anemia or other megaloblastic anemias secondary to a deficiency of vitamin B₁₂. Just as is seen with folic acid, its use can result in an apparent response of the hematopoietic system, but neurological damage may occur or progress if already present.

Untoward Effects. There have been rare reports of reactions to parenteral injections of folic acid and leucovorin. If a patient describes a history of a reaction before the drug is given, caution should be exercised. Oral folic acid usually is not toxic. Even with doses as high as 15 mg/day, there have been no substantiated reports of side effects. Folic acid in large amounts may counteract the antiepileptic effect of phenobarbital, phenytoin, and primidone, and increase the frequency of seizures in susceptible children (Reynolds, 1968). While some studies have not supported these contentions, the FDA recommends that oral tablets of folic acid be limited to strengths of 1 mg or less.

General Principles of Therapy. The therapeutic use of folic acid is limited to the prevention and treatment of deficiencies of the vitamin. As with vitamin B₁₂ therapy, effective use of the vitamin depends on accurate diagnosis and an understanding of the mechanisms that are opera-
tive in a specific disease state. The following general principles of therapy should be respected:

1. Prophylactic administration of folic acid should be undertaken for clear indications. Dietary supplementation is necessary when there is a requirement that may not be met by a “normal” diet. The daily ingestion of a multivitamin preparation containing 400 to 500 μg of folic acid has become standard practice before and during pregnancy to reduce the incidence of neural tube defects and for as long as a woman is breastfeeding. In women with a history of a pregnancy complicated by a neural tube defect, an even larger dose of 4 mg a day has been recommended (MRC Vitamin Study Research Group, 1991). Patients on total parenteral nutrition should receive folate acid supplements as part of their fluid regimen because liver folate stores are limited. Adult patients with a disease state characterized by high cell turnover (e.g., hemolytic anemia) generally require larger doses, 1 mg of folic acid given once or twice a day. The 1-mg dose also has been used in the treatment of patients with elevated levels of homocysteine.

2. As with vitamin B<sub>12</sub> deficiency, any patient with folate deficiency and a megaloblastic anemia should be evaluated carefully to determine the underlying cause of the deficiency state. This should include evaluation of the effects of medications, the amount of alcohol intake, the patient’s history of travel, and the function of the gastrointestinal tract.

3. Therapy always should be as specific as possible. Multivitamin preparations should be avoided unless there is good reason to suspect deficiency of several vitamins.

4. The potential danger of mistreating a patient who has vitamin B<sub>12</sub> deficiency with folic acid must be kept in mind. The administration of large doses of folic acid can result in an apparent improvement of the megaloblastic anemia, inasmuch as PteGlu is converted by dihydrofolate reductase to H<sub>4</sub>PteGlu; this circumvents the methylfolate “trap.” However, folate therapy does not prevent or alleviate the neurological defects of vitamin B<sub>12</sub> deficiency, and these may progress and become irreversible.

_Treatment of the Acutely Ill Patient._ As described in detail in the section on vitamin B<sub>12</sub>, treatment of the patient who is acutely ill with megaloblastic anemia should begin with intramuscular injections of vitamin B<sub>12</sub> and folic acid. Inasmuch as the patient requires therapy before the exact cause of the disease has been defined, it is important to avoid the potential problem of a combined deficiency of vitamin B<sub>12</sub> and folic acid. When the patient is deficient in both, therapy with only one vitamin will not provide an optimal response. Longstanding nontropical sprue is one example of a disease in which combined deficiency of B<sub>12</sub> and folate is common. When indicated, vitamin B<sub>12</sub> (100 μg) and folic acid (1 to 5 mg) should be administered intramuscularly, and the patient should then be maintained on daily oral supplements of 1 to 2 mg of folic acid for the next 1 to 2 weeks.

Oral administration of folate generally is satisfactory for patients who are not acutely ill, regardless of the cause of the deficiency state. Even the patient with tropical or nontropical sprue and a demonstrable defect in absorption of folic acid will respond adequately to such therapy. Abnormalities in the activity of pteroyl-γ-glutamyl carboxypeptidase and the function of mucosal cells will not prevent passive diffusion of sufficient amounts of PteGlu across the mucosal barrier if the dosage is adequate, and continued ingestion of alcohol or other drugs also will not prevent an adequate therapeutic response. The effects of most inhibitors of folate transport or dihydrofolate reductase are overcome easily by administration of pharmacological doses of the vitamin. Folinic acid is the appropriate form of the vitamin for use in chemotherapeutic protocols, including “rescue” from methotrexate (see Chapter 51). Perhaps the only situation in which oral administration of folate will be ineffective is when vitamin C is severely deficient. Patients with scurvy may suffer from a megaloblastic anemia despite increased intake of folate and normal or high concentrations of the vitamin in plasma and cells.

The therapeutic response may be monitored by study of the hematopoietic system in a fashion identical to that described for vitamin B<sub>12</sub>. Within 48 hours of the initiation of appropriate therapy, megaloblastic erythropoiesis disappears, and as efficient erythropoiesis begins, the concentration of iron in plasma falls to normal or below-normal values. The reticulocyte count begins to rise on the second or third day and reaches a peak by the fifth to seventh days; the reticulocyte index reflects the proliferative state of the marrow. Finally, the hematocrit begins to rise during the second week.

It is possible to use the pattern of recovery as the basis for a therapeutic trial. For this purpose, the patient should receive a daily parenteral injection of 50 to 100 μg of folic acid. Administration of doses in excess of 100 μg per day entails the risk of inducing a hematopoietic response in patients who are deficient in vitamin B<sub>12</sub>, while oral administration of the vitamin may be unreliable because of intestinal malabsorption. A number of other complications also may interfere with the therapeutic trial. The patient with sprue and deficiencies of other vitamins or iron may fail to respond because of these inadequacies. In cases of alcoholism, the presence of hepatic disease, inflammation, or iron deficiency can blunt the proliferative response of the marrow and prevent the correction of the anemia. For these reasons, the therapeutic trial for the evaluation of the patient with a potential deficiency of folic acid has not gained great popularity.

**CLINICAL SUMMARY**

Several hematopoietic growth factors are available for clinical use. Recombinant erythropoietin routinely is used for patients with the anemia of renal insufficiency, inflammation, and associated with cancer or the therapy of cancer. Longer-acting growth factors that permit less frequent dosing schedules are coming into increased use. One of the first of these is novel erythropoiesis-stimulat-
ing protein (NESP), produced by the insertion of two extra N-linked sialic acid side chains into the erythropoietin molecule. Myeloid growth factors (e.g., GM-CSF and G-CSF) are used to hasten the recovery of granulocytes after myelosuppressive therapy, to help mobilize hematopoietic stem cells into the peripheral blood to allow their harvest for transplantation, and to augment the number of mature leukocytes in the peripheral blood so that they can be used in patients with overwhelming infection. Finally, the development of IL-11 for use in thrombocytopenia and the investigational use of thrombopoietin or mimics of the molecule may provide many of the same therapeutic advances.

**MONOGRAPHS AND REVIEWS**

This page intentionally left blank
The physiological systems that control blood fluidity are both complex and elegant. Blood must remain fluid within the vasculature and yet clot quickly when exposed to nonendothelial surfaces at sites of vascular injury. When intravascular thrombi do occur, a system of fibrinolysis is activated to restore fluidity. In the normal situation, a delicate balance prevents both thrombosis and hemorrhage and allows physiological fibrinolysis without excess pathological fibrinogenolysis. The drugs described in this chapter have very different mechanisms of action, but all alter the balance between procoagulant and anticoagulant reactions. With these drugs, efficacy and toxicity are necessarily intertwined. For example, the desired therapeutic effect of anticoagulation can be offset by the toxic effect of bleeding due to overdosing of anticoagulant. Similarly, overstimulation of fibrinolysis can lead to systemic destruction of fibrinogen and coagulation factors. This chapter reviews the predominant agents for controlling blood fluidity, including (1) the parenteral anticoagulant heparin and its derivatives, which stimulate a natural inhibitor of coagulant proteases; (2) the coumarin anticoagulants, which block multiple steps in the coagulation cascade; (3) fibrinolytic agents, which lyse pathological thrombi; and (4) antiplatelet agents, especially aspirin.

**OVERVIEW OF HEMOSTASIS: PLATELET FUNCTION, BLOOD COAGULATION, AND FIBRINOLYSIS**

Hemostasis is the cessation of blood loss from a damaged vessel. Platelets first adhere to macromolecules in the subendothelial regions of the injured blood vessel; they then aggregate to form the primary hemostatic plug. Platelets stimulate local activation of plasma coagulation factors, leading to generation of a fibrin clot that reinforces the platelet aggregate. Later, as wound healing occurs, the platelet aggregate and fibrin clot are degraded. The process of platelet aggregation and blood coagulation are summarized in Figures 54–1 and 54–2. The pathway of clot removal, fibrinolysis, is shown in Figure 54–3, along with sites of action of fibrinolytic agents.

Coagulation involves a series of zymogen activation reactions, as shown in Figure 54–2 (Mann et al., 2003). At each stage, a precursor protein, or zymogen, is converted to an active protease by cleavage of one or more peptide bonds in the precursor molecule. The components at each stage include a protease from the preceding stage, a zymogen, a nonenzymatic protein cofactor, Ca²⁺, and an organizing surface that is provided by a phospholipid emulsion in vitro or by platelets in vivo. The final protease generated is thrombin (factor IIa).

**Conversion of Fibrinogen to Fibrin.** Fibrinogen is a 330,000-dalton protein that consists of three pairs of polypeptide chains (designated Aα, Bβ, and γ) covalently linked by disulfide bonds. Thrombin converts fibrinogen to fibrin monomers by cleaving fibrinopeptides A (16 amino acid residues) and B (14 amino acid residues) from the amino-terminal ends of the Aα and Bβ chains, respectively. Removal of the fibrinopeptides allows the fibrin monomers to form a gel, which is the end point of in vitro assays of coagulation (see below). Initially, the fibrin monomers are bound to each other noncovalently. Subsequently, factor XIIIa catalyzes an interchain transglutamination reaction that cross-links adjacent fibrin monomers to enhance the strength of the clot.

**Structure of Coagulation Protease Zymogens.** The protease zymogens involved in coagulation include factors II (prothrombin), VII, IX, X, XI, XII, and prekallikrein. About 200 amino acid residues at the car...
Figure 54–1. Platelet adhesion and aggregation. GPIa/IIa and GPIb are platelet membrane proteins that bind to collagen and von Willebrand factor (vWF), causing platelets to adhere to the subendothelium of a damaged blood vessel. PAR1 and PAR4 are protease-activated receptors that respond to thrombin (IIa); P2Y₁ and P2Y₁₂ are receptors for ADP (adenosine diphosphate); when stimulated by agonists, these receptors activate the fibrinogen-binding protein GPIIb/IIIa and cyclooxygenase-1 (COX-1) to promote platelet aggregation and secretion. Thromboxane A₂ (TXA₂) is the major product of COX-1 involved in platelet activation. Prostaglandin I₂ (PGL₂), synthesized by endothelial cells, inhibits platelet activation.

Figure 54–2. Major reactions of blood coagulation. Shown are interactions among proteins of the “extrinsic” (tissue factor and factor VII), “intrinsic” (factors IX and VIII), and “common” (factors X, V, and II) coagulation pathways that are important in vivo. Boxes enclose the coagulation factor zymogens (indicated by Roman numerals) and the rounded boxes represent the active proteases. TF, tissue factor; activated coagulation factors are followed by the letter “a.” II, prothrombin; IIa, thrombin.
boxyl-terminal end of each zymogen are homologous to trypsin and contain the active site of the protease. In addition, 9 to 12 glutamate residues near the amino-terminal ends of factors II, VII, IX, and X are converted to γ-carboxyglutamate (Gla) residues during biosynthesis in the liver. The Gla residues bind Ca\(^{2+}\) and are necessary for the coagulant activities of these proteins.

Nonenzymatic Protein Cofactors. Factors V and VIII are homologous 350,000-dalton proteins. Factor VIII circulates in plasma bound to von Willebrand factor, while factor V is present both freely in plasma and as a component of platelets. Thrombin cleaves V and VIII to yield activated factors (Va and VIIIa) that have at least 50 times the coagulant activity of the precursor forms. Factors Va and VIIIa have no intrinsic enzymatic activity but serve as cofactors that increase the proteolytic efficiency of Xa and IXa, respectively. Tissue factor (TF) is a nonenzymatic lipoprotein cofactor that greatly increases the proteolytic efficiency of VIIa. It is present on the surface of cells that do not normally contact plasma (e.g., macrophages and smooth muscle cells) and initiates coagulation outside a broken blood vessel. Monocytes and endothelial cells also may express tissue factor when exposed to a variety of stimuli, such as endotoxin, tumor necrosis factor, and interleukin-1. Thus these cells may be involved in thrombus formation under pathological circumstances. High-molecular-weight kininogen is a plasma protein that serves as the cofactor for XIIa when clotting is initiated in vitro in the activated partial thromboplastin time (aPTT) test.

Activation of Prothrombin. Factor Xa cleaves two peptide bonds in prothrombin to form thrombin. Activation of prothrombin by Xa is accelerated by Va, phospholipids, and Ca\(^{2+}\). When these components are all present, prothrombin is activated nearly 20,000 times faster than the rate achieved by Xa and Ca\(^{2+}\) alone. The maximal rate of activation occurs only when prothrombin and Xa both contain Gla residues, and therefore have the ability to bind to phospholipids. Purified platelets can substitute for phospholipids and Va to facilitate activation of prothrombin in vitro, provided that the platelets are stimulated to release endogenous platelet factor Va or that factor Va is added exogenously to unstimulated platelets. The surface of platelets that are aggregated at the site of hemostasis concentrates the factors required for prothrombin activation.

Initiation of Coagulation. Coagulation is initiated in vivo by the extrinsic pathway. Small amounts of factor VIIa in the plasma bind to subendothelial tissue factor following vascular injury. Tissue factor accelerates activation of factor X by VIIa, phospholipids, and Ca\(^{2+}\) about 30,000-fold. VIIa also can activate IX in the presence of tissue factor, providing a convergence between the extrinsic and intrinsic pathways.

Clotting by the intrinsic pathway is initiated in vitro when XII, prekallikrein, and high-molecular-weight kininogen interact with kaolin, glass, or another surface to generate small amounts of XIIa. Activation of XI to Xla and IX to IXa follows. IXa then activates X in a reaction that is accelerated by VIIIa, phospholipids, and Ca\(^{2+}\). Activation of factor X by IXa appears to occur by a mechanism similar to that for activation of prothrombin and may also be accelerated by platelets in vivo. Activation of factor XII is not required for hemostasis, since patients with deficiency of XII, prekallikrein, or high-molecular-

Figure 54–3. Fibrinolysis. Endothelial cells secrete tissue plasminogen activator (t-PA) at sites of injury. t-PA binds to fibrin and cleaves plasminogen to plasmin, resulting in fibrin digestion. Plasminogen activator inhibitors-1 and -2 (PAI-1, PAI-2) inactivate t-PA; α\(_2\)-antiplasmin (α\(_2\)-AP) inactivates plasmin.

Endothelial cells

Smooth muscle cells/macrophages

**Figure 54–3. Fibrinolysis.** Endothelial cells secrete tissue plasminogen activator (t-PA) at sites of injury. t-PA binds to fibrin and cleaves plasminogen to plasmin, resulting in fibrin digestion. Plasminogen activator inhibitors-1 and -2 (PAI-1, PAI-2) inactivate t-PA; α\(_2\)-antiplasmin (α\(_2\)-AP) inactivates plasmin.
weight kininogen do not bleed abnormally, even though their aPTT values are prolonged. Factor XI deficiency is associated with a variable and usually mild bleeding disorder. The mechanism for activation of factor XI in vivo is not known, although thrombin activates factor XI in vitro.

Fibrinolysis and Thrombolysis

The fibrinolytic system dissolves intravascular clots as a result of the action of plasmin, an enzyme that digests fibrin. Plasminogen, an inactive precursor, is converted to plasmin by cleavage of a single peptide bond. Plasmin is a relatively nonspecific protease; it digests fibrin clots and other plasma proteins, including several coagulation factors. Therapy with thrombolytic drugs tends to dissolve both pathological thrombi and fibrin deposits at sites of vascular injury. Therefore, the drugs are toxic, producing hemorrhage as a major side effect.

The fibrinolytic system is regulated such that unwanted fibrin thrombi are removed, while fibrin in wounds persists to maintain hemostasis (Lijnen and Collen, 2001). Tissue plasminogen activator (t-PA) is released from endothelial cells in response to various signals, including stasis produced by vascular occlusion. It is rapidly cleared from blood or inhibited by circulating inhibitors, plasminogen activator inhibitor-1 and plasminogen activator inhibitor-2, and thus exerts little effect on circulating plasminogen. t-PA binds to fibrin and converts plasminogen, which also binds to fibrin, to plasmin. Plasminogen and plasmin bind to fibrin at binding sites located near their amino termini that are rich in lysine residues (see below). These sites also are required for binding of plasmin to the inhibitor α2-antiplasmin. Therefore, fibrin-bound plasmin is protected from inhibition. Any plasmin that escapes this local milieu is rapidly inhibited. Some α2-antiplasmin is bound covalently to fibrin and thereby protects fibrin from premature lysis. When plasminogen activators are administered for thrombolytic therapy, massive fibrinolysis is initiated, and the inhibitory controls are overwhelmed. The pathway of fibrinolysis and sites of pharmacologic perturbation are summarized by Figure 54–3.

Coagulation In Vitro. Blood clots in 4 to 8 minutes when placed in a glass tube. Clotting is prevented if a chelating agent such as ethylenediaminetetraacetic acid (EDTA) or citrate is added to bind Ca2+. Recalcified plasma clots in 2 to 4 minutes. The clotting time after recalcification is shortened to 26 to 33 seconds by the addition of negatively charged phospholipids and a particulate substance such as kaolin (aluminum silicate); this is termed the activated partial thromboplastin time (aPTT). Alternatively, recalcified plasma will clot in 12 to 14 seconds after addition of “thromboplastin” (a mixture of tissue factor and phospholipids); this is termed the prothrombin time (PT).

Two pathways of coagulation are recognized. An individual with a prolonged aPTT and a normal PT is considered to have a defect in the intrinsic coagulation pathway, because all of the components of the aPTT test (except kaolin) are intrinsic to the plasma. A patient with a prolonged PT and a normal aPTT has a defect in the extrinsic coagulation pathway, since thromboplastin is extrinsic to the plasma. Prolongation of both the aPTT and the PT suggests a defect in a common pathway.

Natural Anticoagulant Mechanisms. Platelet activation and coagulation normally do not occur within an intact blood vessel (Edelberg et al., 2001). Thrombosis is prevented by several regulatory mechanisms that require a normal vascular endothelium. Prostacyclin (prostaglandin I2; PGI2), a metabolite of arachidonic acid, is synthesized by endothelial cells and inhibits platelet aggregation and secretion (see Chapter 25). Antithrombin is a plasma protein that inhibits coagulation factors of the intrinsic and common pathways (see below). Heparan sulfate proteoglycans synthesized by endothelial cells stimulate the activity of antithrombin. Protein C is a plasma zymogen that is homologous to II, VII, IX, and X; its activity depends on the binding of Ca2+ to Gla residues within its amino-terminal domain. Activated protein C, in combination with its non-enzymatic Gla-containing cofactor (protein S), degrades cofactors Va and VIIIa and thereby greatly diminishes the rates of activation of prothrombin and factor X (Esmon, 2003). Protein C is activated by thrombin only in the presence of thrombomodulin, an integral membrane protein of endothelial cells. Like antithrombin, protein C appears to exert an anticoagulant effect in the vicinity of intact endothelial cells. Tissue factor pathway inhibitor (TFPI) is found in the lipoprotein fraction of plasma. When bound to factor Xa, TFPI inhibits factor Xa and the factor VIIIa–tissue factor complex. By this mechanism, factor Xa may regulate its own production.

PARENTERAL ANTICOAGULANTS

Heparin

Biochemistry. Heparin is a glycosaminoglycan found in the secretory granules of mast cells. It is synthesized from
Heparin is commonly extracted from porcine intestinal mucosa or bovine lung, and preparations may contain small amounts of other glycosaminoglycans. Despite the heterogeneity in composition among different commercial preparations of heparin, their biological activities are similar (about 150 USP units/mg). The USP unit is the quantity of heparin that prevents 1 ml of citrated plasma from clotting for 1 hour after the addition of 0.2 ml of 1% CaCl₂.

Low-molecular-weight heparins (1000 to 10,000 daltons; mean, 4500 daltons, or 15 monosaccharide units) are isolated from standard heparin by gel filtration chromatography, precipitation with ethanol, or partial depolymerization with nitrous acid and other chemical or enzymatic reagents. Low-molecular-weight heparins differ from standard heparin and from each other in their pharmacokinetic properties and mechanism of action (see below). The biological activity of low-molecular-weight heparin is generally measured with a factor Xa inhibition assay, which is mediated by antithrombin (see below).

**Mechanism of Action.** Heparin catalyzes the inhibition of several coagulation proteases by antithrombin, a glycosylated, single-chain polypeptide composed of 432 amino acid residues (Olson and Chuang, 2002). Antithrombin is synthesized in the liver and circulates in plasma at an approximate concentration of 2.6 µM. It inhibits activated coagulation factors of the intrinsic and common pathways, including thrombin, Xa, and IXa; however, it has relatively little activity against factor VIIa. Antithrombin is a “suicide substrate” for these proteases; inhibition occurs when the protease attacks a specific Arg-Ser peptide bond in the reactive site of antithrombin and becomes trapped as a stable 1:1 complex.

Heparin increases the rate of the thrombin-antithrombin reaction at least a thousandfold by serving as a catalytic template to which both the inhibitor and the protease bind. Binding of heparin also induces a conformational change in antithrombin that makes the reactive site more accessible to the protease. Once thrombin has become bound to antithrombin, the heparin molecule is released from the complex. The binding site for antithrombin on heparin is a specific pentasaccharide sequence that contains a 3-O-sulfated glucosamine residue (Figure 54–4). This structure occurs in about 30% of heparin molecules and less abundantly in heparan sulfate. Other glycosaminoglycans (e.g., dermatan sulfate, chondroitin-4-sulfate, and chondroitin-6-sulfate) lack the antithrombin-binding structure and do not stimulate antithrombin. Heparin molecules containing fewer than 18 monosaccharide units (<5400 daltons) also do not catalyze inhibition of thrombin by antithrombin. Molecules of 18 monosaccharides or greater are required to bind thrombin and antithrombin.
simultaneously. In contrast, the pentasaccharide shown in Figure 54–4 catalyzes inhibition of factor Xa by antithrombin. In this case, catalysis may occur solely by induction of a conformational change in antithrombin that facilitates reaction with the protease. Low-molecular-weight heparin preparations produce an anticoagulant effect mainly through inhibition of Xa by antithrombin, because the majority of molecules are of insufficient length to catalyze inhibition of thrombin.

When the concentration of heparin in plasma is 0.1 to 1 units/ml, thrombin, factor IXa, and factor Xa are inhibited rapidly (half-lives less than 0.1 second) by antithrombin. This effect prolongs both the aPTT and the thrombin time (i.e., the time required for plasma to clot when exogenous thrombin is added); the PT is affected to a lesser degree. Factor Xa bound to platelets in the prothrombinase complex and thrombin bound to fibrin are both protected from inhibition by antithrombin in the presence of heparin. Thus, heparin may promote inhibition of factor Xa and thrombin only after they have diffused away from these binding sites. Platelet factor 4, released from the α-granules during platelet aggregation, blocks binding of antithrombin to heparin or heparan sulfate and may promote local clot formation at the site of hemostasis.

Miscellaneous Pharmacological Effects. High doses of heparin can interfere with platelet aggregation and thereby prolong bleeding time. It is unclear to what extent the antiplatelet effect of heparin contributes to the hemorrhagic complications of treatment with the drug. Heparin “clears” lipemic plasma in vivo by causing the release of lipoprotein lipase into the circulation. Lipoprotein lipase hydrolyzes triglycerides to glycerol and free fatty acids. The clearing of lipemic plasma may occur at concentrations of heparin below those necessary to produce an anticoagulant effect. Rebound hyperlipemia may occur after heparin administration is stopped.

Clinical Use. Heparin is used to initiate treatment of venous thrombosis and pulmonary embolism because of its rapid onset of action (Hirsh et al., 2001). An oral anticoagulant usually is started concurrently, and heparin is continued for at least 4 to 5 days to allow the oral anticoagulant to achieve its full therapeutic effect (see Clinical Use and Monitoring Anticoagulant Therapy). Patients who experience recurrent thromboembolism despite adequate oral anticoagulation (e.g., patients with Trousseau’s syndrome) may benefit from long-term heparin administration. Heparin is used in the initial management of patients with unstable angina or acute myocardial infarction, during and after coronary angioplasty or stent placement, and during surgery requiring cardiopulmonary bypass. Heparin also is used to treat selected patients with disseminated intravascular coagulation. Low-dose heparin regimens are effective in preventing venous thromboembolism in certain high-risk patients. Specific recommendations for heparin use have been reviewed (Hirsh et al., 2001).

Low-molecular-weight heparin preparations were first approved for prevention of venous thromboembolism. They are also effective in the treatment of venous thrombosis, pulmonary embolism, and unstable angina (Hirsh et al., 2001). The principal advantage of low-molecular-weight heparin over standard heparin is a more predictable pharmacokinetic profile, which allows weight-adjusted subcutaneous administration without laboratory monitoring. Thus, therapy of many patients with acute venous thromboembolism can be provided in the outpatient setting. Other advantages of low-molecular-weight heparin include a lower incidence of heparin-induced thrombocytopenia and possibly lower risks of bleeding and osteopenia.

In contrast to warfarin, heparin does not cross the placenta and has not been associated with fetal malformations; therefore it is the drug of choice for anticoagulation during pregnancy. Heparin does not appear to increase the incidence of fetal mortality or prematurity. If possible, the drug should be discontinued 24 hours before delivery to minimize the risk of postpartum bleeding. The safety and efficacy of low-molecular-weight heparin use during pregnancy have not been adequately evaluated.

Absorption and Pharmacokinetics. Heparin is not absorbed through the gastrointestinal mucosa and therefore is given by continuous intravenous infusion or subcutaneous injection. Heparin has an immediate onset of action when given intravenously. In contrast, there is considerable variation in the bioavailability of heparin given subcutaneously, and the onset of action is delayed 1 to 2 hours; low-molecular-weight heparins are absorbed more uniformly.

The half-life of heparin in plasma depends on the dose administered. When doses of 100, 400, or 800 units/kg of heparin are injected intravenously, the half-lives of the anticoagulant activities are approximately 1, 2.5, and 5 hours, respectively (see Appendix II for pharmacokinetic data). Heparin appears to be cleared and degraded primarily by the reticuloendothelial system; a small amount of undegraded heparin also appears in the urine. The half-life of heparin may be shortened in patients with pulmonary embolism and prolonged in patients with hepatic cirrhosis or end-stage renal disease. Low-molecular-weight heparins have longer biological half-lives than do standard preparations of the drug.

Administration and Monitoring. Full-dose heparin therapy usually is administered by continuous intravenous infusion. Treatment of venous thromboembolism is initiated with a bolus injection of 5000 units, followed by 1200 to 1600 units per hour delivered by an infusion pump. Therapy routinely is monitored by the aPTT. The therapeutic range for standard heparin is considered to be
that which is equivalent to a plasma heparin level of 0.3 to 0.7 units/ml as determined with an anti–factor Xa assay (Hirsh et al., 2001). The aPTT value that corresponds to this range varies depending on the reagent and instrument used to perform the assay. A clotting time of 1.8 to 2.5 times the normal mean aPTT value generally is assumed to be therapeutic; however, values in this range obtained with some aPTT assays may overestimate the amount of circulating heparin, and therefore be subtherapeutic. The risk of recurrence of thromboembolism is greater in patients who do not achieve a therapeutic level of anticoagulation within the first 24 hours. Initially, the aPTT should be measured and the infusion rate adjusted every 6 hours; dose adjustments may be aided by use of a nomogram (Hirsh et al., 2001). Once a steady dosage schedule has been established, daily monitoring is sufficient.

Very high doses of heparin are required to prevent coagulation during cardiopulmonary bypass. The aPTT is infinitely prolonged over the dosage range used. Another coagulation test, such as the activated clotting time, is employed to monitor therapy in this situation.

Subcutaneous administration of heparin can be used for the long-term management of patients in whom warfarin is contraindicated (e.g., during pregnancy). A total daily dose of about 35,000 units administered as divided doses every 8 to 12 hours usually is sufficient to achieve an aPTT of 1.5 times the control value (measured midway between doses). Monitoring generally is unnecessary once a steady dosage schedule is established.

Low-dose heparin therapy is used prophylactically to prevent deep venous thrombosis and thromboembolism in susceptible patients. (Until recently a suggested regimen for such treatment was 5000 units of heparin given every 8 to 12 hours.) The body of evidence now suggests that this regimen is clinically less effective than giving heparin every 8 hours in hospitalized medical and surgical patients at high risk for venous thromboembolism (Cade, 1982; Gardlund, 1996; Belch et al., 1981). Laboratory monitoring is unnecessary, since this regimen does not prolong the aPTT.

**Low-Molecular-Weight Heparin Preparations.** Enoxaparin (LOVENOX), dalteparin (FRAGMIN), tinzaparin (INNOHEP, others), ardeparin (NORMIFLO), nadroparin (FRAXIPARINE, others), and reviparin (CLIVARINE) differ considerably in composition, and it cannot be assumed that two preparations that have similar anti–factor Xa activity will produce equivalent antithrombotic effects. The more predictable pharmacokinetic properties of low-molecular-weight heparins, however, permit administration in a fixed or weight-adjusted dosage regimen once or twice daily by subcutaneous injection. Since they have a minimal effect on tests of clotting in vitro, monitoring is not done routinely. Patients with end-stage renal failure may require monitoring with an anti–factor Xa assay because this condition may prolong the half-life of low-molecular-weight heparin. Specific dosage recommendations for various low-molecular-weight heparins may be obtained from the manufacturer’s literature. Nadroparin and reviparin are not currently available in the United States.

**Synthetic Heparin Derivatives.** Fondaparinux (ARIIXTRA) is a synthetic pentasaccharide based on the structure of the antithrombin binding region of heparin. It mediates inhibition of factor Xa by antithrombin but does not cause thrombin inhibition due to its short polymer length. Fondaparinux is administered by subcutaneous injection, reaches peak plasma levels in 2 hours, and is excreted in the urine with a half-life of 17 to 21 hours. It should not be used in patients with renal failure. Because it does not interact significantly with blood cells or plasma proteins other than antithrombin, fondaparinux can be given once a day at a fixed dose without coagulation monitoring. Fondaparinux appears to be much less likely than heparin or low-molecular-weight heparin to trigger the syndrome of heparin-induced thrombocytopenia (see below). Fondaparinux is approved for thromboprophylaxis of patients undergoing hip or knee surgery (Buller et al., 2003) and for the therapy of pulmonary embolism and deep venous thrombosis. Idraparinux (undergoing phase III clinical testing as of 2004) is a more highly sulfated derivative of fondaparinux that has a half-life of 5 to 6 days; the lack of a suitable antidote may limit its clinical application.

**Heparin Resistance.** The dose of heparin required to produce a therapeutic aPTT varies due to differences in the concentrations of heparin-binding proteins in plasma, such as histidine-rich glycoprotein, vitronectin, and platelet factor 4; these proteins competitively inhibit binding of heparin to antithrombin. Occasionally a patient’s aPTT will not be prolonged unless very high doses of heparin (>50,000 units per day) are administered. Such patients may have “therapeutic” concentrations of heparin in plasma at the usual dose when values are measured by other tests (e.g., anti–factor Xa activity or protamine sulfate titration). These patients may have very short aPTT values prior to treatment because of the presence of an increased concentration of factor VIII and may not be truly resistant to heparin. Other patients may require large doses of heparin because of accelerated clearance of the drug, as may occur with massive pulmonary embolism. Patients with inherited antithrombin deficiency ordinarily have 40% to 60% of the normal plasma concentration of this inhibitor and respond normally to intravenous heparin. However, acquired antithrombin deficiency (concentration less than 25% of normal) may occur in patients with hepatic cirrhosis, nephrotic syndrome, or disseminated intravascular coagulation; large doses of heparin may not prolong the aPTT in these individuals.
**Toxicities. Bleeding.** Bleeding is the primary untoward effect of heparin. Major bleeding occurs in 1% to 5% of patients treated with intravenous heparin for venous thromboembolism (Hirsh et al., 2001). The incidence of bleeding is somewhat less in patients treated with low-molecular-weight heparin for this indication. Although the number of bleeding episodes appears to increase with the total daily dose of heparin and with the degree of prolongation of the aPTT, these correlations are weak, and patients can bleed with aPTT values that are within the therapeutic range. Often an underlying cause for bleeding is present, such as recent surgery, trauma, peptic ulcer disease, or platelet dysfunction.

The anticoagulant effect of heparin disappears within hours of discontinuation of the drug. Mild bleeding due to heparin usually can be controlled without the administration of an antagonist. If life-threatening hemorrhage occurs, the effect of heparin can be reversed quickly by the slow intravenous infusion of protamine sulfate, a mixture of basic polypeptides isolated from salmon sperm. Protamine binds tightly to heparin and thereby neutralizes its anticoagulant effect. Protamine also interacts with platelets, fibrinogen, and other plasma proteins and may cause an anticoagulant effect of its own. Therefore, one should give the minimal amount of protamine required to neutralize the heparin present in the plasma. This amount is approximately 1 mg of protamine for every 100 units of heparin remaining in the patient; it is given intravenously at a slow rate (up to 50 mg over 10 minutes).

Protamine is used routinely to reverse the anticoagulant effect of heparin following cardiac surgery and other vascular procedures. Anaphylactic reactions occur in about 1% of patients with diabetes mellitus who have received protamine-containing insulin (NPH insulin or protamine zinc insulin) but are not limited to this group. A less common reaction consisting of pulmonary vasoconstriction, right ventricular dysfunction, systemic hypotension, and transient neutropenia also may occur after protamine administration.

**Heparin-Induced Thrombocytopenia.** Heparin-induced thrombocytopenia (platelet count <150,000/ml or a 50% decrease from the pretreatment value) occurs in about 0.5% of medical patients 5 to 10 days after initiation of therapy with standard heparin (Warkentin, 2003). The incidence of thrombocytopenia is lower with low-molecular-weight heparin. Thrombotic complications that can be life-threatening or lead to amputation occur in about one-half of the affected heparin-treated patients and may precede the onset of thrombocytopenia. The incidence of heparin-induced thrombocytopenia and thrombosis is higher in surgical patients. Venous thromboembolism occurs most commonly, but arterial thromboses causing limb ischemia, myocardial infarction, and stroke also occur. Bilateral adrenal hemorrhage, skin lesions at the site of subcutaneous heparin injection, and a variety of systemic reactions may accompany heparin-induced thrombocytopenia. The development of IgG antibodies against complexes of heparin with platelet factor 4 (or, rarely, other chemokines) appears to cause all of these reactions. These complexes activate platelets by binding to FcγIIa receptors, which results in platelet aggregation, release of more platelet factor 4, and thrombin generation. The antibodies also may trigger vascular injury by binding to platelet factor 4 attached to heparan sulfate on the endothelium.

Heparin should be discontinued immediately if unexplained thrombocytopenia or any of the clinical manifestations mentioned above occur 5 or more days after beginning heparin therapy, regardless of the dose or route of administration. The onset of heparin-induced thrombocytopenia may occur earlier in patients who have received heparin within the previous 3 to 4 months and have residual circulating antibodies. The diagnosis of heparin-induced thrombocytopenia can be confirmed by a heparin-dependent platelet activation assay or an assay for antibodies that react with heparin/platelet factor 4 complexes. Since thrombotic complications may occur after cessation of therapy, an alternative anticoagulant such as lepirudin, argatroban, or danaparoid (see below) should be administered to patients with heparin-induced thrombocytopenia. Low-molecular-weight heparins should be avoided, because these drugs often cross-react with standard heparin in heparin-dependent antibody assays. Warfarin may precipitate venous limb gangrene or multicentric skin necrosis in patients with heparin-induced thrombocytopenia and should not be used until the thrombocytopenia has resolved and the patient is adequately anticoagulated with another agent.

**Other Toxicities.** Abnormalities of hepatic function tests occur frequently in patients who are receiving heparin intravenously or subcutaneously. Mild elevations of the activities of hepatic transaminases in plasma occur without an increase in bilirubin levels or alkaline phosphatase activity. Osteoporosis resulting in spontaneous vertebral fractures can occur, albeit infrequently, in patients who have received full therapeutic doses of heparin (greater than 20,000 units per day) for extended periods of time (e.g., 3 to 6 months). Heparin can inhibit the synthesis of aldosterone by the adrenal glands and occasionally causes hyperkalemia, even when low doses are given. Allergic reactions to heparin (other than thrombocytopenia) are rare.
Other Parenteral Anticoagulants

Lepirudin. Lepirudin (REFLUDAN) is a recombinant derivative (Leu1-Thr2-63-desulfohirudin) of hirudin, a direct thrombin inhibitor present in the salivary glands of the medicinal leech. It is a 65-amino-acid polypeptide that binds tightly to both the catalytic site and the extended substrate recognition site (exosite I) of thrombin. Lepirudin is approved in the United States for treatment of patients with heparin-induced thrombocytopenia. It is administered intravenously at a dose adjusted to maintain the aPTT at 1.5 to 2.5 times the median of the laboratory’s normal range for aPTT. The drug is excreted by the kidneys and has a half-life of about 1.3 hours. Lepirudin should be used cautiously in patients with renal failure, since it can accumulate and cause bleeding in these patients. Patients may develop antihirudin antibodies that occasionally cause a paradoxical increase in the aPTT; therefore, daily monitoring of the aPTT is recommended. There is no antidote for lepirudin.

Bivalirudin. Bivalirudin (ANGIOMAX) is a synthetic, 20-amino-acid polypeptide that directly inhibits thrombin by a mechanism similar to that of lepirudin. Bivalirudin contains the sequence Phe1-Pro2-Arg3-Pro4, which occupies the catalytic site of thrombin, followed by a polyglycine linker and a hirudin-like sequence that binds to exosite I. Thrombin slowly cleaves the Arg3-Pro4 peptide bond and thus regains activity. Bivalirudin is administered intravenously and is used as an alternative to heparin in patients undergoing coronary angioplasty. The half-life of bivalirudin in patients with normal renal function is 25 minutes; dosage reductions are recommended for patients with moderate or severe renal impairment.

Argatroban. Argatroban, a synthetic compound based on the structure of L-arginine, binds reversibly to the catalytic site of thrombin. It is administered intravenously and has an immediate onset of action. Its half-life is 40 to 50 minutes. Argatroban is metabolized by cytochrome P450 enzymes in the liver and is excreted in the bile; therefore, dosage reduction is required for patients with hepatic insufficiency. The dosage is adjusted to maintain an aPTT of 1.5 to 3 times the baseline value. Argatroban can be used as an alternative to lepirudin for prophylaxis or treatment of patients with or at risk of developing heparin-induced thrombocytopenia.

Danaparoid. Danaparoid (ORGARAN) is a mixture of nonheparin glycosaminoglycans isolated from porcine intestinal mucosa (84% heparan sulfate, 12% dermatan sulfate, 4% chondroitin sulfate) with a mean mass of 5500 daltons. Danaparoid is approved in the United States for prophylaxis of deep venous thrombosis. It also is an effective anticoagulant for patients with heparin-induced thrombocytopenia and has a low rate of cross-reactivity with heparin in platelet-activation assays. Danaparoid mainly promotes inhibition of factor Xa by antithrombin, but it does not prolong the PT or aPTT at the recommended dosage. Danaparoid is administered subcutaneously at a fixed dose for prophylactic use and intravenously at a higher, weight-adjusted dose for full anticoagulation. Its half-life is about 24 hours. Patients with renal failure may require monitoring with an anti–factor Xa assay because of a prolonged half-life of the drug. No antidote is available. Danaparoid is no longer available in the United States.

Drotrecogin Alfa. Drotrecogin alfa (XIGRIS) is a recombinant form of human activated protein C that inhibits coagulation by proteolytic inactivation of factors Va and VIIIa. It also has antiinflammatory effects (Esmon, 2003). A 96-hour continuous infusion of drotrecogin alfa decreases mortality in adult patients who are at high risk for death from severe sepsis if given within 48 hours of the onset of organ dysfunction (e.g., shock, hypoxemia, oliguria). The major adverse effect is bleeding.

ORAL ANTICOAGULANTS

Warfarin

History. Following the report of a hemorrhagic disorder in cattle that resulted from the ingestion of spoiled sweet clover silage, Campbell and Link, in 1939, identified the hemorrhagic agent as bishydroxycoumarin (dicoumarol). In 1948, a more potent synthetic congener was introduced as an extremely effective rodenticide; the compound was named warfarin as an acronym derived from the name of the patent holder, Wisconsin Alumni Research Foundation. Warfarin’s potential as a therapeutic anticoagulant was recognized but not widely accepted, partly due to fear of unacceptable toxicity. However, in 1951, an Army inductee uneventfully survived an attempted suicide with massive doses of a preparation of warfarin intended for rodent control. Since then, these anticoagulants have become a mainstay for prevention of thromboembolic disease.

Chemistry. Numerous anticoagulants have been synthesized as derivatives of 4-hydroxycoumarin and of the related compound, indan-1,3-dione (Figure 54–5). Only the coumarin derivatives are widely used; the 4-hydroxycoumarin residue, with a nonpolar carbon substituent at the 3 position, is the minimal structural requirement for activity. This carbon is asymmetrical in warfarin (and in phenprocoumon and acenocoumarol). The enantiomers differ in anticoagulant potency, metabolism, elimination, and interactions with other drugs. Commercial preparations of these anticoagulants
Section XI / Drugs Acting on the Blood and the Blood-Forming Organs

are racemic mixtures. No advantage of administering a single enantiomer has been established.

Mechanism of Action. The oral anticoagulants are antagonists of vitamin K (see section on vitamin K, below). Coagulation factors II, VII, IX, and X and the anticoagulant proteins C and S are synthesized mainly in the liver and are biologically inactive unless 9 to 13 of the amino-terminal glutamate residues are carboxylated to form the \( \text{Ca}^{2+}\)-binding \( \gamma \)-carboxyglutamate (Gla) residues. This reaction of the decarboxy precursor protein requires carbon dioxide, molecular oxygen, and reduced vitamin K, and is catalyzed by \( \gamma \)-glutamyl carboxylase in the rough endoplasmic reticulum (Figure 54–6). Carboxylation is directly coupled to the oxidation of vitamin K to its corresponding epoxide.

Reduced vitamin K must be regenerated from the epoxide for sustained carboxylation and synthesis of biologically competent proteins. The enzyme that catalyzes this, vitamin K epoxide reductase, is inhibited by therapeutic doses of warfarin. Vitamin K (but not vitamin K epoxide) also can be converted to the corresponding hydroquinone by a second reductase, DT-diaphorase. This enzyme requires high concentrations of vitamin K and is less sensitive to coumarin drugs, which may explain why administration of sufficient vitamin K can counteract even large doses of oral anticoagulants.

Therapeutic doses of warfarin decrease by 30% to 50% the total amount of each vitamin K–dependent coagulation factor made by the liver; in addition, the secreted molecules are undercarboxylated, resulting in diminished biological activity (10% to 40% of normal). Congenital deficiencies of the procoagulant proteins to these levels cause mild bleeding disorders. Oral anticoagulants have no effect on the activity of fully carboxylated molecules in the circulation. Thus, the time required for the activity of each factor in plasma to reach a new steady state after therapy is initiated or adjusted depends on its individual

Figure 54–5. Structural formulas of the oral anticoagulants. 4-Hydroxycoumarin and indan-1,3-dione are the parent molecules from which the oral anticoagulants are derived. The asymmetrical carbon atoms in the coumarins are shown in blue.
rate of clearance. The approximate half-lives (in hours) are as follows: factor VII, 6; factor IX, 24; factor X, 36; factor II, 50; protein C, 8; and protein S, 30. Because of the long half-lives of some of the coagulation factors, in particular factor II, the full antithrombotic effect of warfarin is not achieved for several days, even though the PT may be prolonged soon after administration due to the more rapid reduction of factors with a shorter half-life, in particular factor VII. There is no obvious selectivity of the effect of warfarin on any particular vitamin K–dependent coagulation factor, although the antithrombotic benefit and the hemorrhagic risk of therapy may be correlated with the functional level of prothrombin, and to a lesser extent, factor X (Zivelin et al., 1993).

**Dosage.** The usual adult dose of warfarin (COUMADIN) is 5 mg per day for 2 to 4 days, followed by 2 to 10 mg per day as indicated by measurements of the international normalized ratio (INR), a value derived from the patient’s PT (see functional definition of INR in section on laboratory monitoring, below). A lower initial dose should be given to patients with an increased risk of bleeding, including the elderly. Warfarin usually is administered orally; age correlates with increased sensitivity to oral anticoagulants. Warfarin also can be given intravenously without modification of the dose. Intramuscular injection is not recommended because of the risk of hematoma formation.

**Absorption.** The bioavailability of warfarin is nearly complete when the drug is administered orally, intravenously, or rectally. Bleeding has occurred from repeated skin contact with solutions of warfarin used as a rodenticide. However, different commercial preparations of warfarin tablets vary in their rate of dissolution, and this causes some variation in the rate and extent of absorption. Food in the gastrointestinal tract also can decrease the rate of absorption. Warfarin usually is detectable in plasma within 1 hour of its oral administration, and concentrations peak in 2 to 8 hours.

**Distribution.** Warfarin is almost completely (99%) bound to plasma proteins, principally albumin, and the drug distributes rapidly into a volume equivalent to the albumin space (0.14 L/kg). Concentrations in fetal plasma approach the maternal values, but active warfarin is not found in milk (unlike other coumarins and indandiones).

**Biotransformation and Elimination.** Warfarin is a racemic mixture of R (weak) and S (potent) anticoagulant enantiomers. S-warfarin is transformed into inactive metabolites by CYP2C9 and R-warfarin is transformed by CYP1A2, CYP2C19 (minor pathway), and CYP3A4 (minor pathway). The inactive metabolites of warfarin are excreted in urine and stool. The average rate of clearance from plasma is 0.045 ml/min·1·kg⁻¹. The half-life ranges from 25 to 60 hours, with a mean of about 40 hours; the duration of action of warfarin is 2 to 5 days.

**Drug and Other Interactions.** The list of drugs and other factors that may affect the action of oral anticoagulants is prodigious and expanding (Hirsh et al., 2003). Any substance or condition is potentially dangerous if it alters (1) the uptake or metabolism of the oral anticoagulant or vitamin K; (2) the synthesis, function, or clearance of any factor or cell involved in hemostasis or fibrinolysis; or (3) the integrity of any epithelial surface. Patients must be educated to report the addition or deletion of any medication, including nonprescription drugs and food supplements. Some of the more commonly described factors that cause a decreased effect of oral anticoagulants include: reduced absorption of drug caused by binding to cholestyramine in the gastrointestinal tract; increased volume of distribution and a short half-life secondary to hypoproteinemia, as in nephrotic syndrome; increased metabolic clearance of drug secondary to induction of hepatic enzymes, especially CYP2C9, by barbiturates, carbamazepine, or rifampin; ingestion of large amounts of vitamin K–rich foods or supplements; and increased levels of coagulation factors during pregnancy. Hence, the PT can be shortened in any of these cases.

Frequently cited interactions that enhance the risk of hemorrhage in patients taking oral anticoagulants include decreased metabolism due to CYP2C9 inhibition by amiodarone, azole antifungals, cimetidine, clopidogrel, cotrimoxazole, disulfiram, fluoxetine, isoniazid, metronidazole, sulfinpyrazone, tolcapone, or zafirlukast, and displacement from protein binding sites caused by loop diuretics or valproate. Relative deficiency of vitamin K may result from inade-
quate diet (e.g., postoperative patients on parenteral fluids), espe-
cially when coupled with the elimination of intestinal flora by anti-
microbial agents. Gut bacteria synthesize vitamin K and thus are an
important source of this vitamin. Consequently, antibiotics can
cause excessive PT prolongation in patients adequately controlled
on warfarin. In addition to an effect on reducing intestinal flora,
cephalosporins containing heterocyclic side chains also inhibit steps
in the vitamin K cycle. Low concentrations of coagulation factors
may result from impaired hepatic function, congestive heart failure,
or hypermetabolic states, such as hyperthyroidism; generally, these
conditions increase the prolongation of the PT. Serious interactions
that do not alter the PT include inhibition of platelet function by
agents such as aspirin and gastritis or frank ulceration induced by
antiinflammatory drugs. Agents may have more than one effect; for
example, clofibrate increases the rate of turnover of coagulation fac-
tors and inhibits platelet function. Elderly patients are more sensi-
tive to oral anticoagulants.

Resistance to Warfarin. Some patients require more than 20 mg per
day of warfarin to achieve a therapeutic INR. These patients often
have excessive vitamin K intake from the diet or parenteral supple-
mentation. Noncompliance and laboratory error are other causes of
apparent warfarin resistance. A few patients with hereditary war-
farin resistance have been reported, in whom very high plasma con-
centrations of warfarin are associated with minimal depression of
vitamin K–dependent coagulation factor biosynthesis; mutations in
the vitamin K epoxide reductase gene have been identified in some
of these patients (Rost et al., 2004).

Sensitivity to Warfarin. Approximately 10% of patients require less
than 1.5 mg per day of warfarin to achieve an INR of 2 to 3. These
patients are more likely to possess one or two variant alleles of
CYP2C9, which is the major enzyme responsible for converting the
S-enantiomer warfarin to its inactive metabolites (Daly and King,
2003). In comparison with the wild-type CYP2C9*1 allele, the vari-
ant alleles CYP2C9*2 and CYP2C9*3 have been shown to inactivate
S-warfarin much less efficiently in vitro. The variant alleles are
present in 10% to 20% of Caucasians, but in <5% of African-Ameri-
cans or Asians.

Toxicities. Bleeding. Bleeding is the major toxicity of
oral anticoagulant drugs (Hirsh et al., 2003). The risk of
bleeding increases with the intensity and duration of anti-
ocagulant therapy, the use of other medications that inter-
fere with hemostasis, and the presence of a potential ana-
tomical source of bleeding. Especially serious episodes
involve sites where irreversible damage may result from
compression of vital structures (e.g., intracranial, pericar-
dial, nerve sheath, or spinal cord) or from massive internal
blood loss that may not be diagnosed rapidly (e.g., gas-
trointestinal, intraperitoneal, or retroperitoneal). Although
the reported incidence of major bleeding episodes varies
considerably, it is generally less than 5% per year in
patients treated with a target INR of 2 to 3. The risk of
intracranial hemorrhage increases dramatically with an
INR greater than 4, especially in older patients. In a large
outpatient anticoagulation clinic, the most common factors
associated with a transient elevation of the INR (>6) were
use of a new medication known to potentiate warfarin
(e.g., acetaminophen), advanced malignancy, recent diar-
rheal illness, decreased oral intake, and taking more war-
farin than prescribed (Hylek et al., 1998). Patients must be
informed of the signs and symptoms of bleeding, and lab-
oratory monitoring should be done at frequent intervals
during intercurrent illnesses or any changes of medication
or diet.

If the INR is above the therapeutic range but <5 and the
patient is not bleeding or in need of a surgical procedure,
warfarin can be discontinued temporarily and restarted at a
lower dose once the INR is within the therapeutic range
(Hirsh et al., 2003). If the INR is ≥5, vitamin K$_1$ (phytona-
dione, Mephyton, Aquamephyton) can be given orally at
a dose of 1 to 2.5 mg (for an INR between 5 and 9) or 3 to
5 mg (for an INR >9). These doses of oral vitamin K$_1$
gener-
cally cause the INR to fall substantially within 24 to 48
hours without rendering the patient resistant to further war-
farin therapy. Higher doses may be required if more rapid
reduction of the INR is necessary. The effect of vitamin K$_1$
is delayed for at least several hours, because reversal of
anticoagulation requires synthesis of fully carboxylated
coagulation factors. If immediate hemostatic competence is
necessary because of serious bleeding or profound warfarin
overdosage (INR >20), adequate concentrations of vitamin
K–dependent coagulation factors can be restored by trans-
fusion of fresh frozen plasma (10 to 20 ml per kg), supple-
mented with 10 mg of vitamin K$_1$, given by slow intra-
venous infusion. Transfusion of plasma may need to be
repeated, since the transfused factors (particularly factor
VII) are cleared from the circulation more rapidly than the
residual oral anticoagulant. Vitamin K$_1$, administered intra-
venously carries the risk of anaphylactoid reactions, and
therefore should be used cautiously. Patients who receive
high doses of vitamin K$_1$ may become unresponsive to war-
farin for several days, but heparin can be used if continued
anticoagulation is required.

Birth Defects. Administration of warfarin during pregnancy
causes birth defects and abortion. A syndrome characterized by
nasal hypoplasia and stippled epiphyseal calcifications that resemble
chondrodysplasia punctata may result from maternal ingestion of
warfarin during the first trimester. Central nervous system abnor-
malities have been reported following exposure during the second
and third trimesters. Fetal or neonatal hemorrhage and intrauterine
death may occur, even when maternal PT values are in the therapeu-
tic range. Oral anticoagulants should not be used during pregnancy,
but as indicated in the previous section, heparin can be used safely
in this circumstance.

Skin Necrosis. Warfarin-induced skin necrosis is a rare compli-
cation characterized by the appearance of skin lesions 3 to 10 days
after treatment is initiated. The lesions typically are on the extremi-
ties, but adipose tissue, the penis, and the female breast also may be involved. Lesions are characterized by widespread thrombosis of the microvasculature and can spread rapidly, sometimes becoming necrotic and requiring disfiguring débridement or occasionally amputation. Cases have been reported in subjects heterozygous for protein C or protein S deficiency. Since protein C has a shorter half-life than do the other vitamin K–dependent coagulation factors (except factor VII), its functional activity falls more rapidly in response to the initial dose of vitamin K antagonist. It has been proposed that the dermal necrosis is a manifestation of a temporal imbalance between the anticoagulant protein C and one or more of the procoagulant factors and is exaggerated in patients who are partially deficient in protein C or protein S. However, not all patients with heterozygous deficiency of protein C or protein S develop skin necrosis when treated with warfarin, and patients with normal activities of these proteins also can be affected. Morphologically similar lesions can occur in patients with vitamin K deficiency.

**Other Toxicities.** A reversible, sometimes painful, blue-tinged discoloration of the plantar surfaces and sides of the toes that blanches with pressure and fades with elevation of the legs (purple toe syndrome) may develop 3 to 8 weeks after initiation of therapy with warfarin; cholesterol emboli released from atheromatous plaques have been implicated as the cause. Other infrequent reactions include alopecia, urticaria, dermatitis, fever, nausea, diarrhea, abdominal cramps, and anorexia.

Warfarin appears to precipitate the syndromes of venous limb gangrene and multicentric skin necrosis that sometimes are associated with heparin-induced thrombocytopenia (Warkentin, 2003). Other anticoagulant agents, such as lepirudin or argatroban, should be used until the heparin-induced thrombocytopenia has resolved (see Heparin Toxicities, above).

**Clinical Use**

Oral anticoagulants are used to prevent the progression or recurrence of acute deep vein thrombosis or pulmonary embolism following an initial course of heparin. They also are effective in preventing venous thromboembolism in patients undergoing orthopedic or gynecological surgery and in preventing systemic embolization in patients with acute myocardial infarction, prosthetic heart valves, or chronic atrial fibrillation. Specific recommendations for oral anticoagulant use for these and other indications have been reviewed (The Sixth American College of Chest Physicians Guidelines for Antithrombotic Therapy for Prevention and Treatment of Thrombosis, 2001).

Prior to initiation of therapy, laboratory tests are used in conjunction with the patient’s history and physical examination to uncover hemostatic defects that might make the use of oral anticoagulant drugs more dangerous (congenital coagulation factor deficiency, thrombocytope- nia, hepatic or renal insufficiency, vascular abnormalities, etc.). Thereafter, the INR calculated from the patient’s PT is used to monitor efficacy and compliance. Therapeutic ranges for various clinical indications have been established empirically and reflect dosages that reduce the morbidity from thromboembolic disease while minimally increasing the risk of serious hemorrhage. For most indications the target INR is 2 to 3. A higher target INR (e.g., 2.5 to 3.5) generally is recommended for patients with mechanical prosthetic heart valves (Hirsh et al., 2003).

For treatment of acute venous thromboembolism, heparin usually is continued for at least 4 to 5 days after oral anticoagulation is begun and until the INR is in the therapeutic range on 2 consecutive days. This overlap allows for adequate depletion of the vitamin K–dependent coagulation factors with long half-lives, especially factor II. Daily INR measurements are indicated at the onset of therapy to guard against excessive anticoagulation in the unusually sensitive patient. The testing interval can be lengthened gradually to weekly and then to monthly for patients on long-term therapy in whom test results have been stable.

**Monitoring Anticoagulant Therapy: The INR (International Normalized Ratio).** To monitor therapy, a fasting blood sample is usually obtained 8 to 14 hours after the last dose of an oral anticoagulant, and the patient’s PT is determined along with that of a sample of normal pooled plasma. Formerly, the results were reported as a simple ratio of the two PT values. However, this ratio can vary widely depending on the thromboplastin reagent and the instrument used to initiate and detect clot formation. The PT is prolonged when the functional levels of fibrinogen, factor V, or the vitamin K–dependent factors II, VII, or X are decreased. Reduced levels of factor IX or proteins C or S have no effect on the PT. PT measurements are converted to INR measurements by the following equation:

\[
\text{INR} = \left( \frac{\text{PT}_{\text{pt}}}{\text{PT}_{\text{ref}}} \right)^{\text{ISI}}
\]

(54-1)

where INR = International Normalized Ratio

ISI = International Sensitivity Index

The ISI value, generally supplied by the manufacturer, indicates the relative sensitivity of the PT determined with a given thromboplastin to decreases in the vitamin K–dependent coagulation factors in comparison with a World Health Organization human thromboplastin standard. Reagents with lower ISI values are more sensitive to the effects of oral anticoagulants (i.e., the PT is prolonged to a greater extent in comparison with that obtained with a less sensitive reagent having a higher ISI). Ideally, the ISI value of each batch of thromboplastin should be confirmed in each clinical laboratory using a set of reference plasmas to control for local variables of sample handling and instrumentation.

The major practical consequence of standardization to the INR has been an appreciation that the commercial thromboplastins from rabbit tissue, used especially in North America, are relatively insensitive. This property led to administration of larger doses of oral anticoagulants than were considered optimal in many of the original clinical trials in which more sensitive human brain thromboplastins generally were used. Thus, the target INR of 2 to 3 corresponds to a PT ratio of 1.2 to 1.5 if rabbit thromboplastin is used or 2 to 3 if human thromboplastin is used.
The INR does not provide a reliable indication of the degree of anticoagulation in patients with the lupus anticoagulant, in whom the PT and other phospholipid-dependent coagulation tests are prolonged at baseline. In these patients, a chromogenic anti-factor Xa assay or the prothrombin-proconvertin–time assay may be used to monitor therapy (Moll and Ortel, 1997).

**Other Oral Anticoagulants**

**Phenprocoumon and Acenocoumarol.** These agents are not generally available in the United States but are prescribed in Europe and elsewhere. Phenprocoumon (MAR-CUMAR) has a longer plasma half-life (5 days) than warfarin, as well as a somewhat slower onset of action and a longer duration of action (7 to 14 days). It is administered in daily maintenance doses of 0.75 to 6 mg. By contrast, acenocoumarol (SINTHROME) has a shorter half-life (10 to 24 hours), a more rapid effect on the PT, and a shorter duration of action (2 days). The maintenance dose is 1 to 8 mg daily.

**Indandione Derivatives.** Anisindione (MIRADON) is available for clinical use in some countries. It is similar to warfarin in its kinetics of action; however, it offers no clear advantages and may have a higher frequency of untoward effects. Phenindione (DINDEVAN) still is available in some countries. Serious hypersensitivity reactions, occasionally fatal, can occur within a few weeks of starting therapy with this drug, and its use can no longer be recommended.

**Rodenticides.** Bromadiolone, brodifacoum, diphenadione, chlorophacinone, and pindone are long-acting agents (prolongation of the PT may persist for weeks). They are of interest because they sometimes are agents of accidental or intentional poisoning. In this setting, reversal of the coagulopathy can require very large doses of vitamin K (i.e., >100 mg/day) for weeks or months.

**Ximelagatran.** Ximelagatran is a novel drug that is readily absorbed after oral administration and is rapidly metabolized to melagatran, a direct thrombin inhibitor. Therefore, its onset of action is much faster than that of warfarin. Ximelagatran is administered twice daily at a fixed dose and does not appear to require coagulation monitoring. Melagatran is excreted primarily by the kidney; therefore, dosage reduction may be necessary for patients with renal failure. Ximelagatran has been used successfully in clinical trials for prevention of venous thromboembolism (Francis et al., 2003; Schubman et al., 2003). Ximelagatran causes elevation of hepatic transaminases in about 6% of patients, but this side effect usually is asymptomatic and often is transient. The drug has not yet been approved for use in the United States.

**FIBRINOLYTIC DRUGS**

The fibrinolytic pathway is summarized by Figure 54–3. The action of fibrinolytic agents is best understood in conjunction with an understanding of the characteristics of the physiologic components.

**Plasminogen.** Plasminogen is a single-chain glycoprotein that contains 791 amino acid residues; it is converted to an active protease by cleavage at arginine 560. High-affinity binding sites mediate the binding of plasminogen (or plasmin) to carboxyl-terminal lysine residues in partially degraded fibrin; this enhances fibrinolysis. A plasma carboxypeptidase termed thrombin-activatable fibrinolysis inhibitor (TAFI) can remove these lysine residues and thereby attenuate fibrinolysis. The lysine binding sites are in the amino-terminal “kringle” domain of plasminogen between amino acids 80 and 165, and they also promote formation of complexes of plasmin with α₂-antiplasmin, the major physiological plasmin inhibitor. Plasminogen concentrations in human plasma average 2 μM. A degraded form of plasmin termed lys-plasminogen binds to fibrin much more rapidly than does intact plasminogen.

**α₂-Antiplasmin.** α₂-Antiplasmin is a glycoprotein of 452 amino acid residues. It forms a stable complex with plasmin, thereby inactivating it. Plasma concentrations of α₂-antiplasmin (1 μM) are sufficient to inhibit about 50% of potential plasmin. When massive activation of plasminogen occurs, the inhibitor is depleted, and free plasmin causes a “systemic lytic state,” in which hemostasis is impaired. In this state, fibrinogen is destroyed and fibrinogen degradation products impair formation of fibrin and therefore increase bleeding from wounds. α₂-Antiplasmin inactivates plasmin nearly instantaneously, as long as the lysine binding sites on plasmin are unoccupied by fibrin or other antagonists, such as aminocaproic acid (see below).

**Streptokinase.** Streptokinase (STREPTASE) is a 47,000-dalton protein produced by β-hemolytic streptococci. It has no intrinsic enzymatic activity, but it forms a stable, noncovalent 1:1 complex with plasminogen. This produces a conformational change that exposes the active site on plasminogen that cleaves arginine 560 on free plasminogen to form free plasmin. Streptokinase is rarely used clinically for fibrinolysis since the advent of newer agents.

**Tissue Plasminogen Activator (t-PA).** t-PA is a serine protease that contains 527 amino acid residues. It is a poor plasminogen activator in the absence of fibrin (Lijnen and Collen, 2001). t-PA binds to fibrin via lysine binding sites at its amino terminus and activates bound plasminogen several hundredfold more rapidly than it.
activates plasminogen in the circulation. The lysine binding sites on t-PA are in a “finger” domain that is homologous to similar sites on fibronectin. Under physiological conditions (t-PA concentrations of 5 to 10 ng/ml), the specificity of t-PA for fibrin limits systemic formation of plasmin and induction of a systemic lytic state. During therapeutic infusions of t-PA, however, concentrations rise to 300 to 3000 ng/ml. Clearance of t-PA primarily occurs by hepatic metabolism, and its half-life is 5 to 10 minutes. t-PA is effective in lysing thrombi during treatment of acute myocardial infarction. t-PA (alteplase, ACTIVASE) is produced by recombinant DNA technology. The currently recommended (“accelerated”) regimen for coronary thrombolysis is a 15-mg intravenous bolus, followed by 0.75 mg/kg of body weight over 30 minutes (not to exceed 50 mg) and 0.5 mg/kg (up to 35 mg accumulated dose) over the following hour. Recombinant mutant variants of t-PA now are available (reteplase, RETAVASE and tenecteplase, TNKASE). They differ from native t-PA by having increased plasma half-lives that allow convenient bolus dosing (2 doses of 15 milliunits given 30 minutes apart). They also are relatively resistant to inhibition by plasma activator inhibitor-1. Despite these apparent advantages, these agents are similar to t-PA in efficacy and toxicity (GUSTO III Investigators, 1997).

Hemorrhagic Toxicity of Thrombolytic Therapy. The major toxicity of all thrombolytic agents is hemorrhage, which results from two factors: (1) the lysis of fibrin in “physiological thrombi” at sites of vascular injury; and (2) a systemic lytic state that results from systemic formation of plasmin, which produces fibrinogenolysis and destruction of other coagulation factors (especially factors V and VIII). The actual toxicity of streptokinase and t-PA is difficult to assess. In early clinical trials, many bleeding episodes resulted from the extensive invasive monitoring of therapy that was required by the protocol. Many studies to evaluate thrombolyis involved concurrent systemic heparinization, which also contributes to bleeding complications. Analysis of more recent clinical trials suggests that heparin confers no benefit in patients receiving fibrinolytic therapy plus aspirin (Collins et al., 1997; Zijlstra et al., 1999).

The contraindications to fibrinolytic therapy are listed in Table 54–1. Patients with these conditions should not receive such treatment, and invasive procedures (e.g., cardiac catheterization and arterial blood gases) should be avoided. If heparin is used concurrently with either streptokinase or t-PA, serious hemorrhage will occur in 2% to 4% of patients. Intracranial hemorrhage is by far the most serious problem. Hemorrhagic stroke occurs with all regimens and is more common when heparin is used. In several large studies, t-PA was associated with an excess of hemorrhagic strokes of about 0.3% of treated patients. Based on the data of three large trials involving almost 100,000 patients, the efficacies of t-PA and streptokinase in treating myocardial infarction are essentially identical. Both agents reduce death and reinfarction by about 30% in regimens containing aspirin (Zijlstra et al., 1999). Recent studies suggest that angioplasty with or without stent placement, when feasible, is superior to thrombolytic therapy, although direct comparisons using otherwise identical regimens have not been performed (Armstrong et al., 2003; Andersen et al., 2003).

### Inhibition of Fibrinolysis

**Aminocaproic Acid.** Aminocaproic acid (AMICAR) is a lysine analog that competes for lysine binding sites on plasminogen and plasmin, thus blocking the interaction of plasmin with fibrin. Aminocaproic acid is thereby a potent inhibitor of fibrinolysis and can reverse states that are associated with excessive fibrinolysis. The main problem with its use is that thrombi that form during treatment with the drug are not lysed. For example, in patients with hematuria, ureteral obstruction by clots may lead to renal failure after treatment with aminocaproic acid. Aminocaproic acid has been used to reduce bleeding after prostatic surgery or after tooth extractions in hemophilias. Use of aminocaproic acid to treat a variety of other bleeding disorders has been unsuccessful, either because of limited benefit or because of thrombosis (e.g., after subarachnoid hemorrhage). Aminocaproic acid is absorbed rapidly after oral administration, and 50% is excreted unchanged in the urine within 12 hours. For intravenous use, a loading dose of 4 to 5 g is given over 1 hour, followed by an infusion of 1 g per hour until bleeding is controlled. No more than 30 g should be given in a 24-hour period. Rarely, the drug causes myopathy and muscle necrosis.

### Table 54–1

**Contraindications to Thrombolytic Therapy**

| 1. Surgery within 10 days, including organ biopsy, puncture of noncompressible vessels, serious trauma, cardiopulmonary resuscitation |
| 2. Serious gastrointestinal bleeding within 3 months |
| 3. History of hypertension (diastolic pressure >110 mm Hg) |
| 4. Active bleeding or hemorrhagic disorder |
| 5. Previous cerebrovascular accident or active intracranial process |
| 6. Aortic dissection |
| 7. Acute pericarditis |

**ANTIPLATELET DRUGS**

Platelets provide the initial hemostatic plug at sites of vascular injury. They also participate in pathological throm-
bosSES that lead to myocardial infarction, stroke, and peripheral vascular thromboses. Potent inhibitors of platelet function have been developed in recent years. These drugs act by discrete mechanisms, and thus in combination their effects are additive or even synergistic. Their availability has led to a revolution in cardiovascular medicine, whereby angioplasty and vascular stenting of lesions now is feasible with low rates of restenosis and thrombosis when effective platelet inhibition is employed.

**Aspirin.** Processes including thrombosis, inflammation, wound healing, and allergy are modulated by oxygenated metabolites of arachidonate and related polyunsaturated fatty acids that are collectively termed eicosanoids. Interference with the synthesis of eicosanoids is the basis for the effects of many therapeutic agents, including analgesics, antiinflammatory drugs, and antithrombotic agents (see Chapters 25 and 26).

In platelets, the major cyclooxygenase product is thromboxane A₂, a labile inducer of platelet aggregation and a potent vasoconstrictor. Aspirin blocks production of thromboxane A₂ by acetylat-
ing a serine residue near the active site of platelet cyclooxygenase (COX-1), the enzyme that produces the cyclic endoperoxide precursor of thromboxane A₂. Since platelets do not synthesize new proteins, the action of aspirin on platelet cyclooxygenase is permanent, lasting for the life of the platelet (7 to 10 days). Thus, repeated doses of aspirin produce a cumulative effect on platelet function. Complete inactivation of platelet COX-1 is achieved when 160 mg of aspirin is taken daily. Therefore, aspirin is maximally effective as an antithrombotic agent at doses much lower than those required for other actions of the drug. Numerous trials indicate that aspirin, when used as an antithrombotic drug, is maximally effective at doses of 50 to 320 mg per day (Antithrombotic Trialists’ Collaboration, 2002; Patrono et al., 2004). Higher doses do not improve efficacy; moreover, they potentially are less efficacious because of inhibition of prostacyclin production, which can be largely spared by using lower doses of aspirin. Higher doses also increase toxicity, especially bleeding.

Other NSAIDs that are reversible inhibitors of COX-1 have not been shown to have antithrombotic efficacy and in fact may even interfere with low-dose aspirin regimens.

**Dipyridamole.** Dipyridamole (PERSANTINE) is a vasodilator that, in combination with warfarin, inhibits embolization from prosthetic heart valves. Dipyridamole has little or no benefit as an antithrombotic drug. In trials in which a regimen of dipyridamole plus aspirin was compared with aspirin alone, dipyridamole provided no additional beneficial effect (Antithrombotic Trialists’ Collaboration, 2002). A single study suggests that dipyridamole plus aspirin reduces strokes in patients with prior strokes or transient ischemic attack (Dienet et al., 1996). A formulation containing 200 mg of dipyridamole, in an extended-release form, and 25 mg of aspirin (AGGRENOX) is available. Dipyridamole interferes with platelet function by increasing the cellular concentration of adenosine 3′,5′-monophosphate (cyclic AMP). This effect is mediated by inhibition of cyclic nucleotide phosphodiesterase and/or by blockade of uptake of adenosine, which acts at adenosine A₁ receptors to stimulate platelet adenylyl cyclase. The only current recommended use of dipyridamole is in combination with warfarin for postoperative primary prophylaxis of thromboemboli in patients with prosthetic heart valves.

**Ticlopidine.** Purinergic receptors respond to extracellular nucleotides as agonists. Platelets contain two purinergic receptors, P₂Y₁ and P₂Y₁₂; both are GPCRs for ADP. The ADP-activated platelet P₂Y₁ receptor couples to the Gq-PLC-IP₃-Ca²⁺ pathway and induces a shape change and aggregation. The P₂Y₁₂ receptor couples to Gi and, when activated by ADP, inhibits adenylyl cyclase, resulting in lower levels of cyclic AMP and thereby less cyclic AMP–dependent inhibition of platelet activation. Based on pharmacological studies, it appears that both receptors must be stimulated to result in platelet activation (Jin and Kunapuli, 1998), and inhibition of either receptor is sufficient to block platelet activation. Ticlopidine (TICLID) is a thienopyridine (Figure 54–7) that inhibits the P₂Y₁₂ receptor. Ticlopidine is a prodrug that requires conversion to the active thiol metabolite by a hepatic cytochrome P450 enzyme (Savi et al., 2000). It is rapidly absorbed and highly bioavailable. It permanently inhibits the P₂Y₁₂ receptor by forming a disulfide bridge between the thiol on the drug and a free cysteine residue in the extracellular region of the receptor and thus has a prolonged effect. Like aspirin it has a short half-life with a long duration of action, which has been termed “hit-and-run pharmacology” (Hollopeter et al., 2001). Maximal inhibition of platelet aggregation is not seen until 8 to 11 days after starting therapy. Thus, “loading doses” of 500 mg sometimes are given to achieve a more rapid onset of action. The usual dose is 250 mg twice per day. Inhibition of platelet aggregation persists for a few days after the drug is stopped.

**Adverse Effects.** The most common side effects are nausea, vomiting, and diarrhea. The most serious is severe neutropenia (absolute neutrophil count [ANC] <1500/μL), which occurred in 2.4% of stroke patients given the drug during premarketing clinical trials. Fatal agranulocytosis with thrombopenia has occurred within the first 3 months of therapy; therefore, frequent blood counts should be obtained during the first few months of therapy, with immediate dis-

---

**Figure 54–7.** Structure of ticlopidine and clopidogrel.

![Structure of ticlopidine and clopidogrel](image-url)
continuation of therapy should cell counts decline. Platelet counts also should be monitored, as thrombocytopenia has been reported. Rare cases of thrombotic thrombocytopenic purpura-hemolytic uremic syndrome (TTP-HUS) have been associated with ticlopidine with a reported incidence of 1 in 1600 to 4800 patients when the drug is used after cardiac stenting; the mortality associated with these cases is reported to be as high as 18% to 57% (Bennett et al., 1998; Bennett et al., 1999). Remission of TTP has been reported when the drug is stopped (Quinn and Fitzgerald, 1999).

**Therapeutic Uses.** Ticlopidine has been shown to prevent cerebrovascular events in secondary prevention of stroke and is at least as good as aspirin in this regard (Patrono et al., 1998). It also reduces cardiac events in patients with unstable angina; however, its only FDA-approved indication is to reduce the risk of thrombotic stroke in patients who have experienced stroke precursors, and in patients who have had a completed thrombotic stroke. Since ticlopidine has a mechanism of action distinct from that of aspirin, combining the drugs might be expected to provide additive or even synergistic effects. This appears to be the case, and the combination has been used in patients undergoing angioplasty and stenting for coronary artery disease, with a very low frequency of stent thrombosis occurring over a short, 30-day follow-up (<1%) (Leon et al., 1998). As ticlopidine is associated with life-threatening blood dyscrasias and a relatively high rate of TTP, it is generally reserved for patients who are intolerant or allergic to aspirin or who have failed aspirin therapy.

**Clopidogrel.** The thienopyridine clopidogrel (PLAVIX) is closely related to ticlopidine (Figure 54–7) and appears to have a slightly more favorable toxicity profile with less frequent thrombocytopenia and leukopenia, although thrombotic thrombocytopenic purpura has been reported (Bennett et al., 2000). Clopidogrel is a prodrug with a slow onset of action. The usual dose is 75 mg per day with or without an initial loading dose of 300 mg. The drug is equivalent to aspirin in the secondary prevention of stroke, and in combination with aspirin it appears to be as effective as ticlopidine and aspirin. It is used with aspirin after angioplasty and should be continued for at least 1 year (Steinhubl et al., 2002). In one study, the combination of clopidogrel and aspirin clearly was superior to aspirin alone; this finding suggests that the actions of the two drugs are synergistic, as might be expected from their distinct mechanisms of action (Yusuf et al., 2001). The FDA-approved indications for clopidogrel are to reduce the rate of stroke, MI, and death in patients with recent myocardial infarction or stroke, established peripheral arterial disease, or acute coronary syndrome.

**Glycoprotein IIb/IIIa Inhibitors.** Glycoprotein IIb/IIIa is a platelet-surface integrin which, by the integrin nomenclature, is designated α<sub>IIb</sub>β<sub>3</sub>. This dimeric glycoprotein is a receptor for fibrinogen and von Willebrand factor, which anchor platelets to foreign surfaces and to each other, thereby mediating aggregation. The integrin heterodimer/receptor is activated by platelet agonists such as thrombin, collagen, or thromboxane A<sub>2</sub> to develop binding sites for its ligands, which do not bind to resting platelets. Inhibition of binding to this receptor blocks platelet aggregation induced by any agonist. Thus, inhibitors of this receptor are potent antiplatelet agents that act by a mechanism distinct from that of aspirin or the thienopyridine platelet inhibitors. Three agents are approved for use at present, with others under development.

**Abciximab.** Abciximab (REOPRO) is the Fab fragment of a humanized monoclonal antibody directed against the α<sub>IIb</sub>β<sub>3</sub> receptor. It also binds to the vitronectin receptor on platelets, vascular endothelial cells, and smooth muscle cells. The antibody is used in conjunction with percutaneous angioplasty for coronary thromboses, and when used in conjunction with aspirin and heparin, has been shown to be quite effective in preventing restenosis, recurrent myocardial infarction, and death. The reduction in total events is about 50% in various large trials (Scarborough et al., 1999). The unbound antibody is cleared from the circulation with a half-life of about 30 minutes, but antibody remains bound to the α<sub>IIb</sub>β<sub>3</sub> receptor and inhibits platelet aggregation as measured in vitro for 18 to 24 hours after infusion is stopped. It is given as a 0.25-mg/kg bolus followed by 0.125 μg/kg per minute for 12 hours or longer.

**Adverse Effects.** The major side effect of abciximab is bleeding, and the contraindications to its use are similar to those for fibrinolytic agents listed in Table 54–1. The frequency of major hemorrhage in clinical trials varies from 1% to 10%, depending on the intensity of anticoagulation with heparin. Thrombocytopenia of less than 50,000 μL is seen in about 2% of patients and may be due to development of neo-epitopes induced by bound antibody. Since the duration of action is long, if major bleeding or emergent surgery occurs, platelet transfusions can reverse the aggregation defect, because free antibody concentrations fall rapidly after cessation of infusion. Readministration of antibody has been performed in a small number of patients without evidence of decreased efficacy or allergic reactions. The expense of the antibody limits its use.

**Eptifibatide.** Eptifibatide (INTEGRILIN) is a cyclic peptide inhibitor of the fibrinogen binding site on α<sub>IIb</sub>β<sub>3</sub>. It blocks platelet aggregation in vitro after intravenous infusion into patients. Eptifibatide is given as a bolus of 180 μg/kg followed by 2 μg/kg per minute for up to 96 hours. It is used to treat acute coronary syndrome and for angioplasty coronary interventions. In the latter case, myocardial infarction and death have been reduced by about 20%. Although the drug has not been compared directly to abciximab, it appears that its benefit is somewhat less than that obtained with the antibody, perhaps because eptifibatide is specific for α<sub>IIb</sub>β<sub>3</sub> and does not react with the vitronectin receptor. The duration of action of the drug is relatively short and platelet aggregation is restored within 6 to 12 hours after
cessation of infusion. Eptifibatide generally is administered in conjunction with aspirin and heparin.

**Adverse Effects.** The major side effect is bleeding, as is the case with abciximab. The frequency of major bleeding in trials was about 10%, compared with about 9% in a placebo group, which included heparin. Thrombocytopenia has been seen in 0.5% to 1% of patients.

**Tirofiban.** Tirofiban (AGGRASTAT) is a nonpeptide, small-molecule inhibitor of $\alpha_{\text{IIb}}\beta_3$ that appears to have a similar mechanism of action as eptifibatide. Tirofiban has a short duration of action and has efficacy in non-Q-wave myocardial infarction and unstable angina. Reductions in death and myocardial infarction have been about 20% compared to placebo, results similar to those with eptifibatide. Side effects also are similar to those of eptifibatide. The agent is specific to $\alpha_{\text{IIb}}\beta_3$ and does not react with the vitronectin receptor. Meta-analysis of trials using $\alpha_{\text{IIb}}\beta_3$ inhibitors suggests that their value in antiplatelet therapy after acute myocardial infarction is limited (Boersma et al., 2002). Tirofiban is administered intravenously at an initial rate of 0.4 $\mu$g/kg per minute for 30 minutes, and then continued at 0.1 mg/kg per minute for 12 to 24 hours after angioplasty or atherectomy. It is used in conjunction with heparin.

---

**THE ROLE OF VITAMIN K**

Vitamin K is essential in both mammals and in photosynthetic organisms. In certain photosynthetic bacteria, vitamin K is a cofactor in the photosynthetic electron-transport system; in green plants, vitamin K$_1$ is a component of photosystem I, the membrane-bound macromolecular light-sensitive complex. Green plants are a nutritional source of vitamin K for humans, in whom vitamin K is an essential cofactor in the $\gamma$-carboxylation of multiple glutamate (Glu) residues of several clotting factors and anticoagulant proteins. The vitamin K–dependent formation of $\gamma$-carboxy-glutamate (Gla) residues permits the appropriate interactions of clotting factors, Ca$^{2+}$, and membrane phospholipids and modulator proteins (Figures 54–1, 54–2, and 54–3). Oral anticoagulant drugs (coumadin derivatives, Figure 54–5) block Gla formation and thereby inhibit clotting; excess vitamin K$_1$ can reverse the effects of these oral anticoagulants.

**History.** In 1929, Dam observed that chickens fed inadequate diets developed a deficiency disease characterized by spontaneous bleeding and reduced prothrombin in the blood. Subsequently, Dam and coworkers (1935, 1936) found that the condition could be alleviated rapidly by feeding an unidentified fat-soluble substance, named vitamin K (Koagulation vitamin) by Dam. Independently, Almqquist and Stokstad (1935) performed similar work. Quick and coworkers (1935) observed a coagulation defect in jaundiced individuals that was due to a decrease in the plasma concentration of prothrombin. In the same year, Hawkins and Whipple reported that animals with biliary fistulas were likely to develop excessive bleeding. Subsequently, Hawkins and Brinkhous (1936) showed that this, too, was due to a deficiency in prothrombin and that the condition could be relieved by the feeding of bile salts. The culmination of these studies came with the demonstration by Butt and coworkers (1938) and Warner and associates (1938) that combination therapy with vitamin K and bile salts was effective in the treatment of the hemorrhagic diathesis of jaundice. Thus, the relationship between vitamin K, adequate hepatic function, and the physiological mechanisms operating in the normal clotting of blood was established.

**Chemistry and Occurrence.** Vitamin K activity is associated with at least two distinct natural substances, designated as vitamin K$_1$ and vitamin K$_2$. Vitamin K$_1$, or phylloquinone (phytonadione), is 2-methyl-3-phytyl-1,4-naphthoquinone; it is found in plants and is the only natural vitamin K available for therapeutic use. Vitamin K$_2$ is actually a series of compounds (the menaquinones) in which the phytyl side chain of phylloquinone has been replaced by a side chain built up of 2 to 13 prenyl units. Considerable synthesis of menaquinones occurs in gram-positive bacteria; indeed, intestinal flora synthesize the large amounts of vitamin K contained in human and animal feces (Bentley and Meganathan, 1982). In animals, menaquinone-4 can be synthesized from the vitamin precursor menadione (2-methyl-1,4-naphthoquinone), or vitamin K$_3$. Depending on the bioassay system used, menadione is at least as active on a molar basis as phylloquinone. The structures of phylloquinone and the menaquinone series are:

![Phylloquinone](image1)

![Menaquinone](image2)

**Physiological Functions and Pharmacological Actions.** In normal animals and humans, phylloquinone and menaquinones are virtually devoid of pharmacodynamic activity. However, in subjects deficient in vitamin K, the vitamin performs its normal physiological function: to promote the biosynthesis of the $\gamma$-carboxy-glutamate (Gla) forms of factors II (prothrombin), VII, IX, and X, anticoagulant proteins C and S, protein Z (a cofactor to the inhibitor of Xa), the bone Gla protein osteocalcin, matrix Gla protein, growth arrest–specific protein 6 (Gas6), and four transmembrane monospan of unknown function (Brown et al., 2000; Broze, 2001; Kulman et al., 2001).
Figure 54–6 summarizes the coupling of the vitamin K cycle with glutamate carboxylation. Vitamin K, as KH₂, the reduced vitamin K hydroquinone, is an essential cofactor for γ-glutamyl carboxylase (Rishavy et al., 2004). Using KH₂, O₂, CO₂, and the glutamate-containing substrate, the enzyme forms a γ-carboxy-glutamyl protein (Gla protein) and concomitantly, the 2,3-epoxide of vitamin K. A coumarin-sensitive 2,3-epoxide reductase regenerates KH₂. The γ-glutamyl carboxylase and epoxide reductase are integral membrane proteins of the endoplasmic reticulum and seem to function as a multicomponent system that may include the chaperone protein, calumenin, which reportedly inhibits γ-carboxylation (Wajih et al., 2004). Two natural mutations in γ-glutamyl carboxylase lead to bleeding disorders (Mutucumara et al., 2003). With respect to proteins affecting blood coagulation, these reactions occur in the liver, but γ-carboxylation of glutamate also occurs in lung, bone, and other cell types. Vitamin K epoxide reductase recently has been cloned (Rost et al., 2004; Li et al., 2004).

The γ-carboxylation reaction is aided by the grouping of glutamate residues in a Gla domain (about 45 residues in clotting factors) near the amino terminus of the nascent substrate protein; the reaction is guided by an adjacent propeptide (18 to 28 amino acids) that interacts with the carboxylase. In the case of the vitamin K–dependent clotting proteins, the Gla domain is about 45 residues long, and 9 to 13 glutamates are γ-carboxylated in the primary sequence of the Gla domain, C-terminal to the propeptide. The Gla→Glu conversion enables the factors to interact well with Ca²⁺ and thence with phospholipids of platelet membranes, positioning the factors in the proper conformations for interacting with their substrates and modulators. In the absence of vitamin K (or in the presence of a coumarin derivative), newly synthesized vitamin K–dependent clotting factors lack Gla residues and are inactive because the molecular conformations needed for their interactions are not achieved.

**Human Requirements.** The human requirement for vitamin K has not been defined precisely. In patients made vitamin K–deficient by a starvation diet and antibiotic therapy for 3 to 4 weeks, the minimum daily requirement is estimated to be 0.03 μg/kg of body weight (Frick, 1967) and possibly as high as 1 μg/kg, which is approximately the recommended intake for adults (70 μg/day).

**Symptoms of Deficiency.** The chief clinical manifestation of vitamin K deficiency is an increased tendency to bleed (see discussion of hypoprothrombinemia in section on oral anticoagulants, above). Ecchymoses, epistaxis, hematuria, gastrointestinal bleeding, and postoperative hemorrhage are common; intracranial hemorrhage may occur. Hemoptysis is uncommon. The discovery of a vitamin K–dependent protein in bone suggests that the fetal bone abnormalities associated with the administration of oral anticoagulants during the first trimester of pregnancy (“fetal warfarin syndrome”) may be related to a deficiency of the vitamin.

Considerable evidence indicates a role for vitamin K in adult skeletal maintenance and osteoporosis. Low concentrations of the vitamin are associated with deficits in bone mineral density and fractures; vitamin K supplementation increases the carboxylation state of osteocalcin and also improves bone mineral density, but the relationship of these two effects is unclear (Feskanich et al., 1999). Bone mineral density in adults is not changed by therapeutic use of oral anticoagulants (Rosen et al., 1993), but new bone formation may be affected.

**Toxicity.** Phylloquinone and the menaquinones are nontoxic to animals, even when given at 500 times the RDA. However, menadione and its derivatives (synthetic forms of vitamin K) have been implicated in producing hemolytic anemia and kernicterus in neonates, especially in premature infants (Diploma and Ritchie, 1997). For this reason menadione should not be used as a therapeutic form of vitamin K.

**Absorption, Fate, and Excretion.** The mechanism of intestinal absorption of compounds with vitamin K activity varies with their solubility. In the presence of bile salts, phylloquinone and the menaquinones are adequately absorbed from the intestine, almost entirely by way of the lymph. Phylloquinone is absorbed by an energy-dependent, saturable process in proximal portions of the small intestine; menaquinones are absorbed by diffusion in the distal portions of the small intestine and in the colon. Following absorption, phylloquinone is incorporated into chylomicrons in close association with triglycerides and lipoproteins. In a large survey, plasma phylloquinone and triglyceride concentration were well correlated (Sadowski et al., 1989). The extremely low phylloquinone levels in newborns may be partly related to very low plasma lipoprotein concentrations at birth and may lead to an underestimation of vitamin K tissue stores. After absorption, phylloquinone and menaquinones are concentrated in the liver, but the concentration of phylloquinone declines rapidly. Menaquinones, produced in the lower bowel, are less biologically active than phylloquinone due to their long side chain. Very little vitamin K accumulates in other tissues.

Phylloquinone is metabolized rapidly to more polar metabolites, which are excreted in the bile and urine. The major urinary metabolites result from shortening of the side chain to five or seven carbon atoms, yielding carboxylic acids that are conjugated with glucuronate prior to excretion.

Apparently, there is only modest storage of vitamin K in the body. Under circumstances in which lack of bile interferes with absorption of vitamin K, hypoprothrombinemia develops slowly over a period of several weeks.

**Therapeutic Uses.** Vitamin K is used therapeutically to correct the bleeding tendency or hemorrhage associated with its deficiency. Vitamin K deficiency can result from inadequate intake, absorption, or utilization of the vitamin, or as a consequence of the action of a vitamin K antagonist.

Phylloquinone (AQUAMEPHYTON, KONAKION, MEPHYTON) is available as tablets and in a dispersion with buffered polysorbate and propylene glycol (KONAKION) or polyoxyethylated fatty acid derivatives and dextrose (AQUAMEPHYTON). KONAKION is administered only intramuscularly. AQUAMEPHYTON may be given by any parenteral route; however, subcutaneous or intramuscular injection is preferred because severe reactions resembling anaphylaxis have followed its intravenous administration.

**Inadequate Intake.** After infancy, hypoprothrombinemia due to dietary deficiency of vitamin K is extremely rare: The vitamin is present in many foods and also is synthesized by intestinal bacteria. Occasionally, the use of a broad-spectrum antibiotic may itself produce a hypoprothrombinemia that responds readily to small doses of vitamin K and reestablishment of normal bowel flora. Hypoprothrombinemia can occur in patients receiving prolonged intravenous alimentation. It is recommended to give 1 mg of phylloquinone per week (the equivalent of about 150 μg per day) to patients on total parenteral nutrition.

**Hypoprothrombinemia of the Newborn.** Healthy newborn infants show decreased plasma concentrations of vitamin K–dependent clotting factors for a few days after birth, the time required to obtain an adequate dietary intake of the vitamin and to establish a normal
inadequate absorption of bile. Thus, hypoprothrombinemia may be associated with poor response to vitamin K may be poor.

Hemorrhagic disease of the newborn has been associated with breast-feeding; human milk has low concentrations of vitamin K (Haroon et al., 1982). In addition, the intestinal flora of breast-fed infants may lack microorganisms that synthesize the vitamin (Keenan et al., 1971). Commercial infant formulas are supplemented with vitamin K.

In the neonate with hemorrhagic disease of the newborn, the administration of vitamin K raises the concentration of these clotting factors to the level normal for the newborn infant and controls the bleeding tendency within about 6 hours. The routine administration of 1 mg phylloquinone intramuscularly at birth is required by law in the United States. This dose may have to be increased or repeated if the mother has received anticoagulant or anticonvulsant drug therapy or if the infant develops bleeding tendencies. Alternatively, some clinicians treat mothers who are receiving anticonvulsants with oral vitamin K prior to delivery (20 mg per day for 2 weeks) (Vert and Deblay, 1982).

**Inadequate Absorption.** Vitamin K is poorly absorbed in the absence of bile. Thus, hypoprothrombinemia may be associated with either intrahepatic or extrahepatic biliary obstruction or a severe defect in the intestinal absorption of fat from other causes.

**Biliary Obstruction or Fistula.** Bleeding that accompanies obstructive jaundice or biliary fistula responds promptly to the administration of vitamin K. Oral phylloquinone administered with bile salts is both safe and effective and should be used in the care of the jaundiced patient, both preoperatively and postoperatively. In the absence of significant hepatocellular disease, the prothrombin activity of the blood rapidly returns to normal. If oral administration is not feasible, a parenteral preparation should be used. The usual dose is 10 mg of vitamin K per day.

The treatment of a patient during hemorrhage requires transfusion of fresh blood or reconstituted fresh plasma. Vitamin K also should be given. If biliary obstruction has caused hepatic injury, the response to vitamin K may be poor.

**Malabsorption Syndromes.** Among the disorders that result in inadequate absorption of vitamin K from the intestinal tract are: cystic fibrosis, sprue, Crohn’s disease and enterocolitis, ulcerative colitis, dysentery, and extensive resection of bowel. Since drugs that greatly reduce the bacterial population of the bowel are used frequently in many of these disorders, the availability of the vitamin may be further reduced. Moreover, dietary restrictions also may limit the availability of the vitamin. For immediate correction of the deficiency, parenteral therapy should be used.

**Inadequate Utilization.** Hepatocellular disease may be accompanied or followed by hypoprothrombinemia. Hepatocellular damage also may be secondary to long-lasting biliary obstruction. In these conditions, the damaged parenchymal cells may not be able to produce the vitamin K-dependent clotting factors, even if excess vitamin is available. However, if an inadequate secretion of bile salts is contributing to the syndrome, some benefit may be obtained from the parenteral administration of 10 mg of phylloquinone daily. Paradoxically, the administration of large doses of vitamin K or its analogs in an attempt to correct the hypoprothrombinemia associated with severe hepatitis or cirrhosis actually may result in a further depression of the concentration of prothrombin. The mechanism for this action is unknown.

**Drug-Induced Hypoprothrombinemia.** Anticoagulant drugs such as warfarin and its congeners act as competitive antagonists of vitamin K and interfere with the hepatic biosynthesis of Gla-containing clotting factors. The treatment of bleeding caused by oral anticoagulants is discussed above. Vitamin K may be of help in combating the bleeding and hypoprothrombinemia that follow the bite of the tropical American pit viper or other species whose venom destroys or inactivates prothrombin.

---

**CLINICAL SUMMARY**

A variety of anticoagulant, thrombolytic, and antiplatelet agents are available and are among the most widely used drugs. Heparin and its low-molecular-weight derivatives are commonly used to treat venous thromboembolism, unstable angina, and acute myocardial infarction; these agents are also used to prevent thrombosis during and after coronary angioplasty, during surgery requiring cardiopulmonary bypass, and in certain other high-risk patients. The major toxicities of heparin are bleeding and the syndrome of heparin-induced thrombocytopenia, which often precipitates venous or arterial thrombosis. Direct thrombin inhibitors, such as lepirudin or argatroban, are indicated for patients with heparin-induced thrombocytopenia. Warfarin and other vitamin K antagonists are used to prevent the progression or recurrence of acute venous thromboembolism following an initial course of heparin. They also decrease the incidence of systemic embolization in patients with prosthetic heart valves or after acute myocardial infarction. Warfarin causes major bleeding in a significant number of patients and produces fetal abnormalities when given during pregnancy. Fibrinolytic agents, such as t-PA or streptokinase, reduce the mortality of acute myocardial infarction and are used in situations in which angioplasty is not readily available. Antiplatelet agents, including aspirin, ticlopidine, clopidogrel, and glycoprotein IIb/IIIa inhibitors, are often used to prevent restenosis and thrombosis following coronary angioplasty and in the secondary prophylaxis of myocardial infarction and stroke. Bleeding is the major toxicity of the antiplatelet agents, but thrombocytopenia and neutropenia can also occur. New agents, such as the oral direct thrombin inhibitor ximelagatran, may prove to be more effective, less toxic, and easier to use than currently available drugs.

PITUITARY HORMONES AND THEIR HYPOTHALAMIC RELEASING HORMONES

Keith L. Parker and Bernard P. Schimmer

The peptide hormones of the anterior pituitary are essential for the regulation of growth and development, reproduction, responses to stress, and intermediary metabolism. Their synthesis and secretion are controlled by hypothalamic hormones and by hormones from the peripheral endocrine organs. A large number of disease states, as well as a diverse group of drugs, also affect their secretion. The complex interactions among the hypothalamus, pituitary, and peripheral endocrine glands provide elegant examples of integrated feedback regulation. Clinically, an improved understanding of the mechanisms that underlie these interactions provides the rationale for diagnosing and treating endocrine disorders and for predicting certain side effects of drugs that affect the endocrine system. Moreover, the elucidation of the structures of the anterior pituitary hormones and hypothalamic-releasing hormones makes it possible to produce synthetic peptide agonists and antagonists that have important diagnostic and therapeutic applications.

The anterior pituitary hormones can be classified into three different groups based on their structural features (Table 55–1). Growth hormone (GH) and prolactin (PRL) belong to the somatotropic family of hormones, which in humans also includes placental lactogen. The glycoprotein hormones—thyroid-stimulating hormone (TSH, also called thyrotropin), luteinizing hormone (LH), and follicle-stimulating hormone (FSH)—share a common α-subunit but have different β-subunits that determine their distinct biological activities. In humans, the glycoprotein hormone family also includes human chorionic gonadotropin (hCG). Corticotropin (adrenocorticotropic hormone; ACTH) and α-melanocyte-stimulating hormone (α-MSH) are part of a family of peptides derived from pro-opiomelanocortin (POMC) by proteolytic processing (see Chapter 59).

The synthesis and release of anterior pituitary hormones are influenced by the central nervous system. Their secretion is positively regulated by a group of peptides referred to as hypothalamic releasing hormones, which are released from hypothalamic neurons in the region of the median eminence and reach the anterior pituitary through the hypothalamic-adenohypophyseal portal system (Figure 55–1). The hypothalamic releasing hormones include growth hormone–releasing hormone (GHRH), gonadotropin-releasing hormone (GnRH), thyrotropin-releasing hormone (TRH), and corticotropin-releasing hormone (CRH). Somatostatin (SST), another hypothalamic peptide, negatively regulates pituitary secretion of growth hormone and thyrotropin. The catecholamine dopamine inhibits the secretion of prolactin by lactotropes.

The posterior pituitary gland, also known as the neurohypophysis, contains the endings of nerve axons arising from distinct populations of neurons in the supraoptic and
paraventricular nuclei that synthesize either arginine vasopressin or oxytocin (Figure 55–1). Arginine vasopressin plays an important role in water homeostasis (see Chapter 29); oxytocin plays important roles in labor and parturition and in milk let-down, as discussed below.

### GROWTH HORMONE

The gene encoding human growth hormone (GH) resides on the long arm of chromosome 17 (17q22), which also contains three different variants of placental lactogen and a GH variant expressed in the syncytiotrophoblast (chorionic somatomammotropin). Secreted GH is a heterogeneous mixture of peptides; the principal 22,000-dalton form is a single polypeptide chain of 191 amino acids that has two disulfide bonds and is not glycosylated. Alternative splicing deletes residues 32 to 46 of the larger form to produce a smaller form (~20,000 daltons) with equal bioactivity that makes up 5% to 10% of circulating GH. Additional GH species, differing in size or charge, are found in serum, but their physiological significance is unclear. In the circulation, approximately 45% of the 22,000-dalton and 25% of the 20,000-dalton GH are bound by a 55,000-dalton binding protein that contains the extracellular domain of the GH receptor and apparently arises from proteolytic cleavage. A second protein unrelated to the GH receptor also binds approximately 5% to 10% of circulating GH with lower affinity. Bound GH is cleared more slowly and has a biological half-life approximately 10 times that of unbound GH, suggesting that the binding protein may provide a GH reservoir that dampens acute fluctuations in GH levels associated with its pulsatile secretion. Alternatively, the binding protein may decrease GH bioactivity by preventing it from binding to its receptor in target tissues. Obesity and estrogen treatment increase circulating levels of GH binding proteins, and thus may affect the clinical response to exogenous GH.

### Regulation of Growth Hormone Secretion

Growth hormone, the most abundant anterior pituitary hormone, is synthesized and secreted by somatotropes.

The somatotropes account for about 40% of hormone-secreting cells of the anterior pituitary and cluster at the lateral wings of the gland. Daily GH secretion varies throughout life; secretion is high in children, reaches maximal levels at puberty, and then decreases in an age-related manner in adulthood. GH is secreted in discrete but irregular pulses. Between these pulses, circulating GH falls to levels that are undetectable with most current assays. The amplitude of secretory pulses is maximal at night, and the most consistent period of GH secretion is shortly after the onset of deep sleep.

The regulation of GH secretion, as illustrated in Figure 55–2, incorporates many of the features of the classic negative feedback systems seen in other endocrine axes.

Figure 55–1. Organization of the anterior and posterior pituitary gland. Hypothalamic neurons in the supraoptic (SON) and paraventricular (PVN) nuclei synthesize arginine vasopressin (AVP) or oxytocin (OXY). Most of their axons project directly to the posterior pituitary, from which AVP and OXY are secreted into the systemic circulation to regulate their target tissues. Neurons that regulate the anterior lobe cluster in the mediobasal hypothalamus, including the PVN and the arcuate (ARC) nuclei. They secrete hypothalamic releasing hormones, which reach the anterior pituitary via the hypothalamic-adenohypophyseal portal system and stimulate distinct populations of pituitary cells. These cells, in turn, secrete the trophic hormones, which regulate endocrine organs and other tissues.

Figure 55–2. Secretion and actions of growth hormone. Two hypothalamic factors, growth hormone-releasing hormone (GHRH) and somatostatin (SST), act on the somatotropes in the anterior pituitary to regulate growth hormone secretion. SST also inhibits GHRH release. Growth hormone exerts direct effects on target tissues and indirect effects mediated by stimulating the release of insulin-like growth factor-1 (IGF-1). The gastric peptide ghrelin enhances growth hormone release, directly by actions at the anterior pituitary and indirectly by multiple actions on the hypothalamus. IGF-1 feeds back at the anterior pituitary to inhibit growth hormone secretion and also to inhibit further GHRH release by the hypothalamus.

GHRH, produced by hypothalamic neurons found predominantly in the arcuate nucleus, stimulates GH secretion by binding to a specific G protein–coupled receptor on somatotropes that resembles most closely the receptors for secretin, vasoactive intestinal polypeptide, pituitary adenyl cyclase–activating peptide, glucagon, glucagon-like peptide 1, calcitonin, and parathyroid hormone. Upon binding GHRH, the GHRH receptor couples to $G_s$ to elevate intracellular cyclic AMP and Ca$^{2+}$ concentrations and thereby stimulates GH synthesis and secretion. Loss-of-function mutations of the GHRH receptor cause a rare form of dwarfism in human beings, thereby demonstrating the essential role of the GHRH receptor in normal GH secretion.

Typical of other endocrine systems, GH and its predominant peripheral effector, insulin-like growth factor-1 (IGF-1), act in negative feedback loops to suppress GH
secretion. The negative effect of IGF-1 is predominantly through direct effects on the anterior pituitary gland. In contrast, the negative feedback action of GH is mediated in part by SST, which is synthesized by more widely distributed neurons, as well as by neuroendocrine cells in the gastrointestinal tract and pancreas.

Somatostatin is synthesized as a 92-amino-acid precursor and processed by proteolytic cleavage to generate two predominant forms: SST-14 and SST-28. The somatostatins exert their effects by binding to and activating a family of five related G protein–coupled receptors that signal through G_i to inhibit cyclic AMP accumulation and to activate K^+ channels and phosphotyrosine phosphatases. Each of the SST receptor subtypes (abbreviated SSTR or sstr) binds SST with nanomolar affinity; whereas receptor types 1 to 4 (SSTR1–4) bind the two SSTs with approximately equal affinity, type 5 (SSTR5) has a ten- to fifteenfold greater selectivity for somatostatin-28. SSTR2 and SSTR5 are the most important for regulation of GH secretion. SST exerts direct effects on somatotropes in the pituitary and indirect effects mediated via GHRH neurons in the arcuate nucleus. As discussed below, SST analogs play a key role in the therapy of syndromes of GH excess such as acromegaly.

Appreciation of a third regulator of GH secretion has emerged from the development of peptide and nonpeptide compounds, called GH secretagogues, that stimulate GH secretion. These secretagogues act primarily through a distinct G protein–coupled receptor, called the GH secretagogue receptor. Although GH secretagogues directly stimulate GH release by isolated somatotropes, their major action on GH secretion apparently is through actions on the GHRH neurons in the arcuate nucleus. The endogenous ligand for the GH secretagogue receptor is ghrelin, a 28-amino-acid peptide with an octanoylated serine at residue 3. Ghrelin is synthesized predominantly in endocrine cells in the fundus of the stomach, but also is produced at lower levels at a number of other sites. Both fasting and hypoglycemia stimulate circulating ghrelin levels. In human beings and experimental animals, ghrelin stimulates appetite and increases food intake, apparently by central actions on NPY and agouti-related peptide neurons in the hypothalamus. Thus ghrelin and its receptor play complex roles to integrate the gastrointestinal tract, the hypothalamus, and the anterior pituitary (Yoshihara et al., 2002).

Several neurotransmitters, drugs, metabolites, and other stimuli modulate the release of GHRH and/or SST and thereby affect GH secretion. Dopamine, 5-hydroxytryptamine, and α_2 adrenergic receptor agonists stimulate GH release, as do hypoglycemia, exercise, stress, emotional excitement, and ingestion of protein-rich meals. In contrast, β adrenergic receptor agonists, free fatty acids, insulin-like growth factor-1 (IGF-1, see below), and GH itself inhibit release, as does the administration of glucose to normal subjects in an oral glucose tolerance test.

These observations form the basis for provocative tests to assess the ability of the pituitary to secrete GH. Provocative stimuli include arginine, glucagon, insulin-induced hypoglycemia, clonidine, and the dopamine precursor levodopa; these agents all increase circulating GH levels in normal subjects within 45 to 90 minutes. At present, insulin-induced hypoglycemia is preferred by some authorities, whereas the FDA recommends two independent tests of GH deficiency to establish the diagnosis. When excess GH secretion is suspected (see below), the failure of an oral glucose load to suppress GH is diagnostically useful. Finally, as described below, GH secretion in response to GHRH can be used to distinguish pituitary disease from hypothalamic disease.

**Molecular and Cellular Bases of Growth Hormone Action**

All of the effects of GH result from its interactions with the GH receptor, as evidenced by the severe phenotype of rare patients with homozygous mutations of the GH receptor gene (the Laron syndrome of GH-resistant dwarfism). The GH receptor is a widely distributed cell-surface receptor that belongs to the Class I cytokine receptor superfamily and thus shares structural similarity with the receptors for prolactin, erythropoietin, granulocyte-macrophage colony-stimulating factor, and several of the interleukins. Like other members of the cytokine receptor family, the GH receptor contains an extracellular domain that binds GH, a single membrane-spanning region, and an intracellular domain that mediates signal transduction. Receptor activation results from the binding of a single GH molecule to two identical receptor molecules, forming a ligand-occupied receptor dimer that presumably brings the intracellular domains of the receptor into close proximity to activate cytosolic components critical for cell signaling.

The mature human GH receptor contains 620 amino acids, ~250 of which are extracellular, 24 of which are transmembrane, and ~350 of which are cytoplasmic. The GH receptor exists as a dimer and forms a ternary complex with one molecule of GH. The formation of the GH–GH receptor ternary complex is initiated by high-affinity interaction of GH with one monomer of the GH receptor dimer (mediated by GH site 1), followed by a second interaction of GH with the GH receptor (mediated by GH site 2); these interactions induce a conformational change that activates downstream signaling. Guided by structure-function analyses, GH analogs have been engineered with a disrupted site 2; these analogs bind the receptor and induce its internalization but cannot induce a conformational change or stimulate downstream events in the signal transduction pathway. One such analog, pegvisomant, behaves as a GH antagonist and is used for the treatment of acromegaly (Kopchick et al., 2002; see below).
The ligand-occupied receptor dimer does not have inherent tyrosine kinase activity, but rather provides docking sites for two molecules of Jak2, a cytoplasmic tyrosine kinase of the Janus kinase family. The juxtaposition of two Jak2 molecules leads to trans-phosphorylation and autoactivation of Jak2, with consequent tyrosine phosphorylation of cytoplasmic proteins that mediate downstream signaling events (Herrington and Carter-Su, 2001). The GHR also activates the insulin receptor substrate-1 (IRS-1), which may mediate the increased expression of glucose transporters on the plasma membrane. The diagram does not reflect the localization of the intracellular molecules, which presumably exist in multicomponent signaling complexes. B. Pegvisomant, a recombinant pegylated variant of human GH, contains mutations that increase the affinity for the GHR but do not activate downstream signaling by the GHR. It thus interferes with GH signaling in target tissues. JAK2, Janus kinase 2; IRS-1, insulin receptor substrate-1; PI3K, phosphatidylinositol-3 kinase; STAT, signal transducer and activator of transcription; MAPK, mitogen-activated protein kinase; SHC, Src homology containing.

Figure 55–3. Mechanisms of growth hormone and prolactin action and of GH receptor antagonism. A. The binding of GH to two molecules of the growth hormone receptor (GHR) induces autophosphorylation of JAK2. JAK2 then phosphorylates cytoplasmic proteins that activate downstream signaling pathways, including signal transducer and activator of transcription (Stat)5 and mediators upstream of mitogen-activated protein kinase (MAPK), which ultimately modulate gene expression. The structurally related prolactin receptor also is a ligand-activated homodimer that recruits the JAK-Stat signaling pathway (see text for further details). The GHR also activates the insulin receptor substrate-1 (IRS-1), which may mediate the increased expression of glucose transporters on the plasma membrane. The diagram does not reflect the localization of the intracellular molecules, which presumably exist in multicomponent signaling complexes. B. Pegvisomant, a recombinant pegylated variant of human GH, contains mutations that increase the affinity for the GHR but do not activate downstream signaling by the GHR. It thus interferes with GH signaling in target tissues. JAK2, Janus kinase 2; IRS-1, insulin receptor substrate-1; PI3K, phosphatidylinositol-3 kinase; STAT, signal transducer and activator of transcription; MAPK, mitogen-activated protein kinase; SHC, Src homology containing.

Physiological Effects of Growth Hormone

The most striking physiological effect of GH—and the basis for its name—is the stimulation of the longitudinal growth of bones. GH also increases bone mineral density after longitudinal growth ceases and epiphyses have closed. These effects of GH involve the differentiation of prechondrocytes to chondrocytes and stimulation of osteoclast and osteoblast proliferation. Other effects of GH include the stimulation of myoblast differentiation (in experimental animals) and increased muscle mass (in human subjects with growth hormone deficiency), increased glomerular filtration rate, and stimulation of preadipocyte differentiation into adipocytes. GH has potent anti-insulin actions in both the liver and peripheral sites (e.g., adipocytes and muscle) that decrease glucose utilization and increase lipolysis. Finally, GH has been implicated in the development and function of the immune system.

GH acts directly on adipocytes to increase lipolysis and on hepatocytes to stimulate gluconeogenesis, but its anabolic and growth-promoting effects are mediated indirectly through the induction of insulin-like growth factor-1 (IGF-1). Although most circulating IGF-1 is made in the liver, IGF-1 produced locally in many tissues is critical for growth, as revealed by normal growth in mice that
have a hepatocyte-specific inactivation of IGF-1. Circulating IGF-1 is associated with a family of binding proteins that serve as transport proteins, which also may mediate certain aspects of IGF-1 signaling (Firth and Baxter, 2002). The essential role of IGF-1 in GH signaling is evidenced by a patient with loss-of-function mutations in both alleles of the IGF1 gene whose severe intrauterine and postnatal growth retardation was unresponsive to GH but responsive to recombinant human IGF-1 (Comacho-Hubner et al., 1999) and by the association of mutations in the IGF-1 receptor with intrauterine growth retardation (Abuzzahab et al., 2003).

After its synthesis and release, IGF-1 interacts with receptors on the cell surface that mediate its biological activities. The type 1 IGF receptor is closely related to the insulin receptor, consisting of a hetero-tetramer with intrinsic tyrosine kinase activity. This receptor is present in essentially all tissues and binds IGF-1 and the related growth factor, IGF-2, with high affinity; insulin also can activate the type 1 IGF receptor, but with an affinity approximately two orders of magnitude less than that of the IGFS. The signal transduction pathway for the insulin receptor is described in detail in Chapter 60.

**Clinical Disorders of Growth Hormone**

Although the manifestations vary depending on the age of onset, GH deficiency and excess are associated with defined diseases that form an important part of endocrine practice.

**Diagnosis of Growth Hormone Deficiency.** Clinically, children with GH deficiency present with short stature, delayed bone age, and a low age-adjusted growth velocity. Most commonly, these children have an isolated deficiency of GH without other documented pathology (e.g., idiopathic, isolated GH deficiency) and are presumed to have a hypothalamic defect. Because GH secretion is episodic, random sampling of serum GH is insufficient to diagnose GH deficiency. Tests that provide an estimate of integrated GH levels over time (e.g., IGF-1 and IGF-binding protein 3 levels) are more useful, although provocative tests usually are required. After excluding other causes of poor growth, the diagnosis of GH deficiency should be entertained in patients with height more than 2 to 2.5 standard deviations below normal, delayed bone age, a decreased growth velocity, and a predicted adult height substantially below the mean parental height (Vance and Mauras, 1999). In this setting, a serum GH level of less than 10 ng/ml following provocative testing (e.g., insulin-induced hypoglycemia, arginine, levodopa, or glucagon) indicates GH deficiency; a stimulated value of less than 5 ng/ml reflects severe deficiency.

In adults, overt GH deficiency almost always results from pituitary disease due either to a functioning or nonfunctioning pituitary adenoma or secondary to surgery or radiotherapy for a pituitary or suprasellar mass. Almost all patients with multiple deficits in other pituitary hormones also will have deficient GH secretion, and some experts incorporate the number of other pituitary deficiencies into a diagnostic algorithm for diagnosing GH deficiency (Molitch, 2002b). Others will accept a serum IGF-1 level below the age- and sex-adjusted normal value as indicative of GH deficiency in a patient with known pituitary disease. Finally, some experts require an inadequate GH response to provocative testing, with either insulin-induced hypoglycemia or a combination of arginine and GHRH, as the preferred stimulus for GH secretion. The risk of false-positive provocative tests (i.e., a subnormal GH response) is increased in obese subjects.

**Indications for Growth Hormone Treatment.** GH deficiency in children is a well-accepted cause of short stature, and replacement therapy has been used for more than 30 years to treat children with severe GH deficiency. With the advent of essentially unlimited supplies of recombinant GH, therapy has been extended to children with other conditions associated with short stature despite adequate GH production, including Turner’s syndrome, Prader-Willi syndrome (in the absence of morbid obesity or obstructive sleep apnea), chronic renal insufficiency, children born small for gestational age, and children with idiopathic short stature (i.e., more than 2.25 standard deviations below mean height for age and sex but normal laboratory indices of growth hormone levels).

In adults, GH deficiency is associated with a defined endocrinopathy that includes increased mortality from cardiovascular causes, probably secondary to deleterious changes in fat distribution, increases in circulating lipids, and increased inflammation; decreased muscle mass and exercise capacity; decreased bone density; and impaired psychosocial function (Cummings and Merriam, 2003). With the ready availability of recombinant human GH, attention also has shifted to the proper role of GH therapy in GH-deficient adults. While this is an area of ongoing debate, the consensus is that at least the most severely affected GH-deficient adults may benefit from GH replacement therapy. The FDA also has approved GH therapy for AIDS-associated wasting and for malabsorption associated with the short bowel syndrome. The latter indication is based on GH action to stimulate adaptation of gastrointestinal epithelial cells; in this setting, GH is administered once daily for 4 weeks.

Based on controlled clinical trials showing increased mortality, GH should not be used in patients with acute critical illness due to complications after open heart or abdominal surgery, multiple accidental trauma, or acute respiratory failure. GH also should not be used in patients who have any evidence of neoplasia, and antitumor therapy should be completed before initiation of GH therapy.

**Treatment of Growth Hormone Deficiency.** Humans do not respond to GH from nonprimate species. GH for therapeutic use formerly was purified from human cadav-
er pituitaries and thus was available in very limited quantities and carried the risk of Creutzfeldt-Jakob disease. The production of human GH by recombinant DNA technology not only increased availability of the hormone, but also eliminated the risk of disease transmission associated with the pituitary-derived hormone.

GH is used for replacement therapy in GH-deficient children, whether the deficiency is congenital or acquired (Vance and Mauras, 1999). By convention, somatropin refers to the many GH preparations whose sequences match that of native GH (SEROSTIM, GENOTROPIN, HUMATROPE, NUTROPIN, NORDITROPIN, SAIZEN), while somatrem refers to a derivative of GH with an additional methionine at the amino terminus (PROTROPIN). Although the microbi-al systems used to express the recombinant hormone subtly affect the structures of these preparations, they all have similar biological actions and potencies. To mimic the normal pattern of secretion, they typically are administered to GH-deficient children in a dose of 40 μg/kg per day subcutaneously in the evening; although the circulating half-life of GH is only 20 minutes, its biological half-life is in the range of 9 to 17 hours, and once-daily administration is sufficient. Higher daily doses (e.g., 50 μg/kg) are employed for patients with Turner’s syndrome, who have partial GH resistance. In children with overt GH deficiency, measurements of serum IGF-1 levels are used to monitor initial response and compliance; long-term response is monitored by close evaluation of height, sometimes in conjunction with measurements of serum IGF-1 levels. Although the most pronounced increase in growth velocity occurs within the first 2 years of therapy, GH is continued until the epiphyses are fused, and also may be extended into the transition period from childhood to adulthood (Quigley, 2003).

Newer GH formulations are supplied in prefilled syringes, which may be more convenient for the patient, or in non-needle injection systems. The FDA also has approved an encapsulated form of somatropin (NUTROPIN DEPOT) that is injected intramuscularly either monthly (1.5 mg/kg body weight) or every 2 weeks (0.75 mg/kg body weight). The depot formulation was associated with local reactions at the site of injection, and the manufacturer has announced a decision to discontinue commercialization of this product. The relative advantages of any specific formulations over others in clinical use have not been definitively established.

In addition to GH, sermorelin acetate (GEREF), a synthetic form of human GHRH, is FDA approved for treatment of GH deficiency (Anonymous, 1999). Sermorelin generally is well tolerated and is less expensive than somatropin, but at recommended doses (30 μg/kg per day given subcutaneously) it has been less effective than GH in clinical trials. Moreover, this agent will not work in patients whose GH deficiency results from defects in the anterior pituitary. Therefore, a GH response (>2 ng/ml) to a test dose of sermorelin should be documented before initiating therapy, and patients must be monitored frequently to ascertain continued growth on therapy. Sermorelin also has been employed diagnostically to distinguish between pituitary and hypothalamic disease, although its clinical utility for this purpose is not fully established.

In view of the increased appreciation of the effects of GH on bone density and the manifestations of GH deficiency in adults, some experts continue therapy into adulthood for children with GH deficiency. However, many patients who clearly were GH deficient in childhood, especially those with idiopathic, isolated GH deficiency, respond normally to provocative tests as adults. Thus it is essential to confirm GH deficiency after optimal growth has been achieved so as to identify patients who will benefit from continuing GH treatment.

Growth impairment also may be associated with elevated GH levels and GH resistance, most frequently secondary to mutations in the GH receptor (Laron dwarfism). These patients can be treated effectively with recombinant human IGF-1 (IGF), which is administered subcutaneously either once or twice daily in doses ranging from 40 to 120 μg/kg (Comacho-Hubner et al., 1999). Although this therapy clearly is beneficial in promoting growth, the optimal regimen remains to be established, and novel approaches to modulate the IGF-1 pathway are under investigation (Torrado and Carrascosa, 2003).

For adults, the FDA recommends a starting dose of 3 to 4 μg/kg, given once daily by subcutaneous injection, with a maximum dose of 25 μg/kg in patients ≤35 years old and 12.5 μg/kg in older patients. Other experts recommend a starting dose of 150 to 300 μg/day regardless of body weight. Clinical response is monitored by serum IGF-1 levels, which should be restored to the mid-normal range adjusted for age and sex. Either an elevated serum IGF-1 or persistent side effects are grounds for decreasing the dose; conversely, the dose can be increased if serum IGF-1 has not reached the normal range after 2 months of GH therapy. Because estrogen increases the levels of GH binding proteins, women taking oral—but not transdermal—estrogen often require larger GH doses to achieve the target IGF-1 level. In clinical trials in the setting of AIDS-related wasting, considerably higher doses (e.g., 100 μg/kg) have been used.
Based on the known age-related decline in GH levels, the use of GH therapy to ameliorate or even reverse the consequences of aging has been widely promoted. Many of the studies supporting this use were not placebo-controlled and involved small numbers of subjects. Moreover, at least one well-designed trial showed no improvement in strength or aerobic performance with GH therapy in elderly subjects. In violation of regulations and standard medical practice, some athletes also use injectable GH preparations as anabolic agents to enhance performance. In addition to the parenteral GH preparations, oral preparations containing “stacked” amino acids that reportedly stimulate GH release have been marketed as nutritional supplements. Despite the absence of validation in controlled trials, these formulations are part of multibillion dollar anti-aging and performance-enhancing programs.

**Side Effects of GH Therapy.** In children, GH therapy is associated with remarkably few side effects. Rarely, generally within the first 8 weeks of therapy, patients develop intracranial hypertension, with papilledema, visual changes, headache, nausea, and/or vomiting. Because of this, funduscopic examination is recommended at the initiation of therapy and at periodic intervals thereafter. Leukemia has been reported in some children receiving GH therapy; a causal relationship has not been established, and conditions associated with GH deficiency (e.g., Down’s syndrome, cranial irradiation for CNS tumors) probably explain the apparent increased incidence of leukemia. Despite this, the consensus is that GH should not be administered in the first year after treatment of pediatric tumors, including leukemia, or during the first 2 years after therapy for medulloblastomas or ependymomas. An increased incidence of type 2 diabetes mellitus has been reported. Finally, too-rapid growth may be associated with slipped epiphyses or scoliosis.

In adults, side effects associated with the initiation of GH therapy include peripheral edema, carpal tunnel syndrome, arthralgia, and myalgia. These symptoms, which occur most frequently in patients who are older or more obese, generally respond to a decrease in dose. Although there are potential concerns about impaired glucose tolerance secondary to anti-insulin actions of GH, this generally has not been a major problem with clinical use at the recommended doses. In fact, changes in visceral fat composition associated with GH replacement may improve insulin sensitivity in some patients.

** Syndromes of GH Excess**

GH excess causes distinct clinical syndromes depending on the age of the patient. If the epiphyses are unfused, GH excess causes increased longitudinal growth, resulting in gigantism. In adults, GH excess causes acromegaly. The symptoms and signs of acromegaly (e.g., arthropathy, carpal tunnel syndrome, generalized visceromegaly, macroglossia, hypertension, glucose intolerance, headache, lethargy, excess perspiration, and sleep apnea) progress slowly, and diagnosis often is delayed. Life expectancy is shortened in these patients; mortality is increased at least twofold relative to age-matched controls due to increased death from cardiovascular disease, upper airway obstruction, and gastrointestinal malignancies.

**Diagnosis of GH Excess.** While the diagnosis of acromegaly should be suspected in patients with the appropriate symptoms and signs, confirmation requires the demonstration of increased circulating GH or IGF-1. The gold standard diagnostic test for acromegaly is the oral glucose tolerance test. While normal subjects suppress their GH level to <1 ng/ml in response to a 75-g glucose challenge (the absolute value may vary depending on the sensitivity of the assay), patients with acromegaly either fail to suppress or show a paradoxical increase in GH level.

Treatment options in acromegaly include transsphenoidal surgery, radiation, and drugs that inhibit GH secretion or action. Pituitary surgery traditionally has been viewed as the treatment of choice. In patients with microadenomas (i.e., tumors <1 cm in diameter), skilled neurosurgeons can achieve cure rates of 60% to 90%; however, the long-term success rate for patients with macroadenomas (i.e., tumors ≥1 cm in diameter) typically is less than 50%. In addition, there is increasing appreciation that acromegalic patients previously considered cured by pituitary surgery actually have persistent GH excess, with its attendant complications, and that pituitary irradiation may be associated with significant long-term complications. Thus, more attention has been given to the pharmacological management of acromegaly, either as a primary treatment modality or for the treatment of persistent GH excess after transsphenoidal surgery.

**Somatostatin Analogs.** The development of analogs of SST (Figure 55–4) revolutionized the medical treatment of acromegaly. Based on structure-function studies of SST and its derivatives, the amino acid residues in positions 7 to 10 [FWKT] are the major determinants of biological activity. Residues W8 and K9 appear to be essential, whereas conservative substitutions at F7 and T10 are permissible. Active SST analogs retain this core segment constrained in a cyclic structure—formed either by a disulfide bond or amide linkage that stabilizes the optimal conformation (Weckbecker et al., 2003). The endogenous peptides, SST-14 and SST-28, do not show specificity for SSTR subtypes except for SSTR5, for which SST-28 shows some preference. Some of the somatostatin analogs exhibit greater selectivity. For example, the octapeptides octreotide, lanreotide, and vapreotide and the hexapeptide seglitide all bind to the SSTR subtypes with the following order of selectivity: SSTR2 > SSTR5 > SSTR3 >> SSTR1 and SSTR4. The octapeptide analog BIM23268 exhibits modest selectivity for SSTR5, and the undecapeptide CH275 appears to bind preferentially to SSTR1 and SSTR4. More recently, small nonpeptide agonists that exhibit high selectivity for SSTR subtypes have been isolated from combinatorial chemical libraries; these compounds may lead to a new class of highly selective, orally active somatostatin mimetics (Weckbecker et al., 2003).
Currently, the most widely used somatostatin analog is octreotide (SANDOSTATIN), an 8-amino-acid synthetic derivative of somatostatin that has a longer half-life and binds preferentially to SSTR-2 and SSTR-5 receptors. Typically, octreotide (100 μg) is administered subcutaneously three times daily; bioactivity is virtually 100%, peak effects are seen within 30 minutes, serum half-life is approximately 90 minutes, and duration of action is approximately 12 hours. The goal of treatment is to decrease GH levels to less than 2 ng/ml after an oral glucose tolerance test and to bring IGF-1 levels to within the normal range for age and gender. Depending on the biochemical response, higher or lower octreotide doses may be used in individual patients.

In addition to its effect on GH secretion, octreotide can decrease tumor size—although tumor growth generally resumes after octreotide treatment is stopped. Octreotide also has significant inhibitory effects on thyrotropin secretion, and it is the treatment of choice for patients who have thyrotrope adenomas that oversecrete TSH and who are not good candidates for surgery. The use of octreotide in gastrointestinal disorders is discussed in Chapter 37.

Gastrointestinal side effects—including diarrhea, nausea, and abdominal pain—occur in up to 50% of patients receiving octreotide. In most patients, these symptoms diminish over time and do not require cessation of therapy. Approximately 25% of patients receiving octreotide develop gallstones, presumably due to decreased gallbladder contraction and gastrointestinal transit time. In the absence of symptoms, gallstones are not a contraindication to continued use of octreotide. Compared to somatostatin, octreotide reduces insulin secretion to a lesser extent and only infrequently affects glycemic control.

The need to inject octreotide three times daily poses a significant obstacle to patient compliance. A long-acting, slow-release form (SANDOSTATIN LAR) is a more convenient alternative that can be administered intramuscularly once every 4 weeks; the recommended dose is 20 or 30 mg (McKeage et al., 2003). The long-acting preparation is at least as effective as the regular formulation and is used in patients who have responded favorably to a trial of the shorter-acting formulation of octreotide. Like the shorter-acting formulation, the longer-acting formulation of octreotide generally is well tolerated and has a similar incidence of side effects (predominantly gastrointestinal and/or discomfort at the injection site) that do not require cessation of therapy.

Lanreotide (SOMATULINE LA) is another long-acting octapeptide analog of somatostatin that causes prolonged suppression of GH secretion when administered in a 30-mg dose intramuscularly. Although its efficacy appears comparable to that of the long-acting formulation of octreotide, its duration of action is shorter; thus it must be administered either at 10- or 14-day intervals. A 60-mg formulation of lanreotide (SOMATULINE AUTOGEL) has recently been introduced that reduces the required dosing frequency to once every 4 weeks; current results are com-

---

**Figure 55–4. Structures of the somatostatins and clinically available analogs.** The amino acid sequences of SST-28 and SST-14 are shown. Residues that play key roles in receptor binding, as discussed in the text, are shown in blue. Also shown are the structures of the synthetic somatostatin analogs, octreotide, lanreotide, seglitide, and vapreotide. Abbreviation: D-Nal, 3-(2-naphthyl)-D-alanyl.
parable to those with the slow-release octreotide formulation, as are the incidence and severity of side effects. Lanreotide has not been approved by the FDA for use in the United States.

Somatostatin blocks not only GH secretion, but also the secretion of other hormones, growth factors, and cytokines. Thus, octreotide and the delayed-release somatostatin analogs have been used to treat symptoms associated with metastatic carcinoid tumors (e.g., flushing and diarrhea) and adenosomas secreting vasoactive intestinal peptide (e.g., watery diarrhea). Octreotide also is used for treatment of acute variceal bleeding, for perioperative prophylaxis in pancreatic surgery, and for TSH-secreting adenosomas in patients who are not candidates for surgery. Novel uses under evaluation currently include the treatment of eye diseases associated with excessive proliferation and inflammation (e.g., Graves’ orbitopathy and diabetic retinopathy), diabetic nephropathy, and various systemic diseases associated with inflammation (e.g., rheumatoid arthritis, inflammatory bowel disease, and psoriasis). Finally, modified forms of octreotide labeled with indium or technetium have been used for diagnostic imaging of neuroendocrine tumors such as pituitary adenomas and carcinoids; modified forms labeled with β emitters such as ⁹⁰Y have been used in selective destruction of SSTR-2–positive tumors.

**Dopamine-Receptor Agonists.** The dopamine-receptor agonists are described in more detail below in the section dealing with treatment of prolactin excess. Although dopamine-receptor agonists normally stimulate GH secretion, they paradoxically decrease GH secretion in some patients with acromegaly. The best responses have been seen in patients whose tumors secrete both GH and prolactin. The long-acting dopamine-receptor agonist cabergoline (DOSTINEX) may lower GH and IGF-1 levels into the target range and thus may be of value in patients who are unwilling to undergo treatment with drugs administered by injection. Doses used in treating acromegaly typically are considerably higher than those employed in prolactinomas.

**Growth Hormone Antagonists.** Pegvisomant (SOMAVERT) is a GH antagonist that is FDA approved for the treatment of acromegaly. Pegvisomant binds to the GH receptor but does not activate Jak-Stat signaling or stimulate IGF-1 secretion (Figure 55–3). Pegvisomant is administered subcutaneously as a 40-mg loading dose under physician supervision, followed by self-administration of 10 mg/day. Based on serum IGF-1 levels, the dose is titrated at 4- to 6-week intervals to a maximum of 40 mg/day. Liver function should be monitored in all patients, and pegvisomant should not be used in patients with elevated levels of liver transaminases. Because there are concerns that loss of negative feedback by GH and IGF-1 may increase the growth of GH-secreting adenomas, careful follow-up by pituitary MRI is mandatory. Pegvisomant differs structurally from native GH and induces the formation of specific antibodies in ~15% of patients despite the covalent coupling to lysine residues of 4 to 5 molecules of a polyethylene glycol polymer per modified GH molecule. Nevertheless, the development of tachyphylaxis due to these antibodies has not been reported.

In clinical trials, pegvisomant at higher doses significantly decreased serum IGF-1 to normal age- and sex-adjusted levels in >90% of patients, and significantly improved clinical parameters such as ring size, soft-tissue swelling, excessive perspiration, and fatigue. Thus, while its ultimate role in the management of acromegaly remains to be determined, pegvisomant is an exciting new pharmacologic agent, particularly for those acromegalic patients who do not respond to somatostatin analogs.

**PROLACTIN**

As a member of the somatotropin family, prolactin is related structurally to GH and placental lactogen (Table 55–1). Human prolactin is a 23,000-dalton protein of 199 amino acids with three intramolecular disulfide bonds. It is synthesized by lactotropes in the anterior pituitary gland, and a portion of secreted prolactin is glycosylated at a single asparagine residue. In circulation, dimeric and polymeric forms of prolactin also are found, as are degradation products of 16,000 and 18,000 daltons; the biological significance of these different forms is not known.

**Secretion**

Prolactin synthesis and secretion in the fetal pituitary start in the fifth week of gestation. Serum prolactin levels decline shortly after birth. Whereas serum prolactin levels remain low throughout life in normal males, they are elevated somewhat in normal cycling females. Prolactin levels rise markedly during pregnancy, reach a maximum at term, and decline thereafter unless the mother breastfeeds the child. Suckling or breast manipulation in nursing mothers stimulates circulating prolactin levels, which can rise ten- to one hundredfold within 30 minutes of stimulation. This response is transmitted from the breast to the hypothalamus via the spinal cord and the median forebrain bundle, and is distinct from milk let-down, which is mediated by oxytocin release by the posterior pituitary gland. The precise mechanism for suckling-induced prolactin secretion is not known but involves both decreased secretion of dopamine by tuberoinfundibular neurons and possibly increased release of factors that stimulate prolactin secretion (see below). The suckling response becomes less pronounced after several months of breast-feeding, and prolactin concentrations eventually decline to prepregnancy levels.

Prolactin detected in maternal and fetal blood originates from maternal and fetal pituitaries, respectively. Prolactin also is synthesized by decidual cells near the end of the luteal phase of the menstrual cycle and early in pregnancy; the latter source is responsible for the very high levels of prolactin in amniotic fluid during the first trimester.

Many of the physiological factors that influence prolactin secretion are similar to those that affect GH secre-
tion. Thus, sleep, stress, hypoglycemia, exercise, and estrogen increase the secretion of both hormones.

Like other anterior pituitary hormones, prolactin is secreted in a pulsatile manner. Prolactin is unique among the anterior pituitary hormones in that hypothalamic regulation of its secretion is predominantly inhibitory. The major regulator of prolactin secretion is dopamine, which is released by tuberoinfundibular neurons and interacts with the D2 receptor on lactotropes to inhibit prolactin secretion (Figure 55–5). A number of putative prolactin-releasing factors have been described, including thyrotropin-releasing hormone (TRH), vasoactive intestinal peptide, prolactin-releasing peptide, and pituitary adenyl cyclase–activating peptide (PACAP), but their physiological roles are unclear. Under certain pathophysiological conditions, such as severe primary hypothyroidism, persistently elevated levels of TRH can induce hyperprolactinemia and galactorrhea.

**Molecular and Cellular Bases of Prolactin Action**

The effects of prolactin result from interactions with specific receptors that are widely distributed among a variety of cell types within many tissues (Goffin et al., 2002). The prolactin receptor is encoded by a single gene on chromosome 5. Alternative splicing of this gene gives rise to multiple forms of the receptor, including a short form of 310 amino acids, a long form of 610 amino acids, and an intermediate form of 412 amino acids. In addition, soluble forms that correspond to the extracellular domain of the receptor are found in the circulation. The membrane-bound prolactin receptor is related structurally to receptors for GH and several cytokines and uses similar signaling mechanisms. Like the GH receptor, the prolactin receptor lacks intrinsic tyrosine kinase activity; prolactin induces a conformational change leading to recruitment and activation of Jak kinases (Figure 55–3). The activated Jak2 kinase, in turn, induces phosphorylation, dimerization, and nuclear translocation of the transcription factor Stat5. Unlike human GH and placental lactogen, which bind to the prolactin receptor and are lactogenic, prolactin binds specifically to the prolactin receptor and has no somatotropic (GH-like) activity.

**Physiological Effects of Prolactin**

A number of hormones—including estrogens, progesterone, placental lactogen, and GH—stimulate development of the breast and prepare it for lactation. Prolactin, acting via prolactin receptors, plays an important role in inducing growth and differentiation of the ductal and lobuloalveolar epithelium and is essential for lactation. Target genes by which prolactin induces mammary development include those encoding milk proteins (e.g., caseins), genes important for intracellular structure (e.g., keratins), genes important for cell-cell communication (e.g., amphiregulin and Wnt4), and components of the extracellular matrix (e.g., laminin and collagen).

Prolactin receptors are present in many other sites, including the hypothalamus, liver, testes, ovaries, prostate, and immune system, prompting the hypothesis that prolactin plays multiple roles outside the breast. The physiological effects of prolactin at these sites, however, remain poorly characterized. For example, a considerable body of evidence suggests that prolactin can stimulate immune function via effects on multiple cell types; however, knockout mice lacking either prolactin or its receptor exhibit neither immunodeficiency nor autoimmune disease. Some have therefore proposed that prolactin modulates immune function during stress rather than under normal circumstances.

**Agents Used to Treat Syndromes of Prolactin Excess**

Prolactin has no therapeutic uses. Hyperprolactinemia is a relatively common endocrine abnormality that can result from hypothalamic or pituitary diseases that interfere with the delivery of inhibitory dopaminergic signals, from renal failure, from primary hypothyroidism associated...
with increased TRH levels, or from treatment with dopamine-receptor agonists. Most often, hyperprolactinemia is caused by prolactin-secreting pituitary adenomas—either microadenomas or macroadenomas. Manifestations of prolactin excess in women include galactorrhea, amenorrhea, and infertility. In men, hyperprolactinemia causes loss of libido, impotence, and infertility.

The therapeutic options for patients with prolactinomas include transsphenoidal surgery, radiation, and treatment with dopamine-receptor agonists that suppress prolactin production via activation of D2 dopamine receptors. Inasmuch as initial surgical cure rates are only 50% to 70% with microadenomas and 30% with macroadenomas, most patients with prolactinomas ultimately require drug therapy. Thus, dopamine-receptor agonists have become the initial treatment of choice for many patients (Molitch, 2002a). These agents generally decrease both prolactin secretion and the size of the adenoma, thereby improving the endocrine abnormalities, as well as the neurological symptoms caused directly by the adenoma (including visual field deficits).

Bromocriptine. Bromocriptine (PARLODEL) is the dopamine-receptor agonist against which newer agents are compared. Bromocriptine is a semisynthetic ergot alkaloid that interacts with D2 dopamine receptors to inhibit spontaneous and TRH-induced release of prolactin; to a lesser extent, it also activates D1 dopamine receptors. Bromocriptine normalizes serum prolactin levels in 70% to 80% of patients with prolactinomas and decreases tumor size in more than 50% of patients, including those with macroadenomas. It is worth noting that bromocriptine does not cure the underlying adenoma, and hyperprolactinemia and tumor growth typically recur upon cessation of therapy.

Frequent side effects of bromocriptine include nausea and vomiting, headache, and postural hypotension—particularly on initial use. Less-frequent side effects include nasal congestion, digital vasospasm, and CNS effects such as psychosis, hallucinations, nightmares, or insomnia. These side effects can be diminished by starting at a low dose (1.25 mg) administered at bedtime with a snack. After 1 week, a morning dose of 1.25 mg can be added. If clinical symptoms persist or serum prolactin levels remain elevated, the dose can be increased gradually, every 3 to 7 days, to 5 mg twice per day or 2.5 mg three times a day as tolerated. Patients often develop tolerance to the side effects of bromocriptine. Those who do not respond to bromocriptine or who develop intractable side effects may respond to a different dopamine agonist. Although a high fraction of the oral dose of bromocriptine is absorbed, only 7% of the dose reaches the systemic circulation because of a high extraction rate and extensive first-pass metabolism in the liver. Furthermore, bromocriptine has a relatively short elimination half-life (between 2 and 8 hours). To avoid the need for frequent dosing, a slow-release oral form is available outside the United States. Bromocriptine may be administered intravaginally (2.5 mg once daily), reportedly with fewer gastrointestinal side effects. At higher concentrations, bromocriptine is used in the management of acromegaly, as noted above, and at still higher concentrations is used in the management of Parkinson’s disease. A parenteral long-acting form of bromocriptine incorporated into biodegradable microspheres (PARLODEL-LAR) has been developed, but is not available in the United States. In clinical trials, this product has produced results that are comparable to those with oral bromocriptine.

Pergolide. Pergolide (PERMAX), an ergot derivative approved by the FDA for treatment of Parkinson’s disease, also is used “off label” to treat hyperprolactinemia. If the cost of therapy is the key consideration, pergolide is the least expensive dopamine-receptor agonist currently available. It induces many of the same side effects as does bromocriptine, but it can be given once a day, starting at 0.025 mg at bedtime and increased gradually to a maximum daily dose of 0.5 mg.

Cabergoline. Cabergoline (DOSTINEX) is an ergot derivative with a longer half-life (approximately 65 hours), higher affinity, and greater selectivity for the D2 receptor (approximately four times more potent) than bromocriptine. It has been approved by the FDA for the treatment of hyperprolactinemia and likely will play an increasing role in the treatment of this syndrome. Compared to bromocriptine, cabergoline has a much lower tendency to induce induce nausea, although it still may cause hypotension and dizziness. In some clinical trials, cabergoline has been more effective than bromocriptine in decreasing serum prolactin in patients with hyperprolactinemia, although this may reflect improved adherence to therapy due to decreased side effects. Therapy is initiated at a dose of 0.25 mg twice a week or 0.5 mg once a week. If the serum prolactin remains elevated, the dose can be increased to a maximum of 1.5 to 2 mg two or three times a week as tolerated; however, the dose should not be increased more often than once every 4 weeks.

Quinagolide. Quinagolide (NORPROLAC) is a nonergot D2 dopamine agonist with a half-life of 22 hours. Quinagolide is administered once daily at doses of 0.1 to 0.5 mg/day. It is not approved by the FDA but has been used extensively in Europe.

Patients with prolactinomas who wish to become pregnant comprise a special subset of hyperprolactinemic patients. In this setting, drug safety during pregnancy is an important consideration. Bromocriptine, cabergoline, and quinagolide all relieve the inhibitory effect of prolactin on ovulation and permit most patients with prolactinomas to become pregnant without apparent detrimental effects on pregnancy or fetal development. However, experience with cabergoline and quinagolide is less extensive than that with bromocriptine. Therefore, bromocriptine is recommended as the first-line treatment in this setting; this opinion may change as experience with cabergoline or quinagolide increases.
The regulation of gonadotropin secretion is described in detail in Chapters 57 and 58. LH and FSH are synthesized and secreted by gonadotropes, which make up approximately 20% of the hormone-secreting cells in the anterior pituitary. hCG, which is produced only in primates and horses, is synthesized by syncytiotrophoblast cells of the placenta. Pituitary gonadotropin production is stimulated by GnRH and is further regulated by feedback effects of the gonadal hormones (Figure 55–6; see also Figure 57–2).

**Regulation of Release of GnRH.** GnRH is a decapeptide with blocked amino and carboxyl termini (Table 55–2) that is derived by proteolytic cleavage of a 92-amino-acid precursor peptide. GnRH release is intermittent and is governed by a neural pulse generator in the mediobasal hypothalamus, primarily in the arcuate nucleus, that controls the frequency and amplitude of GnRH release. The GnRH pulse generator is active late in fetal life and for approximately one year after birth, but decreases considerably thereafter, presumably secondarily to CNS inhibition. Shortly before puberty, CNS inhibition decreases and the amplitude and frequency of GnRH pulses increase, particularly during sleep. As puberty progresses, the GnRH pulses increase further in amplitude and frequency until the normal adult pattern is established. The intermittent release of GnRH is crucial for the proper synthesis and release of the gonadotropins; the continuous administration of GnRH leads to desensitization and down-regulation of GnRH receptors on pituitary gonadotropes. This down-regulation forms the basis for the clinical use of long-acting GnRH analogs to suppress gonadotropin secretion (see below).

**Molecular and Cellular Bases of GnRH Action.** GnRH signals through a specific G protein–coupled receptor on gonadotropes that activates Gq/11 and stimulates the PLC-IP3-Ca2+ pathway (see Chapter 1) resulting in increased synthesis and secretion of LH and FSH. Although cyclic AMP is not the major mediator of GnRH action, binding of GnRH to its receptor also increases adenylyl cyclase activity. GnRH receptors also are present in the ovary and testis, where their physiological significance remains to be determined.

**Other Regulators of Gonadotropin Production.** Gonadal steroids regulate gonadotropin production at the level of the pituitary and the hypothalamus, but effects on the hypothalamus predominate. The feedback effects of gonadal steroids are sex-, dosage-, and time-dependent. In women, low levels of estradiol and progesterone inhibit gonadotropin production, largely through opioid action on the neural pulse generator that controls GnRH secretion. Higher and more sustained levels of estradiol have positive feedback effects that ultimately result in the gonadotropin surge that precedes ovulation. In men, testosterone inhibits gonadotropin production, in part through direct actions and in part via its conversion to estradiol.

Gonadotropin production also is regulated by the inhibins, which are members of the bone morphogenetic protein family of secreted signaling proteins. Inhibins are made by granulosa cells in the ovary and Sertoli cells in the testis in response to the gonadotropins and local growth factors. They act directly in the pituitary to inhibit FSH secretion without affecting that of LH.

**Molecular and Cellular Bases of Gonadotropin Action**

The gonadotropins (LH, FSH, and hCG), together with TSH, constitute the glycoprotein family of pituitary hor-

Physiological Effects of Gonadotropins

In men, LH acts on testicular Leydig cells to stimulate the de novo synthesis of androgens, primarily testosterone, from cholesterol. Testosterone is required for gametogenesis within the seminiferous tubules and for maintenance of libido and secondary sexual characteristics (see Chapter 58). FSH acts on the Sertoli cells to stimulate the production of proteins and nutrients required for sperm maturation, thereby indirectly supporting germ cell maturation.

In women, the actions of FSH and LH are more complicated. FSH stimulates the growth of developing ovarian follicles and induces the expression of LH receptors on theca and granulosa cells. FSH also regulates the activity of aromatase in granulosa cells, thereby stimulating the production of 17β-estradiol. LH acts on the theca cells to stimulate the de novo synthesis of androstenedione, the major precursor of ovarian 17β-estradiol in premenopausal women (see Figure 57–1). LH also is required for the rupture of the dominant follicle during ovulation and for the synthesis of progesterone by the corpus luteum.

Mutations in genes encoding the gonadotropin subunits or their cognate receptors impair sexual development and reproduction (Achermann and Jameson, 1999). Women with mutations in either FSHβ or its receptor present clinically with primary amenorrhea, infertility, and the absence of breast development. Histologically, the ovarian follicles fail to mature and corpora lutea are missing. In men, mutations of FSHβ or the FSH receptor are associated with decreased testes size and oligospermia, although several subjects have been fertile.

An inactivating mutation of LHβ has been reported in a 46-year-old XY subject with Leydig cell hypoplasia, lack of spontaneous puberty, and infertility. The external genitalia were masculinized, suggesting that androgen production in utero was driven by hCG. In contrast, apparently complete loss-of-function mutations of the LH receptor cause phenotypes ranging from male hypogonadism to male-to-female sex reversal of the external genitalia and failure to initiate puberty. Presumably, the loss of the LH receptor leads to a combined loss of responsiveness to both hCG and LH signaling in utero, which prevents virilization of the external genitalia. Women with homozygous inactivating mutations of the LH receptor present with primary amenorrhea or oligomenorrhea and infertility and have cystic ovaries on histological examination.

Mutations that constitutively activate the LH receptor cause an autosomal dominant syndrome of precocious puberty in males, a condition called testotoxicosis. The excessive production of testosterone before true puberty commences induces virilization in an LH-independent manner. A subset of these LH receptor mutations that also activate the phosphoinositide pathway has been associated with familial testicular tumors.

As illustrated in Table 55–2, a number of clinically useful GnRH analogs have been synthesized. These include synthetic GnRH (gonadorelin) and GnRH analogs that contain substitutions at position 6 that protect against proteolysis and substitutions at the C-terminus that improve receptor-binding affinity. The analogs exhibit enhanced potency and a prolonged duration of action compared to GnRH, which has a half-life of approximately 2 to 4 minutes.

Pure GnRH antagonists have been developed that do not cause the initial increase in gonadotropin secretion seen when long-acting GnRH agonists are used to down-regulate gonadotropin secretion. The antagonists used currently elicit fewer of the manifestations of local and systemic release of histamine that hampered the development of earlier compounds for clinical use.

Diagnostic Use of GnRH. Synthetic GnRH (gonadorelin hydrochloride; FACTREL) is marketed for diagnostic purposes to differentiate between pituitary and hypothalamic defects in patients with hypogonadotropic hypogonadism. After a blood sample is obtained for the baseline LH value, a single 100-μg dose of GnRH is administered subcutaneously or intravenously and serum LH levels are measured over the next 2 hours (at 15, 30, 45, 60, and 120 minutes after injection). A normal LH response to >10 mIU/ml indicates the presence of functional pituitary gonadotropes and prior exposure to GnRH.
Inasmuch as the long-term absence of GnRH can result in a decreased responsiveness of otherwise normal gonadotropes, the absence of a response does not always indicate intrinsic pituitary disease. Thus, some experts advocate use of multiple doses of GnRH in an effort to restore responsiveness of the gonadotropes. GnRH-stimulation testing also is used to determine whether a subject with precocious puberty has central (i.e., GnRH-dependent) or peripheral (i.e., GnRH-independent) precocious puberty. A GnRH-induced rise in plasma LH to greater than 10 mIU/ml in boys or 7 mIU/ml in girls is indicative of true precocious puberty rather than a GnRH-independent process. Due to intermittent problems with gonadorelin availability, some experts have employed GnRH agonists off-label as the stimulating agent for diagnostic assessment.

**Therapeutic Uses of GnRH**

**Management of Infertility.** Until recently, synthetic GnRH (gonadorelin acetate, LUTRELPULSE) was used to treat patients with reproductive disorders secondary to disordered secretion of GnRH or GnRH deficiency. In women, it was administered either intravenously or subcutaneously by a pump in pulses that promoted a physiological cycle, with a starting dose of 2.5 μg per pulse every 120 minutes. If necessary, the dose was increased to 10 to 20 μg per pulse until ovulation was induced. Advantages of gonadotropin therapy (see below) included a lower risk of multiple pregnancies and a decreased need to monitor plasma estrogen levels or follicle size by ovarian ultrasonography. Side effects generally were minimal; the most common was local irritation due to the infusion device. In women, normal cycling levels of ovarian steroids could be achieved, leading to ovulation and menstruation. Because of its complexity, this regimen was previously available only in specialized centers of reproductive endocrinology. Production was discontinued by the United States manufacturer in 2003 and GnRH is no longer available.

Two GnRH antagonists, ganirelix (ANTAGON) and cetorelix (CETROTIDE) (Table 55–2), have been used to suppress the LH surge and thus prevent premature follicular luteinization in ovarian-stimulation protocols that are part of assisted reproduction techniques. The GnRH antagonist is given either in the follicular phase (termed the “short protocol”) or in the midluteal phase (termed the “long protocol”)—in conjunction with gonadotropins—to induce follicular maturation (see below). Ovulation is then induced with hCG or LH. Because they lack the initial stimulation of gonadotropin secretion seen with GnRH agonists, the GnRH antagonists provide a more rapid effect and are likely to become the preferred drugs in this setting.

**Suppression of Gonadotropin Secretion.** As noted above, long-acting GnRH analogs eventually desensitize GnRH signaling pathways, markedly inhibiting gonadotropin secretion and decreasing the production of gonadal steroids. This pharmacological castration is useful in disorders that respond to reductions in gonadal steroids. A clear indication for this therapy is in children with gonadotropin-dependent precocious puberty, whose premature sexual maturation can be arrested with minimal side effects by chronic administration of a GnRH agonist.

Long-acting GnRH agonists are used for palliative therapy of hormonally responsive tumors (e.g., prostate or breast cancer), generally in conjunction with agents that block steroid biosynthesis or action to avoid transient increases in hormone levels (see Chapter 51). Because it does not transiently increase sex steroid production, an extended-release form of the GnRH antagonist abarelix (PLENAXIS) also is marketed for use in prostate cancer patients in whom serious adverse consequences might accompany any stimulus to tumor growth (e.g., in patients with spinal cord metastases where increased tumor growth could lead to paralysis). The GnRH agonists also are used to suppress steroid-responsive conditions such as endometriosis, uterine leiomyomas, and acute intermittent porphyria. Depot preparations of goserelin (ZOLADEX), leuprolide (LUPRON DEPOT, ELEGARD) or triptorelin (TRELSTAR LA), which can be administered subcutaneously or intramuscularly monthly or every 3 months, can be used in these settings and may be particularly useful for pharmacological castration in disorders such as paraphilia, for which strict patient compliance is problematic.

The long-acting agonists generally are well tolerated, and side effects are those that would be predicted to occur when gonadal steroidogenesis is inhibited (e.g., hot flashes, vaginal dryness and atrophy, decreased bone density). Because of these effects, therapy in non–life-threatening diseases such as endometriosis or uterine leiomyomas generally is limited to 6 months unless add-back therapy with estrogens and/or progestins is incorporated into the regimen. In addition to these predicted effects, abarelix has been associated with a significant incidence of hypersensitivity reactions, and its therapeutic role remains to be defined. For safety reasons, abarelix distribution is limited to physicians who are enrolled in the manufacturer’s prescribing program.

**Clinical Uses of Gonadotropins**

The gonadotropins are used increasingly in the arena of reproductive endocrinology. As a result, a number of formulations are available for clinical use.

**Diagnostic Uses of Gonadotropins**

**Diagnosis of Pregnancy.** Significant amounts of hCG are present in the maternal bloodstream and urine during
pregnancy and can be detected immunologically with antisera specific for its unique β-subunit. This provides the basis for commercial pregnancy kits that qualitatively assay for the presence or absence of hCG in the urine. These kits offer a rapid, noninvasive means of detecting pregnancy within a few days after a woman’s first missed menstrual period and are widely available without a prescription.

Quantitative measurements of plasma hCG concentration are made by immunoassay. These assays typically are used to assess whether or not pregnancy is proceeding normally or to help detect the presence of an ectopic pregnancy, hydatidiform mole, or choriocarcinoma. They also are employed to follow the therapeutic response of malignancies, such as germ cell tumors, that secrete hCG.

**Timing of Ovulation.** Ovulation occurs approximately 36 hours after the onset of the LH surge (10 to 12 hours after the peak of LH). Therefore, urinary concentrations of LH can be used to predict the time of ovulation. Kits are available over the counter that use LH-specific antibodies to provide a semiquantitative assessment of LH levels in urine. Urine LH levels are measured every 12 to 24 hours, beginning on day 10 to 12 of the menstrual cycle (assuming a 28-day cycle), to detect the rise in LH and thus estimate the time of ovulation. Such estimates facilitate the timing of sexual intercourse to achieve pregnancy.

**Differential Diagnosis of Diseases of Male and Female Reproduction.** Measurements of plasma LH and FSH levels, as determined by quantitative β-subunit–specific immunoassays, are useful in the diagnosis of several reproductive disorders. Low or undetectable levels of LH and FSH are indicative of hypogonadotropic hypogonadism and suggest hypothalamic or pituitary disease, whereas high levels of gonadotropins suggest primary gonadal diseases. Therefore, in cases of amenorrhea in women or delayed puberty in men and women, measurements of plasma gonadotropins can be used to distinguish between gonadal failure and hypothalamic-pituitary failure.

The FSH level on day 3 of the menstrual cycle is useful in assessing relative fertility. An FSH level of ≥10 mIU/ml is associated with reduced fertility, even if a woman is menstruating normally, and predicts a lower likelihood of success in assisted reproduction techniques such as in vitro fertilization.

The administration of hCG also is used to stimulate testosterone production and thus to assess Leydig cell function in men suspected of having Leydig cell failure (for example, in delayed puberty). Serum testosterone levels are assayed after multiple injections of hCG. A diminished testosterone response to hCG indicates Leydig cell failure; a normal testosterone response suggests a hypothalamic-pituitary disorder.

**Therapeutic Uses of Gonadotropins**

Gonadotropins are purified from human urine or prepared using recombinant DNA technology. Several preparations of urinary gonadotropins have been developed. Chorionic gonadotropin (PREGNYL, NOVAREL, PROFASI, others), which mimics the action of LH, is obtained from the urine of pregnant women. Urine from postmenopausal women is the source of menotropins (PERGONAL, REPRONEX), which contain roughly equal amounts of FSH and LH, as well as a number of other urinary proteins. Because of their relatively low purity, menotropins are administered intramuscularly to decrease the incidence of hypersensitivity reactions. Urofollitropin (uFSH; BRAVELLE) is a highly purified FSH prepared by immunoconcentration with monoclonal antibodies and pure enough to be administered subcutaneously.

Recombinant preparations of gonadotropins are assuming an increasing role in clinical practice. Recombinant FSH (rFSH) is prepared by expressing cDNAs encoding the α and β subunits of FSH in a mammalian cell line, yielding products whose glycosylation pattern mimics that of FSH produced by gonadotropes. The two rFSH preparations that are available ( follitropin α [GONAL-F] and follitropin β [PUREGON, FOLLISTIM]) differ slightly in their carbohydrate structures; both exhibit less inter-batch variability than do preparations purified from urine and can be administered subcutaneously, since they are considerably purer. The recombinant preparations are more expensive than the naturally derived hormones, and their relative advantages (i.e., efficacy, lower frequency of side effects such as ovarian hyperstimulation) have not been definitively established despite much debate in the published literature.

Recombinant forms of hCG (chorioogonadotropin alfa; OVIDREL) and LH (LUVERIS, LHADI) also have been developed and are being investigated for the treatment of infertility. Providing that their cost-benefit ratios are favorable, it is likely that these recombinant gonadotropin preparations will have an increasing role in the future, possibly replacing the urinary preparations entirely. In addition, recombinant technology is likely to lead to improved forms of gonadotropins with increased half-lives or higher clinical efficacy.

**Female Infertility.** Infertility affects approximately 10% of couples of reproductive age. Gonadotropins are used in
the treatment of infertility, either for the induction of ovulation or in conjunction with assisted reproduction technologies (Huine et al., 2004). The administration of gonadotropins in these settings should be limited to physicians experienced in the treatment of infertility or endocrine disorders. Although most clearly indicated for ovulation induction in anovulatory women with hypogonadotropic hypogonadism secondary to hypothalamic or pituitary dysfunction, gonadotropins also are used to induce ovulation in women with the polycystic ovary syndrome who do not respond to clomiphene citrate (see Chapter 57). Gonadotropins also are used in women who are infertile despite normal ovulation, although therapy with clomiphene citrate typically is attempted first.

The goal of ovulation induction in anovulatory women is to induce the formation and ovulation of a single dominant follicle. A typical therapeutic regimen is to administer 75 IU of FSH daily in a “low-dose, step-up protocol.” This dose is given daily until cycle day 6 or 7, after which transvaginal ultrasound is used to assess the number and size of developing follicles. Scans typically are performed every 2 to 3 days and focus on identifying intermediate follicles. Although the criteria used at different centers vary, the finding of a follicle larger than 18 mm in diameter indicates that follicular development has progressed adequately. If three or more follicles >16 mm are present, gonadotropin therapy generally is stopped and pregnancy prevented by barrier contraception to decrease the likelihood of multiple pregnancies or the ovarian hyperstimulation syndrome (OHSS; see below). Measurements of serum estradiol levels also may be helpful. The target estradiol range is from 500 to 1500 pg/ml, with lower levels indicating inadequate gonadotropin stimulation and higher values portending an increased risk of OHSS. If laboratory assessment indicates impaired ovarian response, the dose of FSH can be increased in increments of 37.5 IU daily to a maximum range of 225 to 450 IU/day.

To complete follicular maturation and induce ovulation, hCG (5000 to 10,000 IU) is given one day after the last dose of FSH. Despite the precautions outlined above, gonadotropin-induced ovulation results in multiple births in up to 10% to 20% of cases, due to the nonphysiological development of more than one preovulatory follicle and the release of more than one ovum.

Gonadotropin induction also is used for ovarian stimulation in conjunction with in vitro fertilization (IVF) and intracytoplasmic sperm injection (ICSI). In this setting, larger doses of FSH (typically 225 IU/day) are administered to induce the maturation of multiple follicles, thus permitting the retrieval of multiple oocytes for IVF and intratuterine transfer. In the most common “long protocol,” FSH is administered in conjunction with a GnRH analog to prevent premature ovulation. Thereafter, hCG is given to induce final oocyte development (with typical doses of 5000 to 10,000 IU of urine-derived product or 250 µg of recombinant hCG), and then the mature eggs are retrieved from the preovulatory follicles at 32 to 36 hours after hCG administration. The ova are retrieved transvaginally under ultrasound guidance, fertilized in vitro with sperm (IVF) or by sperm injection (ICSI), and then transferred to the uterus (IVF) or less frequently to the fallopian tubes (gametome intrafallopian transfer). With these approaches, the increased risk of multiple births is related to the number of embryos that are transferred to the woman, and there is a trend towards decreasing the number of embryos transferred to diminish this risk.

Aside from the risk of multiple births and its attendant complications, the major side effect of gonadotropin treatment is OHSS, which is believed to result from increased ovarian secretion of substances that increase vascular permeability and is characterized by rapid accumulation of fluid in the peritoneal cavity, thorax, and even the pericardium. Signs and symptoms include abdominal pain and/or distention, nausea and vomiting, diarrhea, marked ovarian enlargement, dyspnea, and oliguria. OHSS can lead to hypovolemia, electrolyte abnormalities, abnormal fluid accumulation (e.g., ascites, pleural effusions, and hemoperitoneum), acute respiratory distress syndrome, thromboembolic events, and hepatic dysfunction. If there is clinical suspicion that OHSS is developing, or if routine laboratory investigation reveals the presence of more than 2 follicles greater than 17 mm or an estrogen level of >1500 pg/ml, then hCG should be withheld. Clinical data suggest that ovulation induction with either a GnRH agonist or recombinant LH, whose half-life is considerably shorter than that of hCG, may diminish the incidence of OHSS.

Apart from OHSS, there is debate about the potential deleterious effects of gonadotropins. Some studies have suggested that gonadotropins are associated with an increased risk of ovarian cancer, but this conclusion is controversial. Similarly, although there is emerging evidence that IVF itself may be associated with abnormal imprinting that increases the risk of developmental syndromes such as Angelman and Beckwith-Wiedemann syndromes (Gosden et al., 2003), there is no evidence that the gonadotropins themselves increase the rate of congenital abnormalities in babies born from stimulated oocytes.

**Male Infertility.** In men with impaired fertility secondary to gonadotropin deficiency, gonadotropins can establish or restore fertility. Due to expense and to the occasional development of resistance to gonadotropins with prolonged use, standard treatment is to induce sexual development with androgens, retaining gonadotropins until fertility is desired.

Treatment typically is initiated with hCG (1500 to 2000 IU intramuscularly or subcutaneously) three times per week until clinical parameters and the plasma testosterone level indicate full induction of steroidogenesis. Thereafter, the dose of hCG is reduced to 2000 IU twice a week or 1000 IU three times a week, and menotropins (FSH + LH) or recombinant FSH is injected three times a week (typical doses for menotropins range from 75 to 150 IU or 37.5 IU for rFSH) to fully induce spermatogenesis. The most common side effect of gonadotropin therapy is gynecomastia, which occurs in up to one-third of patients and presumably reflects increased production of estrogens due to the induction of aromatase. Maturation of the prepubertal testes typically requires treatment for more than 6 months, and optimal spermatogenesis in some patients may require treatment for up to 2 years. Once spermatogenesis has been initiated by this combined therapy or in patients who develop hypogonadotropic hypogonadism after sexual maturation, ongoing treatment with hCG alone usually is sufficient to support sperm production. As discussed in the section entitled “Female Infertility,” regimens employing recombinant LH, FSH, and hCG very likely will play increasing clinical roles.
Cryptorchidism. Cryptorchidism, the failure of one or both testes to descend into the scrotum, affects up to 3% of full-term male infants and becomes less prevalent with advancing postnatal age. Cryptorchid testes have defective spermatogenesis and are at increased risk for developing germ cell tumors. Hence, the current approach is to reposition the testes as early as possible, typically at 1 year of age but definitely before 2 years of age. The local actions of androgens stimulate descent of the testes; thus, hCG can be used to induce testicular descent if the cryptorchidism is not secondary to anatomical blockage. Therapy usually consists of injections of hCG (3000 IU/m² body surface area) intramuscularly every other day for 6 doses. If this does not induce testicular descent, orchiopexy should be performed.

Physiological Roles of Oxytocin

Uterus. The human uterus has a very low level of motor activity during the first two trimesters of pregnancy. During the third trimester, spontaneous motor activity increases progressively until the sharp rise that constitutes the initiation of labor. Oxytocin stimulates the frequency and force of uterine contractions. Uterine responsiveness to oxytocin roughly parallels this increase in spontaneous activity and is highly dependent on estrogen, which increases the expression of the oxytocin receptors. Progesterone antagonizes the stimulant effect of oxytocin in vitro, and a decline in progesterone receptor signaling in late pregnancy may contribute to the normal initiation of human parturition. Because of difficulties associated with the measurement of oxytocin levels (see above) and because loss of pituitary oxytocin apparently does not compromise labor and delivery, the physiological role of oxytocin in pregnancy has been highly debated. Exogenous oxytocin can initiate or enhance rhythmic contractions at any time, but a considerably higher dose is required in early pregnancy. An eightfold increase in uterine sensitivity to oxytocin occurs in the last half of pregnancy, mostly in the last 9 weeks, accompanied by a thirtyfold increase in oxytocin receptor number between early pregnancy and early labor. The finding that the oxytocin antagonist atosiban (TRACTOCILE) is effective in suppressing preterm labor (see below) further supports the physiological importance of oxytocin in this setting.

Breast. Oxytocin plays an important physiological role in milk ejection. Stimulation of the breast through suckling or mechanical manipulation induces oxytocin secretion, causing contraction of the myoepithelium that surrounds alveolar channels in the mammary gland. This action forces milk from the alveolar channels into large collecting sinuses, where it is available to the suckling infant.

Biosynthesis of Oxytocin

Oxytocin is a cyclic nonapeptide that differs from vasopressin by only two amino acids. It is synthesized as a larger precursor molecule in cell bodies of the paraventricular nucleus, and to a lesser extent, the supraoptic nucleus in the hypothalamus. The precursor is rapidly converted by proteolysis to the active hormone and its neurophysin, packaged into secretory granules as an oxytocin-neurophysin complex, and secreted from nerve endings that terminate primarily in the posterior pituitary gland (neurohypophysis). In addition, oxytocinergic neurons that regulate the autonomic nervous system project to regions of the hypothalamus, brainstem, and spinal cord. Other sites of oxytocin synthesis include the luteal cells of the ovary, the endometrium, and the placenta.

Stimuli for oxytocin secretion include sensory stimuli arising from dilation of the cervix and vagina and from suckling at the breast. Increases in circulating oxytocin in women in labor are difficult to detect, partly because of the pulsatile nature of oxytocin secretion and partly because of the activity of circulating oxytocinase. Nevertheless, increased oxytocin in maternal circulation is detected in the second stage of labor, likely triggered by sustained distension of the uterine cervix and vagina. Estradiol stimulates oxytocin secretion, whereas the ovarian polypeptide relaxin inhibits release. The inhibitory effect of relaxin appears to be the net result of a direct stimulatory effect on oxytocin-producing cells and an inhibitory action mediated indirectly by endogenous opioids. Other factors that primarily affect vasopressin secretion also have some impact on oxytocin release (e.g., ethanol inhibits release, while pain, dehydration, hemorrhage, and hypovolemia stimulate release). Although peripheral actions of oxytocin appear to play no significant role in the response to dehydration, hemorrhage, or hypovolemia, oxytocin may participate in the central regulation of blood pressure. As described below, pharmacological doses of oxytocin can inhibit free water clearance by the kidney through activity similar to that of arginine vasopressin at vasopressin V₂ receptors, occasionally causing water intoxication if administered with large volumes of hypotonic fluid.
Mechanism of Action

Oxytocin acts via specific G protein–coupled receptors closely related to the V₁a and V₂ vasopressin receptors. In the human myometrium, these receptors couple to G₉ and G₁₁, activating the PLCβ-IP₃-Ca²⁺ pathway and enhancing activation of voltage-sensitive Ca²⁺ channels. Oxytocin also increases local prostaglandin production, which further stimulates uterine contractions.

Clinical Use of Oxytocin

Induction of Labor. Uterine-stimulating agents are used most frequently to induce or augment labor in selected pregnant women. Indications for induction of labor include situations in which the risk of continued pregnancy to the mother or fetus is considered to be greater than the risks of delivery or of pharmacological induction. Such circumstances include premature rupture of the membranes, isoimmunization, fetal growth restriction, and uteroplacental insufficiency (as in diabetes, preeclampsia, or eclampsia). Before labor is induced, it is essential to verify that the fetal lungs are sufficiently mature (i.e., the lecithin-sphingomyelin ratio in amniotic fluid is >2) and to exclude potential contraindications (e.g., abnormal fetal position, evidence of fetal distress, placental abnormalities, or previous uterine surgery that predisposes the uterus to rupture during labor).

Oxytocin (PITOCIN, SYNOTCINON) is the drug of choice for labor induction. It is administered by intravenous infusion of a diluted solution (typically 10 mIU/mL), preferably by means of an infusion pump. Although there is continuing debate concerning the optimal dose to induce labor, some physicians use a protocol involving an initial dose of 1 mIU/minute, with dose increases of no greater than 1 mIU/minute every 30 to 40 minutes. Other authorities advocate a more aggressive approach, with starting doses of 6 mIU/minute and increases of up to 2 mIU/minute at 20-minute intervals. Some published trials have suggested that the higher-dose regimens result in a lower rate of cesarean sections. If doses of 40 mIU/minute fail to initiate satisfactory uterine contractions, higher rates of infusion are unlikely to be successful. As labor progresses, the dose of oxytocin required to maintain good uterine contractions may decrease.

During labor induction, a physician must be immediately available, and the mother and fetus should be monitored continuously to determine fetal and maternal heart rates, maternal blood pressure, and the strength of uterine contractions. If uterine hyperstimulation occurs, as evidenced by too-frequent contractions or the development of uterine tetany, the oxytocin should be discontinued immediately. The half-life of intravenous oxytocin is short (~3 minutes); thus the hyperstimulatory effects of oxytocin should resolve within several minutes after the infusion is stopped. Because of its structural similarity to vasopressin, oxytocin at higher doses has antidiuretic effects and infusions of ≥20 mIU/minute decrease free water clearance by the kidney. Particularly if hypotonic fluids (e.g., dextrose in water) are infused too liberally, water intoxication may result in convulsions, coma, and even death. Vasodilating actions of oxytocin also have been noted, particularly at high doses, which may provoke hypotension and reflex tachycardia. Deep anesthesia may exaggerate the hypotensive effect of oxytocin by preventing the reflex tachycardia.

Augmentation of Labor. Because the resulting uterine hyperstimulation often is too forceful and sustained to be compatible with the safety of the mother and fetus, oxytocin generally should not be used to augment labor that is progressing normally. To augment hypotonic contractions in dysfunctional labor, it rarely is necessary to exceed an infusion rate of 10 mIU/minute, and doses of >20 mIU/minute rarely are effective when lower concentrations fail. Potential complications of overstimulation include trauma of the mother or fetus due to forced passage through an incompletely dilated cervix, uterine rupture, and compromised fetal oxygenation due to decreased uterine perfusion. In the setting of dysfunctional labor, as seen most frequently in nulliparous women, oxytocin can be used to advantage by experienced obstetricians to facilitate labor progression. Oxytocin usually is effective when there is a prolonged latent phase of cervical dilation and when, in the absence of cephalopelvic disproportion, there is an arrest of dilation or descent. Epidural anesthesia can impair the reflex stimulation of endogenous oxytocin during the second stage of labor; in this setting, the cautious administration of oxytocin may facilitate labor progression.

Third Stage of Labor and Puerperium. Postpartum hemorrhage is a significant problem in developed nations and is of even greater importance in underdeveloped countries. After delivery of the fetus or after therapeutic abortion, a firm, contracted uterus greatly reduces the incidence and extent of hemorrhage. Oxytocin (10 IU/minute intramuscularly) often is given immediately after delivery to help maintain uterine contractions and tone. Alternatively, 20 IU of oxytocin is diluted in 1 L of intravenous solution and infused at a rate of 10 ml/minute until the uterus is contracted. Then the infusion rate is reduced to 1 to 2 ml/minute until the mother is ready for transfer
to the postpartum unit. If this is ineffective, ergot alkaloids such as ergonovine maleate (ERGOTRATE) or its methyl analog methylergonovine maleate (METHERGINE) or the prostaglandin analog misoprostol may be used in normotensive patients. The ergot alkaloids are discussed in more detail in Chapter 11; prostaglandins are discussed in Chapter 25.

**Oxytocin Challenge Test.** In patients whose pregnancy holds increased risk for maternal or fetal complications (e.g., maternal diabetes mellitus or hypertension), an oxytocin challenge test can be used to assess fetal well-being. Oxytocin is infused intravenously, initially at a rate of 0.5 mIU/minute; this rate is increased slowly until 3 uterine contractions occur in 10 minutes. Concurrent monitoring of the fetal heart rate indicates whether or not the uterine contractions are associated with changes in fetal heart rate known to be associated with fetal distress. The outcome of the oxytocin challenge test is helpful in determining the presence of adequate placental reserve for continuation of high-risk pregnancies.

**Oxytocin-Receptor Antagonists**

Peptide analogs that competitively inhibit the interaction of oxytocin with its membrane receptor have been developed, and one such antagonist, atosiban, has been introduced in a number of countries for the treatment of preterm labor. In clinical trials, atosiban decreased the frequency of uterine contractions and increased the number of women who remained undelivered, with at least comparable efficacy to β-adrenergic agonists but with a lower incidence of side effects (Tsatsaris et al., 2004). To date, however, studies have not demonstrated a significant improvement in infant outcome. Establishing the relative roles of atosiban and other oxytocin receptor antagonists under development versus agents such as calcium channel blockers in premature labor remains an area of active investigation.

**CLINICAL SUMMARY**

We continue to make advances in the pharmacotherapy of certain endocrine and reproductive disorders. In children, the indications for growth hormone therapy have been expanded beyond patients with classic, unequivocal growth hormone deficiency, and the drug increasingly is used in conditions such as Turner’s syndrome, chronic renal failure, cystic fibrosis, and other conditions associated with short stature, including idiopathic short stature. Although it remains controversial, growth hormone also is used increasingly to treat adults with growth hormone deficiency, with proposed benefits that include increased muscle mass, decreased adiposity, increased bone mineral density, and improved subjective well-being. Adverse effects occur more commonly in adults, and the dose should be adjusted so that the serum IGF-1 level is in the mid-normal range.

Pharmacotherapy also plays an important role in the treatment of functional tumors that produce growth hormone (acromegaly) or prolactin (prolactinomas). For acromegaly, sustained-release preparations of somatostatin analogs normalize growth hormone and IGF-1 levels in approximately 65% of patients. Pegvisomant, a growth hormone receptor antagonist, is even more effective, normalizing these parameters in up to 90% of patients. For prolactinomas, dopamine receptor antagonists remain the mainstay of treatment; cabergoline is preferred by many patients because of its lower incidence of side effects relative to other agents.

Another important use of the pituitary hormones is in reproductive medicine. Both GnRH receptor agonists and GnRH receptor antagonists can be used to down-regulate gonadotropin levels and block endogenous production of sex steroids. Indications include interruption of precocious puberty, therapy of cancers whose growth is stimulated by sex steroids (e.g., breast, prostate), and suppression of endogenous gonadotropins in assisted reproduction technologies. Gonadotropins are frequently used in assisted reproduction technologies to stimulate follicular maturation and to induce ovulation. Although debate continues about relative efficacy and cost-benefit factors of these alternative therapies, recombinant gonadotropins largely are replacing gonadotropins purified from human urine in clinical use.

Oxytocin is used to induce labor or to augment its progression. After delivery, oxytocin also can be used to increase uterine tone and diminish postpartum hemorrhage. In contrast, the oxytocin receptor antagonist, atosiban, can be used to suppress uterine contractions in the setting of premature labor; its precise role relative to other drugs is still under evaluation.

**BIBLIOGRAPHY**

Section XII / Hormones and Hormone Antagonists

Thyroid hormones, the only known iodine-containing compounds with biological activity, have two important functions. In developing animals and human beings, they are crucial determinants of normal development, especially in the central nervous system (CNS). In the adult, thyroid hormones act to maintain metabolic homeostasis, affecting the function of virtually all organ systems. To meet these requirements, the thyroid gland contains large stores of preformed hormone. Metabolism of the thyroid hormones occurs primarily in the liver, although local metabolism also occurs in target tissues such as the brain. Serum concentrations of thyroid hormones are precisely regulated by the pituitary hormone, thyrotropin, in a classic negative-feedback system. The predominant actions of thyroid hormone are mediated via binding to nuclear thyroid hormone receptors (TRs) and modulating transcription of specific genes. In this regard, thyroid hormones share a common mechanism of action with steroid hormones, vitamin D, and retinoids, whose receptors make up a superfamily of nuclear receptors (see Chapter 1). As with steroid hormones, it has become clear that thyroid hormones also have diverse nongenomic actions (Yen and Chin, 2005).

Disorders of the thyroid are common. They consist of two general presentations: changes in the size or shape of the gland or changes in secretion of hormones from the gland. Thyroid nodules and goiter in the euthyroid patient are the most common endocrinopathies and can be caused by benign and malignant tumors. Overt hyper- and hypothyroidism often exhibit dramatic clinical manifestations; however, more subtle presentations require the use of biochemical tests of thyroid function. Screening of the newborn population for congenital hypothyroidism, followed by the institution of appropriate thyroid hormone replacement therapy, has dramatically decreased the incidence of mental retardation and cretinism in the United States. Congenital hypothyroidism due to iodine deficiency remains the major preventable cause of mental retardation worldwide, although much progress has been made to eradicate iodine deficiency.

Effective treatment of most thyroid disorders is readily available. Treatment of the hypothyroid patient is straightforward and consists of hormone replacement. There are more options for treatment of the hyperthyroid patient, including the use of antithyroid drugs to decrease hormone synthesis and secretion and destruction of the gland by the administration of radioactive iodine or by surgical removal. Treatment of thyroid disorders in general is extremely satisfying, as most patients can be either cured or have their diseases controlled (Braverman and Utiger, 2005).

The thyroid gland is the source of two fundamentally different types of hormones. The iodothyronine hormones include thyroxine (T₄) and 3,5,3′-triiodothyronine (T₃); they are essential for normal growth and development and play an important role in energy metabolism. The other known secretory product of the thyroid, calcitonin, is produced by the parafollicular (C–) cells and is discussed in Chapter 61.

**History.** The thyroid gland was described by Galen and was named “glandulae thyroidaeae” by Wharton in 1656. For two centuries thereafter, various clinicians offered opinions about the gland’s function (Harington, 1935): that the viscous fluid within the follicles lubricated the trachea and that the gland was larger in women, to serve a cosmetic function in giving grace to the contour of the neck (Wharton); that the liberal blood supply of the gland provided a vascular shunt for the brain; that the larger size of the gland in women was “necessary to guard the female system from the influence of the...
more numerous causes of irritation and vexation of mind to which they are exposed than the male sex” (Rush), a view opposed by Hoffrichter, who pointed out, “If it were indeed true that the thyroid contains more blood at some times than at others, this effect would be visible to the naked eye; in this case women would certainly have long ceased to go about with bare necks, for husbands would have learned to recognize the swelling of this gland as a danger signal of threatening trouble from their better halves.” Reading this, one cannot but wonder at how future scientists will look upon some of the biomedical opinions of our own age.

The thyroid was first recognized as an organ of importance when enlargement was observed to be associated with changes in the eyes and the heart in the condition we now call hyperthyroidism. This condition, the manifestations of which can be as striking as any in medicine, escaped description until Parry saw his first case in 1786. Parry’s account, published in 1825, was followed in 1835 and 1840 by those of Graves and Basedow, whose names became applied to the disorder. In 1874, Gull associated atrophy of the gland with the symptoms now known to be characteristic of hypothyroidism, also known in adults as Gull’s disease. The term myxedema was applied to the clinical syndrome in 1878 by Ord in the belief that the characteristic thickening of the subcutaneous tissues was due to excessive formation of mucus.

Extripation experiments to elucidate the function of the thyroid were at first misinterpreted because of the simultaneous removal of the parathyroids. However, Gley’s research on the parathyroid glands in the late 19th century allowed the functional differentiation of these two endocrine glands. Only after calcitonin was discovered in 1961 was it realized that the thyroid also plays a role in the regulation of Ca$^{2+}$. In 1891, Murray first treated a case of hypothyroidism by injecting an extract of the thyroid gland; in 1892, Howitz, Mackenzie, and Fox independently discovered that thyroid tissue was fully effective when given by mouth.

Magnus-Levy discovered the effect of the thyroid on metabolic rate in 1895; he found that Gull’s disease was characterized by a low rate of metabolism and that the administration of thyroid to hypothyroid or normal individuals increased oxygen consumption.

Chemistry of Thyroid Hormones. The principal hormones of the thyroid gland are the iodine-containing amino acid derivatives of thyronine—$T_4$ and $T_3$; Figure 56–1). Thyroxine was isolated and crystallized from a hydrolysate of thyroid by Kendall in 1915; he found that the crystalline product exerted the same physiological effects as the extract from which it was obtained. Eleven years later, Harington elucidated the structural formula of thyroxine, and in 1927 Harington and Barger synthesized the hormone.

Following the isolation and the chemical identification of thyroxine, it was generally believed that all the hormonal activity of thyroid tissue could be accounted for by its content of thyroxine. However, careful studies revealed that crude thyroid preparations possessed greater calorigenic activity than could be accounted for by their thyroxine content. The enigma was resolved with the detection of its content of thyroxine. The enigma was resolved with the detection of triiodothyronine by Gross and Pitt-Rivers (1952). Triiodothyronine is qualitatively similar to thyroxine but is much more potent on a molar basis.

The structural requirements for a significant degree of thyroid hormone activity have been defined (Cody, 2005; Baxter et al., 2004). The 3'-monosubstituted compounds are more active than the 3',5'-disubstituted molecules. Thus, triiodothyronine is five times more potent than thyroxine, while 3'-isopropyl-3,5-diiodothyronine has seven times the activity.

Figure 56–1. Thyronine, thyroid hormones, and precursors.

---

Section XII / Hormones and Hormone Antagonists
Although the chemical nature of the 3, 5, 3′, and 5′ substituents is important, their effects on the conformation of the molecule are even more so. In thyronine, the two rings are angulated at about 120˚ at the ether oxygen and are free to rotate on their axes. As depicted schematically in Figure 56–2, the 3,5 iodines restrict rotation of the two rings, which tend to take up positions perpendicular to one another. While not potent, even halogen-free derivatives possess some activity if they have the proper conformation. In general, the affinity of iodothyronines for the TRs parallels their biological potency (Yen and Chin, 2005), but additional factors can affect therapeutic potency, including affinity for plasma proteins, rate of metabolism, and rate of entry into cell nuclei. There are, for instance, T4 transporters resembling the monocarboxylate transporter MCT8.

Recent structure–activity correlations indicate that certain plant flavonoids that are long-standing folk remedies can exhibit antithyroid properties, including inhibition of the enzyme that catalyzes 5′ (outer, or tyrosyl ring) deiodination of T4 (type I iodothyronine 5′-deiodinase) (Cody, 2005). These compounds are also potent competitors of thyroxine binding to transthyretin. Computer graphic modeling suggests that the best structural homology between thyroid hormones and flavonoids involves their respective phenolic rings.

**Biosynthesis of Thyroid Hormones.** The synthesis of the thyroid hormones is unique, complex, and seemingly grossly inefficient. The thyroid hormones are synthesized and stored as amino acid residues of thyroglobulin, a protein constituting the vast majority of the thyroid follicular colloid. The thyroid gland is unique in storing great quantities of potential hormone in this way, and extracellular thyroglobulin can represent a large portion of the thyroid mass. Thyroglobulin is a complex glycoprotein made up of two apparently identical subunits, each of 330,000 daltons. Interestingly, molecular cloning has revealed that thyroglobulin belongs to a superfamily of serine hydrolases, including acetylcholinesterase (see Chapter 7).

The major steps in the synthesis, storage, release, and interconversion of thyroid hormones are the following: (1) uptake of iodide ion (I−) by the gland; (2) oxidation of iodide and the iodination of tyrosyl groups of thyroglobulin; (3) coupling of iodothyrosine residues by ether linkage to generate the iodothyronines; (4) resorption of the thyroglobulin colloid from the lumen into the cell; (5) proteolysis of thyroglobulin and the release of thyroxine and triiodothyronine into the blood; (6) recycling of the iodine within the thyroid cell via de-iodination of mono- and diiodothyrosines and reuse of the I−; and (7) conversion of thyroxine (T4) to triiodothyronine (T3) in peripheral tissues as well as in the thyroid. These processes are summarized in Figure 56–3 and described in the correspondingly labeled sections below.

**1. Uptake of Iodide.** Iodine ingested in the diet reaches the circulation in the form of iodide. Under normal circumstances, its concentration in the blood is very low (0.2 to 0.4 μg/dl; about 15 to 30 nM), but the thyroid efficient...
ly and actively transports the ion via a specific, membrane-bound protein, termed the sodium-iodide symporter (NIS) (Dohan et al., 2003). As a result, the ratio of thyroid to plasma iodide concentration is usually between 20 and 50 and can far exceed 100 when the gland is stimulated. The iodide transport mechanism is inhibited by a number of ions such as thiocyanate and perchlorate (Figure 56–3). Thyrotropin (thyroid-stimulating hormone [TSH]; see below) stimulates the NIS, which is controlled by an autoregulatory mechanism. Thus, decreased stores of thyroid iodine enhance iodide uptake, and the administration of iodide can reverse this situation by decreasing NIS protein expression (Eng et al., 1999).

The NIS is more easily studied when further metabolism of I\(^-\) is inhibited by antithyroid drugs. Thus, the NIS has been identified in many other tissues, including the salivary glands, gastric mucosa, midportion of the small intestine, choroid plexus, skin, mammary gland, and perhaps the placenta, all of which maintain a concentration of iodide greater than that of the blood (Carrasco, 2005). Iodide accumulation by the placenta and mammary gland may provide adequate supplies for the fetus and infant; no obvious purpose is served by the accumulation of iodide at the other sites.

2. Oxidation and Iodination. Consistent with the conditions generally necessary for halogenation of aromatic rings, the iodination of tyrosine residues requires the iodinating species to be in a higher state of oxidation than is the anion. The exact nature of the iodinating species was uncertain for many years. However, Magnusson and coworkers (1984) have provided convincing evidence that it is hypooiodate, either as hypooiodous acid or as an enzyme-linked species.

The oxidation of iodide to its active form is accomplished by thyroid peroxidase, a heme-containing enzyme that utilizes hydrogen peroxide (H\(_2\)O\(_2\)) as the oxidant (Arvan, 2005). The peroxidase is membrane-bound and appears to be concentrated at or near the apical surface of the thyroid cell. The reaction results in the formation of moniodotyrosyl and diiodotyrosyl residues in thyroglobulin just prior to its extracellular storage in the lumen of the thyroid follicle. The formation of the H\(_2\)O\(_2\) occurs as a substrate for the peroxidase probably occurs near its site of utilization and is stimulated by a rise in cytosolic Ca\(^{2+}\) (Takasu et al., 1987). The TSH receptor is notably promiscuous in its coupling, stimulating members of four G protein families including G\(_{12}\) which couples to the PLC-IP\(_3\)-Ca\(^{2+}\) pathway (Laugwitz et al., 1996); thus, a Ca\(^{2+}\)-dependent effect on H\(_2\)O\(_2\) production may be a means by which TSH stimulates the organification of iodide in thyroid cells.

3. Formation of Thyroxine and Triiodothyronine from Iodotyrosines. The remaining synthetic step is the coupling of two diiodotyrosyl residues to form thyroxine or of moniodotyrosyl and diiodotyrosyl residues to form triiodothyronine. These oxidative reactions apparently are catalyzed by the same peroxidase discussed above. The mechanism involves the enzymatic transfer of groups, perhaps as iodotyrosyl free radicals or positively charged ions, within thyroglobulin. Although many other proteins can serve as substrates for the peroxidase, none is as efficient as thyroglobulin in yielding thyroxine. The conformation of the protein is thus presumed to facilitate this coupling reaction. Thyroxine formation primarily occurs near the amino terminus of the protein, while most of the triiodotyrosine is synthesized near the carboxy terminus (Dunn and Dunn, 2000). The relative rates of synthetic activity at the various sites depend on the concentration of TSH and the availability of iodide. This may account, at least in part, for the long-known relationship between the proportion of thyroxine and triiodothyronine formed in the thyroid and the availability of iodide or the relative quantities of the two iodotyrosines. For example, when there is a deficiency of iodine in rat thyroid, the ratio of thyroxine to triiodothyronine decreases from 4:1 to 1:3 (Greer et al., 1968). Because triiodothyronine is the transcriptionally active iodothyronine and contains only three-fourths as much iodine, a decrease in the quantity of available iodine need have little impact on the effective amount of thyroid hormone elaborated by the gland. Although a decrease in the availability of iodide and the associated increase in the proportion of moniodotyrosine favor the formation of triiodothyronine over thyroxine, a deficiency in diiodotyrosine ultimately can impair the formation of both compounds. In addition to the coupling reaction, intrathyroidal and secreted T\(_3\) is generated by the 5′-deiodination of thyroxine.

4. Resorption; 5. Proteolysis of Colloid; 6. Secretion of Thyroid Hormones. Since T\(_4\) and T\(_3\) are synthesized and stored within thyroglobulin, proteolysis is an important part of the secretory process. This process is initiated by endocytosis of colloid from the follicular lumen at the apical surface of the cell, with the participation of a thyroglobulin receptor, megalin. This “ingested” thyroglobulin appears as intracellular colloid droplets, which apparently fuse with lysosomes containing the requisite proteolytic enzymes. It is generally believed that thyroglobulin must be completely broken down into its constituent amino acids for the hormones to be released. As the molecular mass of thyroglobulin is 660,000 daltons, and the protein is made up of about 300 carbohydrate residues and 5500 amino acid residues, only two to five of which are thyrox-
ine, this is an extravagant process. TSH appears to enhance the degradation of thyroglobulin by increasing the activity of several thiol endopeptidases of the lysosomes. The endopeptidases selectively cleave thyroglobulin, yielding hormone-containing intermediates that subsequently are processed by exopeptidases (Dunn and Dunn, 2000). The liberated hormones then exit the cell, presumably at its basal membrane. When thyroglobulin is hydrolyzed, monoiodotyrosine and diiodotyrosine also are liberated but usually do not leave the thyroid. Instead, they are selectively metabolized; the iodine, liberated in the form of iodide, is reincorporated into protein. Normally, all this iodide is reused; however, when proteolysis is activated intensely by TSH, some of the iodide reaches the circulation, at times accompanied by trace amounts of the iodotyrosines.

7. Conversion of Thyroxine to Triiodothyronine in Peripheral Tissues. The normal daily production of thyroxine is estimated to range between 70 and 90 μg, while that of triiodothyronine is between 15 and 30 μg. Although triiodothyronine is secreted by the thyroid, metabolism of thyroxine by sequential monodeiodination in the peripheral tissues accounts for about 80% of circulating triiodothyronine (Figure 56–4). Removal of the 5′, or outer ring, iodine leads to the formation of triiodothyronine and is the “activating” metabolic pathway. The major nonthyroidal site of conversion of T4 to T3 is the liver. Thus, when thyroxine is given to hypothyroid patients in doses that produce normal plasma concentrations of thyroxine, the plasma concentration of T3 also normalizes (Braverman et al., 1970). Most peripheral target tissues utilize T3 that is derived from the circulating hormone. Notable exceptions are the brain and pituitary, where local generation of T3 is the major source of intracellular hormone. Removal of the iodine on position 5 of the inner ring produces the metabolically inactive 3,3′,5′-triiodothyronine (reverse T3, rT3; Figure 56–1). Under normal conditions, about 41% of T4 is converted to T3, about 38% is converted to reverse T3, and about 21% is metabolized via other pathways, such as conjugation in the liver and excretion in the bile. Normal circulating concentrations of T4 in plasma range from 4.5 to 11 μg/dl, while those of T3 are about one hundredfold less (60 to 180 ng/dl).

The enzymes that convert thyroxine to triiodothyronine are iodothyronine 5′-deiodinases, which exist as two distinct isozymes that are differentially expressed and regulated in peripheral tissues (Figure 56–5). Type I 5′-deiodinase (D1) is found in the liver, kidney, and thyroid and generates circulating T3 that is utilized by most peripheral target tissues. Although 5′-deiodination is the major

---

**Figure 56–4. Pathways of iodothyronine deiodination.**
function of this isozyme, D1 also catalyzes 5-deiodination. D1 is inhibited by a variety of factors (Table 56–1), including the antithyroid drug propylthiouracil (see below). The decreased plasma triiodothyronine concentrations observed in nonthyroidal illnesses result from inhibition of D1 (Farwell and Dubord-Tomasetti, 1999) and decreased entrance of thyroxine into cells. D1 is up-regulated in hyperthyroidism and down-regulated in hypothyroidism. The cloning of D1 identified the enzyme as a selenoprotein that contains a selenocystine at the active site. Type II 5′-deiodinase (D2), also a selenoprotein, is distributed in the brain, pituitary, skeletal and cardiac muscle, and in the rat, in brown fat. It primarily supplies intracellular triiodothyronine to these tissues (Visser et al., 1982). D2 has a much lower $K_m$ for thyroxine than does D1 (nM vs. μM $K_m$ values), and its activity is unaffected by propylthiouracil. D2 is dynamically regulated by its substrate, thyroxine, such that elevated levels of the enzyme are found in hypothyroidism and suppressed levels are found in hyperthyroidism. Thus, D2 appears to autoregulate the intracellular supply of triiodothyronine in the brain and pituitary. A D2-like selenoprotein DNA has been cloned from frog skin and from mammalian sources; however, some controversy still exists on the exact biochemical nature of D2. Inner ring- or 5-deiodination, a main inactivating pathway for T3, is catalyzed by type III deiodinase (D3), which is found in placenta, skin, uterus, and brain. The three deiodinases comprise a family of selenoproteins encoded by different genes (Bianco and Larsen, 2005).

**Transport of Thyroid Hormones in the Blood.** Iodine in the circulation is normally present in several forms, with 95% as organic iodine and approximately 5% as iodide. Most organic iodine is thyroxine (90% to 95%), while triiodothyronine represents a relatively minor fraction (about 5%). The thyroid hormones are transported in the blood in strong but noncovalent association with certain plasma proteins (Benvenga, 2005).

Thyroxine-binding globulin (TBG) is the major carrier of thyroid hormones. It is an acidic glycoprotein with a molecular mass of approximately 63,000 daltons that binds one molecule of T4 per molecule of protein with a very high affinity (the equilibration association constant, $K_a$, is approximately $10^{10} \text{ M}^{-1}$). T3 is bound less avidly. Thyroxine, but not triiodothyronine, also is bound by transthyretin (thyroxine-binding prealbumin), a retinol-binding protein. This protein is present in higher concentration than is TBG and primarily binds thyroxine with an equilibrium association constant near $10^7 \text{ M}^{-1}$. Transthyretin has four apparently identical subunits but only a single high-affinity binding site. Albumin also can bind thyroxine when the more avid carriers are saturated but it is difficult to estimate its quantitative or physiological importance except in familial dysalbuminemic hyperthyroxinemia. This syndrome is an autosomal dominant disorder characterized by the increased affinity of albumin for thyroxine due to a point mutation in the albumin gene. Thyroxine binds also to the apolipoproteins of the high density lipoproteins, HDL$_2$ and HDL$_3$, the significance of which is unclear (Benvenga et al., 1992).

Binding of thyroid hormones to plasma proteins protects the hormones from metabolism and excretion, resulting in their long half-lives in the circulation. The free (unbound) hormone is a small percentage (about 0.03% of thyroxine and about 0.3% of triiodothyronine) of the total hormone in plasma. The differential binding affinities for serum proteins also are reflected in the ten- to one hundredfold differences in circulating hormone concentrations and half-lives of T4 and T3.

Essential to understanding the regulation of thyroid function is the “free hormone” concept: only the unbound hormone has metabolic activity. Thus, because of the high degree of binding of thyroid hormones to plasma proteins,
changes in either the concentrations of these proteins or the binding affinity of the hormones for the proteins has major effects on the total serum hormone levels. Certain drugs and a variety of pathological and physiological conditions, such as the changes in circulating concentrations of estrogens during pregnancy or during the administration of oral estrogens, can alter both the binding of thyroid hormones to plasma proteins and the amounts of these proteins (Table 56–2). However, since the pituitary responds to and regulates circulating free hormone levels, minimal changes in free hormone concentrations are seen. Therefore laboratory tests that measure only total hormone levels can be misleading. Appropriate tests of thyroid function are discussed later in this chapter.

Degradation and Excretion (Figure 56–6). Thyroxine is eliminated slowly from the body, with a half-life of 6 to 8 days. In hyperthyroidism, the half-life is shortened to 3 or 4 days, whereas in hypothyroidism it may be 9 to 10 days. These changes presumably reflect altered rates of metabolism of the hormone. In conditions associated with increased binding to TBG, such as pregnancy, clearance is retarded. The increase in TBG is due to the estrogen-induced increase in the sialic acid content of the synthesized TBG, resulting in decreased TBG clearance. The opposite effect is observed when there is reduced protein binding of thyroid hormones or when binding to protein is inhibited by certain drugs (Table 56–2). T3, which is less avidly bound to protein, has a half-life of approximately 1 day.

The liver is the major site of non-deiodinative degradation of thyroid hormones; T4 and T3 are conjugated with glucuronic and sulfuric acids through the phenolic hydroxyl group and excreted in the bile. Some thyroid hormone is liberated by hydrolysis of the conjugates in the intestine and reabsorbed. A portion of the conjugated material reaches the colon unchanged, where it is hydrolyzed and eliminated in feces as the free compounds.

As discussed above, the major route of metabolism of T4 is deiodination to either T3 or reverse T3. Triiodothyronine and reverse T3 are deiodinated to three different diiodothyronines, which are further deiodinated to two monoiodothyronines (Figure 56–4), inactive metabolites that are normal constituents of human plasma. Additional metabolites (monoiodotyrosine and diiodotyrosine) in which the diphenyl ether linkage is cleaved have been detected both in vitro and in vivo.

Regulation of Thyroid Function. Cellular changes occur in the anterior pituitary in association with endemic goiter or following thyroidectomy. The classical observations of Cushing in 1912 and of Simmonds two years later estab-
lished that ablation or disease of the pituitary causes thyroid hypoplasia (Simmonds, 1914). It eventually was determined that thyrotropes of the anterior pituitary secrete thyrotropin, or TSH. TSH is a glycoprotein hormone with α and β subunits analogous to those of the gonadotropins. Its structure is discussed with those of other glycoprotein hormones in Chapter 55. Although there was evidence that thyroid hormone or its lack causes cellular changes in the pituitary, the control of secretion of TSH by the negative-feedback action of thyroid hormone was not appreciated fully until its central role in the pathogenesis of goiter was elucidated in the early 1940s. TSH is secreted in a pulsatile manner and circadian pattern, its levels in the circulation being highest during sleep at night. TSH secretion is precisely controlled by the hypothalamic peptide thyrotropin-releasing hormone (TRH) and by the concentration of free thyroid hormones in the circulation. Extra thyroid hormone inhibits transcription of both the TRH gene (Wilber and Xu, 1998) and the genes encoding the α and β subunit of thyrotropin, which suppresses the secretion of TSH and causes the thyroid to become inactive and regress. Any decrease in the normal rate of thyroid hormone secretion by the thyroid evokes an enhanced secretion of TSH in an attempt to stimulate the thyroid to secrete more hormone. Additional mechanisms of the effect of thyroid hormone on TSH secretion appear to be a reduction in TRH secretion by the hypothalamus and a reduction in the number of TRH receptors on pituitary cells. Figure 56–7 summarizes the regulation of thyroid hormone secretion.

**Thyrotropin-Releasing Hormone (TRH).** TRH stimulates the release of preformed TSH from secretory granules and also stimulates the subsequent synthesis of both α and β subunits of TSH. Somatostatin (SST), dopamine, and pharmacological doses of glucocorticoids inhibit TRH-stimulated TSH secretion.

TRH is a tripeptide with both terminal amino and carboxyl groups blocked (L-pyroglutamyl-L-histidyl-L-proline amide). The mature hormone is derived from a precursor protein that contains six copies of the tripeptide flanked by dibasic residues. TRH is synthesized by the hypothalamus and released into the hypophyseal-portal circulation, where it interacts with TRH receptors on thyrotropes. The binding of TRH to its receptor, a GPCR, stimulates the G_\text{q}\text{-PLC-IP}_3\text{-Ca}^{2+} pathway and activates protein kinase C, ultimately stimulating the synthesis and release of TSH by the thyrotropes.

TRH also has been localized in the CNS in the cerebral cortex, circumventricular structures, neurohypophysis, pineal gland, and spinal cord. These findings, as well as its localization in nerve endings, suggest that TRH may act as a neurotransmitter or neuromodulator outside of the hypothalamus. Administration of TRH to animals produces CNS-mediated effects on behavior, thermoregulation, autonomic tone, and cardiovascular function, including increases in blood pressure and heart rate. TRH also has been identified in pancreatic islets, heart, testis, and parts of the gastrointestinal tract. Its physiological role in these sites is not known. TRH has been administered both intravenously and intrathecally as a therapeutic agent in refractory depression (Marangell et al., 1997). TRH is no longer available in the United States.

**Actions of TSH on the Thyroid.** When TSH is given to experimental animals, the first measurable effect on thyroid hormone metabolism is increased secretion, which is detectable within minutes. All phases of hormone synthesis and release are eventually stimulated: iodide uptake and organification, hormone synthesis, endocytosis, and proteolysis of colloid. There is increased vascularity of the gland and hypertrophy and hyperplasia of thyroid cells.

These effects follow the binding of TSH to its receptor on the plasma membrane of thyroid cells. The TSH receptor is a GPCR that is structurally similar to the receptors for luteinizing hormone and follicle-stimulating hormone (see Chapter 55) (Vassart et al., 2004). These
receptors share significant amino acid homology and have large extracellular domains that are involved in hormone binding.

Binding of TSH to its receptor stimulates the $G_s$-adenyl cyclase–cyclic AMP pathway. Higher concentrations of TSH activate the $G_q$-PLC pathway. Both the adenylyl cyclase and the phospholipase C signaling pathways appear to mediate effects of TSH on thyroid function in human beings (Vassart, 2005).

Multiple mutations of the TSH receptor result in clinical thyroid dysfunction (Tonacchera et al., 1996b). Germ-line mutations can present as congenital, nonautoimmune hypothyroidism (Kopp et al., 1995) or as autosomal dominant toxic thyroid hyperplasia (Tonacchera et al., 1996a). Germ-line mutations of the TSH receptor can cause gestational hyperthyroidism due to a hypersensitivity of the receptor to HCG (Rodien et al., 1998). Somatic mutations that result in constitutive activation of the receptor are associated with hyperfunctioning thyroid adenomas (Paschke et al., 1994). Finally, resistance to TSH has been described, both in families with mutant TSH receptors (Sunthornthepvarakul et al., 1995) and in those with no apparent mutations in either the TSH receptor or in TSH itself (Xie et al., 1997).

Relation of Iodine to Thyroid Function. Normal thyroid function obviously requires an adequate intake of iodine; without it, normal amounts of hormone cannot be made, TSH is secreted in excess, and the thyroid becomes hyperplastic and hypertrophies. The enlarged and stimulated thyroid becomes remarkably efficient at extracting the residual traces of iodide from the blood, developing an iodine gradient that may be ten times normal; in mild-to-moderate iodine deficiency, the thyroid usually succeeds in producing sufficient hormone and preferentially secreting $T_3$. In more severe iodine deficiency, adult hypothyroidism and cretinism may occur.

In some areas of the world, simple or nontoxic goiter is prevalent because of insufficient dietary iodine (Dunn and Delange, 2005). Regions of iodine deficiency exist in Central and South America, Africa, Europe, Southeast Asia, and China. The daily requirement for iodine in adults is 1 to 2 μg/kg body weight. In the United States, recommended daily allowances for iodine range from 40 to 120 μg for children, 150 μg for adults, 220 μg for pregnancy, and 270 μg for lactation (Food and Nutrition Board, 2001). Vegetables, meat, and poultry contain minimal amounts of iodine, whereas dairy products and fish are relatively high in iodine content (Table 56–3) (Braverman, 2003). Potable water usually contains negligible amounts of iodine.

SOURCE: Adapted from Braverman et al., 1994.

Iodine has been used empirically for the treatment of iodine-deficiency goiter for 150 years; however, its modern use evolved from extensive studies using iodine to prevent goiter in schoolchildren in Akron, Ohio, where endemic iodine-deficiency goiter was prevalent. The success of these experiments led to the adoption of iodine prophylaxis and therapy in many regions throughout the world where iodine-deficiency goiter was endemic.

The most practical method for providing small supplements of iodine for large segments of the population is the addition of iodide or iodate to table salt; iodate is now preferred. In some countries, the use of iodized salt is required by law; in others, including the United States, the use is optional. In the United States, iodized salt provides 100 μg of iodine per gram. However, while the United States population remains iodine-sufficient, iodine intake has steadily decreased over the last 20 years, a trend that needs to be monitored (Hollowell et al., 1998). Other vehicles for supplying iodine to large populations who are iodine-deficient include oral or intramuscular injection of iodized oil (Elnagar et al., 1995), iodized drinking water supplies, iodized irrigation systems, and iodized animal feed.

Actions of Thyroid Hormones. Although the precise biochemical mechanisms by which thyroid hormones exert their developmental and tissue-specific effects are the subject of ongoing investigation, most actions of thyroid hormones seem to be mediated by nuclear receptors (for review, see Yen, 2001; Yen and Chin, 2005). Triiodothyronine binds to high-affinity nuclear receptors, which then bind to specific DNA sequences (thyroid hormone response elements, TREs) in the promoter/regulato-
Western regions of target genes. In this fashion, triiodothyronine modulates gene transcription, and ultimately, protein synthesis. In general, the unliganded T3 receptor is bound to thyroid response elements in the basal state. Typically, this represses gene transcription, although there are some examples of constitutive gene activation. Binding by T3 may activate gene transcription by releasing the repression; the T3-receptor complex also may have direct activation or repressive actions. T4 also binds to these receptors, but with a much lower affinity than T3. Despite its capacity to bind to nuclear receptors, thyroxine has not been shown to alter gene transcription. Thus, it is likely that T4 serves principally as a “prohormone,” with essentially all transcriptional actions of thyroid hormone caused by T3.

Nuclear thyroid hormone receptors are the cellular homologs of an avian retroviral oncprotein, denoted c-erb A. There is considerable homology between the thyroid hormone receptors and the steroid hormone receptors, which make up a gene superfamily that includes the retinoic acid and vitamin D receptors (see Chapters 1 and 61). The thyroid hormone receptors (TRs) are derived from two genes, c-erb Aα (TRα) and c-erb Aβ (TRβ), with multiple isoforms identified (Figure 56–8) (Lazar, 1993). TRα1 and TRβ1 are found in virtually all tissues that respond to thyroid hormone; the other isoforms exhibit a more restricted distribution. For example, TRβ2 is expressed solely in the anterior pituitary, c-erb Aα2, an isoform that binds to the TRE but does not bind T3, is the most abundant isoform in the brain (Strait et al., 1990). Another level of complexity in the regulation of thyroid hormone action at the transcriptional level was added with the identification of co-activators (Takeshita et al., 1996) and co-repressors (Chen and Evans, 1995; Hörlein et al., 1995) that are associated with the T3-receptor complex and mediate hormone action (Lee and Yen, 1999). Resistance to thyroid hormone has been shown to alter gene transcription. Thus, it is likely that T4 to bind to nuclear receptors, thyroxine has not been shown to alter gene transcription. Thus, it is likely that T4 serves principally as a “prohormone,” with essentially all transcriptional actions of thyroid hormone caused by T3.

ties in the auditory system, the thyroid-pituitary axis, the heart, the skeletal system, and the small intestine (Forrest et al., 1996; Forrest et al., 1990; Fraichard et al., 1997; Wikström et al., 1998). Despite the well-documented roles of thyroid hormone during brain development (Oppenheimer and Schwartz, 1997), knockout mice devoid of all known thyroid hormone receptors had few, if any, obvious abnormalities in brain development (Göthe et al., 1996; Gauthier et al., 2001). Since the overall deficits observed in the absence of TRs are markedly less than what one would expect if the T3-binding thyroid hormone receptors were the sole mediator(s) of thyroid hormone action, the unliganded TRs may participate in this developmental program and the action of T3 on target genes during brain development may be to relieve gene repression, rather than to activate gene expression (Hashimoto et al., 2001; Flamant and Samarut, 2003). As noted above, the most abundant thyroid hormone receptor isoform in the brain throughout development is c-erb Aα2 (Strait et al., 1990), which is obligatorily unliganded since it cannot bind T3; this form continues to be expressed in most knockout mice due to the strategy used for thyroid hormone receptor gene deletion.

In addition to nuclear receptor–mediated actions, there are several well-characterized, nongenomic actions of thyroid hormones, including those occurring at the level of the plasma membrane and on the cellular cyto-architecture (Bassett et al., 2003). In addition, there are thyroid hormone binding sites on mitochondria (Sterling, 1989). In several of these processes, thyroxine is the hormone that produces the response. Previously, the overall contribution of nongenomic actions to the general mechanism of thyroid hormone action was considered to be minor. However, at least in some species, this concept may need to be reassessed in light of the paucity of abnormalities in knockout mice, especially during brain development.

**Figure 56–8. Thyroid hormone receptor isoforms.** The percentage of amino acid identity in the DNA binding region is indicated. Identical patterns in the hypervariable and ligand binding regions indicate 100% homology. Three thyroid hormone receptor (TR) isoforms bind thyroid hormone (TRβ1, TRβ2, and TRα1); c-erb Aα2 does not.
must envy, so influences the tail that it is digested away and used to build new tissue elsewhere.

Thyroid hormone plays a critical role in brain development (Bernal et al., 2003; Koibuchi et al., 2003). The appearance of functional, chromatin-bound thyroid hormone receptors coincides with neurogenesis in the brain (Strait et al., 1990). The absence of thyroid hormone during the period of active neurogenesis (up to 6 months postpartum) leads to irreversible mental retardation (cretinism) and is accompanied by multiple morphological alterations in the brain. These severe morphological alterations result from disturbed neuronal migration, deranged axonal projections, and decreased synaptogenesis. Thyroid hormone supplementation during the first 2 weeks of life prevents the development of these disturbed morphological changes.

Myelin basic protein, a major component of myelin, is regulated by thyroid hormone during development (Farsetti et al., 1991), and decreased expression of myelin basic protein in the hypothyroid brain impairs myelinization. The appearance of laminin, an extracellular matrix protein that provides key guidance signals to migrating neurons, is delayed and the content is diminished in the developing cerebellum of the hypothyroid rat (Farwell and Dubord-Tomasetti, 1999). Altered expression of laminin likely alters neuronal migration and leads to the morphological abnormalities observed in the cretinous brain. Several other brain-specific genes reportedly are developmentally regulated by thyroid hormone (Bernal et al., 2003). A common characteristic of many of these proteins is that their expression appears to be merely delayed in the hypothyroid animal; normal levels are eventually achieved in the adult.

The actions of thyroid hormones on protein synthesis and enzymatic activity are certainly not limited to the brain, and a large number of tissues are affected by the administration of thyroid hormone or by its deficiency. The extensive defects in growth and development in cretins vividly illustrate the pervasive effects of thyroid hormones in normal individuals.

Cretinism is usually classified as endemic or sporadic. Endemic cretinism occurs in regions of endemic goiter and usually is caused by extreme iodine deficiency. Goiter may or may not be present. Sporadic cretinism is a consequence of failure of the thyroid to develop normally or the result of a defect in the synthesis of thyroid hormone. Goiter is present if a synthetic defect is at fault.

While detectable at birth, cretinism often is not recognized until 3 to 5 months of age. When untreated, the condition eventually leads to such gross changes as to be unmistakable: The child is dwarfed, with short extremities, mentally retarded, inactive, uncomplaining, and listless. The face is puffy and expressionless, and the enlarged tongue may protrude through the thickened lips of the half-opened mouth. The skin may have a yellowish hue and feel doughy, and dry, and cool to the touch. The heart rate is slow, the body temperature may be low, closure of the fontanels is delayed, and the teeth erupt late. Appetite is poor, feeding is slow and interrupted by choking, constipation is frequent, and there may be an umbilical hernia.

For treatment to be fully effective, the diagnosis must be made long before these changes are obvious. In regions of endemic cretinism due to iodine deficiency, iodine replacement is best instituted prior to pregnancy. However, iodine replacement given to pregnant women up to the end of the second trimester has been shown to enhance the neurological and psychological development of the children (Cao et al., 1994). Screening of newborn infants for deficient thyroid function is carried out in the United States and in most industrialized countries. Concentrations of TSH and thyroxine are measured in blood from the umbilical cord or from a heel stick. The incidence of congenital dysfunction of the thyroid is about 1 per 4000 births.

Calorigenic Effects. A characteristic response of homeothermic animals to thyroid hormone is increased O₂ consumption. Most peripheral tissues contribute to this response; heart, skeletal muscle, liver, and kidney are stimulated markedly by thyroid hormone. Indeed, 30% to 40% of the thyroid hormone–dependent increase in O₂ consumption can be attributed to stimulation of cardiac contractility. Several organs, including brain, gonads, and spleen, are unresponsive to the calorigenic effects of thyroid hormone. The mechanism of the calorigenic effect of thyroid hormone has been elusive (Silva, 2003). It once was erroneously believed that thyroid hormone uncoupled mitochondrial oxidative phosphorylation. Thyroid hormone–dependent lipogenesis may constitute a quantitatively important energy sink, and studies in rats have demonstrated that about 4% of the increased caloric expenditure induced by thyroid hormone is accounted for by lipogenesis. The observation that T₃ stimulates lipolysis provides a link between lipogenesis and thermogenesis. Further, thyroid hormone induces expression of several lipogenic enzymes, including malic enzyme and fatty acid synthase. Although the entire picture is not clear, there appears to be an integrated program by which thyroid hormone regulates the set-point of energy expenditure and maintains the metabolic machinery necessary to sustain it. Indeed, even small changes in L-thyroxine replacement doses may significantly alter the set-point for resting energy expenditure in the hypothyroid patient (al-Adsani et al., 1997).

Cardiovascular Effects. Thyroid hormone influences cardiac function by direct and indirect actions; changes in the cardiovascular system are prominent clinical consequences in thyroid dysfunctional states. In hypothyroidism, there is tachycardia, increased stroke volume, increased cardiac index, cardiac hypertrophy, decreased peripheral vascular resistance, and increased pulse pressure. In hyperthyroidism, there is bradycardia, decreased cardiac index, pericardial effusion, increased peripheral vascular resistance, decreased pulse pressure, and elevation of mean arterial pressure (Klein, 2005a; Klein, 2005b).
Thyroid hormones directly regulate myocardial gene expression. T₃ regulates genes encoding the isoforms of the sarcomeric myosin heavy chains by increasing the expression of the α gene and decreasing the expression of the β gene. A TRE has been located in the 5-flanking region of the α myosin heavy chain gene. T₃ also upregulates the gene encoding the sarcoplasmic reticulum Ca²⁺-ATPase, which plays a critical role in myocardial contraction (Röhr er and Dillman, 1988). Regulation of these two genes results in altered contractility observed in hyper- and hypothyroidism. Indeed, stress echocardiography in hyperthyroid patients revealed abnormalities in cardiac contractility that reverted to normal when euthyroidism was restored (Kahaly et al., 1999). Similarly, left ventricular diastolic dysfunction in hypothyroidism was reversed with L-thyroxine replacement therapy (Biondi et al., 1999).

Observations in transgenic mice have provided insight into the action of thyroid hormone on heart rate. Previously, alterations in the sensitivity of the cardiac myocyte to catecholamines (enhanced in hyperthyroidism and depressed in hypothyroidism) were considered an indirect effect of thyroid hormone, possibly due to changes in expression of myocardial β adrenergic receptors. This is the basis for the use of β adrenergic receptor antagonists in relieving some of the cardiac manifestations in hyperthyroidism. However, basal heart rate is decreased in mice lacking the TRα₁ gene (Johansson et al., 1998) and increased in mice lacking TRβ (Johansson et al., 1999), suggesting a more direct role for thyroid hormone in cardiac pacemaking. Finally, T₃ leads to peripheral hemodynamic effects that alter the chronotropic and inotropic state of the myocardium. Interestingly, T₃ appears to have a direct, nongenomic vasodilating effect on vascular smooth muscle (Park et al., 1997; Ojamaa et al., 1996).

**Metabolic Effects.** Thyroid hormones stimulate metabolism of cholesterol to bile acids, and hypercholesterolemia is a characteristic feature of hypothyroid states. Thyroid hormones increase the specific binding of low-density lipoprotein (LDL) by liver cells (Salter et al., 1988), and the concentration of hepatic receptors for LDL is decreased in hypothyroidism. The number of LDL receptors on the surface of hepatocytes is a strong determinant of the plasma cholesterol concentration (see Chapter 35).

Thyroid hormones enhance the lipolytic responses of fat cells to other hormones (e.g., catecholamines) and elevated plasma free fatty acid concentrations are seen in hyperthyroidism. In contrast to other lipolytic hormones, thyroid hormones do not directly increase the accumulation of cyclic AMP. They may, however, regulate the capacity of other hormones to enhance cyclic AMP accumulation by decreasing the activity of a microsomal phosphodiesterase that hydrolyzes cyclic AMP. There also is evidence that thyroid hormones act to maintain normal coupling of the β adrenergic receptor to the catalytic subunit of adenylyl cyclase in fat cells. Fat cells from hypothyroid rats have increased concentrations of G proteins that inhibit adenylyl cyclase. This could account for both the decreased response to lipolytic hormones and the increased sensitivity to inhibitory regulators (e.g., adenosine) that are found in hypothyroidism (Ros et al., 1988).

Thyrotoxicosis is an insulin-resistant state (Gottlieb and Braverman, 1994). Postreceptor defects in the liver and peripheral tissues, manifested by depleted glycogen stores and enhanced gluconeogenesis, lead to insulin insensitivity. In addition, there is increased absorption of glucose from the gut. Compensatory increases in insulin secretion result in order to maintain euglycemia. This may precipitate clinical diabetes in previously undiagnosed patients and increase insulin requirements of diabetic patients already on insulin. Conversely, hypothyroidism results in decreased absorption of glucose from the gut, decreased insulin secretion, and a reduced rate of peripheral glucose uptake; however, glucose utilization by the brain is unaffected. Insulin requirements are decreased in the hypothyroid patient with diabetes.

**Thyroid Hyperfunction.** Thyrotoxicosis is a condition caused by elevated concentrations of circulating free thyroid hormones. Various disorders of different etiologies can result in this syndrome. The term hyperthyroidism is restricted to those conditions in which thyroid hormone production and release are increased due to gland hyperfunction. Iodine uptake by the thyroid gland is increased, as determined by the measurement of the percent uptake of ¹²³I or ¹³¹I in a 24-hour radioactive iodine uptake (RAIU) test. In contrast, thyroid inflammation or destruction resulting in excess “leak” of thyroid hormones or excess exogenous thyroid hormone intake results in a low 24-hour RAIU. The term subclinical hyperthyroidism is defined as few if any symptoms with a low serum TSH and normal concentrations of T₄ and T₃.

Graves’ disease, or toxic diffuse goiter, is the most common cause of high RAIU thyrotoxicosis. It accounts for 60% to 90% of cases, depending upon age and geographic region. Graves’ disease is an autoimmune disorder characterized by hyperthyroidism, diffuse goiter, and IgG antibodies that bind to and activate the TSH receptor. This is a relatively common disorder, with an incidence of 0.02% to 0.4% in the United States. Endemic areas of iodine deficiency have a lower incidence of autoimmune thyroid disease. As with most types of thyroid dysfunction, women are affected more than men, with a ratio ranging from 5:1 to 7:1. Graves’ disease is more common between the ages of 20 and 50, but may occur at any age. Major histocompatibility alleles (HLA) B₈ and DR₃ are associated with Graves’ disease in Caucasians. Graves’ disease is commonly associated with other autoimmune diseases. The characteristic exophthalmos associated with Graves’ disease is an infiltrative ophthalmopathy and is considered an autoimmune-mediated inflammation of the periorbital connective tissue and extraocular muscles. This disorder is clinically evident with various degrees of severity in about 50% of patients with Graves’ disease, but it is present on radiological studies, such as ultrasound or CT scan, in almost all patients. The pathogenesis of Graves’ ophthalmopathy, including the role of the TSH receptor present in retro-orbital tissues, and the management of this disorder, are reviewed by Rapoport and McLachlan (2000).

Toxic uniodinar/multinodular goiter accounts for 10% to 40% of cases of hyperthyroidism and is more common in older patients. Infiltrative ophthalmopathy is absent.

A low RAIU is seen in the destructive thyroiditides and in thyrotoxicosis resulting from exogenous thyroid hormone ingestion. Low RAIU thyrotoxicosis caused by subacute (painful) and silent (painless or lymphocytic) thyroiditis represents about 5% to 20% of all cases. Silent thyroiditis occurs in 7% to 10% of postpartum women in the United States (Lazarus, 2005). Other causes of thyrotoxicosis are much less common.

Most of the signs and symptoms of thyrotoxicosis stem from the excessive production of heat and from increased motor activity and increased activity of the sympathetic nervous system. The skin is
flushed, warm, and moist; the muscles are weak and tremulous; the heart rate is rapid, the heartbeat is forceful, and the arterial pulses are prominent and bounding. Increased expenditure of energy gives rise to increased appetite, and if intake is insufficient, to loss of weight. There also may be insomnia, difficulty in remaining still, anxiety and apprehension, intolerance to heat, and increased frequency of bowel movements. Angina, arrhythmias, and heart failure may be present in older patients. Some individuals may show extensive muscular wasting as a result of thyroid myopathy. Patients with long-standing undiagnosed or undertreated thyrotoxicosis may develop osteoporosis due to increased bone turnover (Sheppard, 2005a; Sheppard, 2005b).

The most severe form of hyperthyroidism is thyroid storm, which is discussed below, under therapeutic uses of antithyroid drugs.

Thyroid Hypofunction. Hypothyroidism, known as myxedema when severe, is the most common disorder of thyroid function. Worldwide, hypothyroidism results most often from iodine deficiency. In nonendemic areas where iodine is sufficient, chronic autoimmune thyroiditis (Hashimoto’s thyroiditis) accounts for the majority of cases. This disorder is characterized by high levels of circulating antibodies directed against thyroid peroxidase, and less commonly, thyroglobulin. In addition, blocking antibodies directed at the TSH receptor may be present, exacerbating the hypothyroidism (Botero and Brown, 1998). Finally, thyroid destruction may result from apoptotic cell death due to the interaction of Fas with the Fas ligand in the thyrocytes (Giordano et al., 1997). Failure of the thyroid to produce sufficient thyroid hormone is the most common cause of hypothyroidism and is referred to as primary hypothyroidism. Central hypothyroidism occurs much less often and results from diminished stimulation of the thyroid by TSH because of pituitary failure (secondary hypothyroidism) or hypothalamic failure (tertiary hypothyroidism). Hypothyroidism present at birth (congenital hypothyroidism) is the most common preventable cause of mental retardation in the world. Diagnosis and early intervention with thyroid hormone replacement prevent the development of cretinism, as discussed above.

Nongoitrous hypothyroidism is associated with degeneration and atrophy of the thyroid gland. The same condition follows surgical removal of the thyroid or its destruction by radioactive iodine. Since it also may occur years after antithyroid drug therapy for Graves’ disease, some have speculated that hypothyroidism can be the end stage of this disorder (“burnt-out” Graves’ disease). Goitrous hypothyroidism occurs in Hashimoto’s thyroiditis or when there is a severe defect in synthesis of thyroid hormone. When the disease is mild, it may be subtle in its presentation. By the time it has become severe, however, all of the signs are overt. The appearance of the patient is pathognomonic. The face is quite expressionless, puffy, and pallid. The skin is cold and dry, the scalp is scaly, and the hair is coarse, brittle, and sparse. The fingernails are thickened and brittle, the subcutaneous tissue appears to be thickened, and there may be true edema. The voice is husky and low-pitched, speech is slow, hearing is often faulty, mentation is impaired, and depression may be present. The appetite is poor, gastrointestinal activity is diminished, and constipation is common. Atony of the bladder is rare and suggests that the function of other smooth muscles may be impaired. The voluntary muscles are weak and the relaxation phase of the deep-tendon reflexes is delayed. The heart can be dilated, and there is frequently a pericardial effusion, although this is rarely clinically significant. There also may be pleural effusions and ascites. Anemia, most commonly normochromic and normocytic, is often present, although menstrual irregularity with menorrhagia may result in iron deficiency anemia. Hyperlipidemia often is present in hypothyroid patients. Patients are lethargic and tend to sleep a lot and often complain of cold intolerance.

Thyroid Function Tests. The development of radioimmunoassays, and more recently, chemiluminescent and enzyme-linked immunoassays for T4, T3, and TSH have greatly improved the laboratory diagnosis of thyroid disorders (Demers and Spencer, 2003). However, measurement of the total hormone concentration in plasma may not give an accurate picture of the activity of the thyroid gland. The total hormone concentration changes with alterations in either the amount of TBG in plasma or the binding affinity of TBG for hormones. Although equilibrium dialysis of undiluted serum and radioimmunoassay for free thyroxine in the dialysate represent the gold standard for determining free thyroxine concentrations, this assay is typically not available in routine clinical laboratories. The free thyroxine index is an estimation of the free thyroxine concentration and is calculated by multiplying the total thyroxine concentration by the thyroid hormone binding ratio, which estimates the degree of saturation of TBG. Additional assays commonly in use for estimating the free T4 and free T3 concentrations employ labeled analogs of these iodothyronines in chemiluminescence and enzyme-linked immunoassays. These assays correlate well with free T4 concentrations measured by the more cumbersome equilibrium dialysis method and are easily adaptable to routine clinical laboratory use. However, the analog assays may be affected by a wide variety of nonthyroidal disease states, including acute illness, and by certain drugs to a greater degree than are the free T4 index and free T4 determined by equilibrium dialysis.

Serum measurements of TSH have been available since 1965. In individuals whose pituitary function and TSH secretion are normal, serum measurement of TSH is the thyroid function test of choice (Danese et al., 1996; Helfand and Redfern, 1998), because pituitary secretion of TSH is sensitively regulated in response to circulating concentrations of thyroid hormones. The first “sensitive” TSH assay was developed in 1985, utilizing a dual-antibody approach. Application of this method resulted in the expansion of the assay detection limit below the normal range. Thus, any assay of this type is referred to as a sensitive TSH assay (Demers and Spencer, 2003). A major use of the sensitive TSH assay is to differentiate between normal and thyrotoxic patients, who should exhibit suppressed TSH values. Indeed, the sensitive TSH assay has replaced evaluation of the response of TSH to injection of synthetic TRH (TRH stimulation test) in the thyrotoxic patient. While the serum TSH assay is extremely useful in determining the euthyroid state and titrating the replacement dose of thyroid hormone in patients with primary hypothyroidism, abnormal serum TSH concentrations may not always indicate thyroid dysfunction. In such patients, assessment of the circulating thyroid hormone levels will further determine whether or not thyroid dysfunction is truly
present. Synthetic preparations of TRH (protirelin, THYREL) are no longer available in the United States for the evaluation of pituitary or hypothalamic failure as a cause of secondary hypothyroidism.

Recombinant human TSH (thyrotropin alfa, THYROGEN) is now available as an injectable preparation to test the ability of thyroid tissue, both normal and malignant, to take up radioactive iodine and release thyroglobulin (Haugen et al., 1999). This preparation replaces bovine TSH (THYROPAR), which was associated with a high incidence of side effects, including anaphylaxis.

Therapeutic Uses of Thyroid Hormone. The major indications for the therapeutic use of thyroid hormone are for hormone replacement therapy in patients with hypothyroidism or cretinism and for TSH suppression therapy in patients with thyroid cancer (Mazzaferrri and Kloos, 2001), and occasionally those with nontoxic goiter. While the consensus has been that thyroid hormone therapy is not indicated for treatment of the “low T4 syndrome” (“sick euthyroid syndrome”) that results from nonthyroidal illness (Brent and Hershman, 1986; Farwell, 2003), this concept has been challenged with the suggestion that severely ill patients may benefit by treatment with T₃ (DeGroot, 1999). However, there is no published evidence supporting this recommendation, which remains a minority opinion. For example, T₃ treatment does not decrease mortality in the sick euthyroid syndrome that occurs in patients undergoing coronary artery bypass surgery (Klemperer et al., 1995).

The synthetic preparations of the sodium salts of the natural isomers of the thyroid hormones are available and widely used for thyroid hormone therapy. Levothyroxine sodium (L-T₄, SYNTHROID, LEVOXYL, LEVOTHROID, UNITHROID, others) is available in tablets and as a lyophilized powder for injection. L-thyroxine has a narrow therapeutic index, and the FDA has recently altered its recommendations for approval of the various L-thyroxine preparations to assure biological equivalence. Liothyronine sodium (L-T₃) is the salt of triiodothyronine and is available in tablets (CYTOMEL) and as an injectable form (TRIOSTAT). A mixture of thyroxine and triiodothyronine is marketed as liotrix (THYKOLAR). Desiccated thyroid preparations, derived from whole animal thyroids, contain both T₄ and T₃ and have highly variable biologic activity, making these preparations much less desirable.

Thyroid Hormone Replacement Therapy. Thyroxine (levothyroxine sodium) is the hormone of choice for thyroid hormone replacement therapy because of its consistent potency and prolonged duration of action. The absorption of thyroxine occurs in the small intestine and is variable and incomplete, with 50% to 80% of the dose absorbed. Absorption is slightly increased when the hormone is taken on an empty stomach. In addition, certain drugs may interfere with absorption of levothyroxine in the gut, including sucralfate, cholestyramine resin, iron and calcium supplements, aluminum hydroxide, and certain soy products. Enhanced biliary excretion of levothyroxine occurs during the administration of drugs that induce hepatic CYPs, such as phenytoin, carbamazepine, and rifampin. This enhanced excretion may necessitate an increase in the dose of orally administered levothyroxine. Triiodothyronine (liothyronine sodium) may be used occasionally when a quicker onset of action is desired, e.g., in the rare presentation of myxedema coma or for preparing a patient for ¹³¹I therapy for treatment of thyroid cancer. It is less desirable for chronic replacement therapy because of the requirement for more frequent dosing, higher cost, and transient elevations of serum T₃ concentrations above the normal range. Combination therapy with levothyroxine and liothyronine has been suggested for use in hypothyroid patients that remain symptomatic on levothyroxine alone and have serum TSH concentrations in the normal range (Bunevicius et al., 1999). However, three recent studies have not confirmed these findings (Sawka et al., 2003; Walsh et al., 2003; Clyde et al., 2003). Furthermore, this combination may lead to transient elevations of circulating T₃ concentrations in contrast to the steady levels of T₄ during levothyroxine administration due to conversion of T₄ to T₃ in peripheral tissues.

The average daily adult replacement dose of levothyroxine sodium in a 68-kg person is 112 μg as a single dose, while that of liothyronine sodium is 50 to 75 μg in divided doses. Institution of therapy in healthy younger individuals can begin at full replacement doses. Because of the prolonged half-life of thyroxine (7 days), new steady-state concentrations of the hormone will not be achieved until 5 half-lives have elapsed, or at least 5 weeks after a change in dose. Thus, re-evaluation with determination of serum TSH concentration should not be performed at intervals less than 6 to 8 weeks. The goal of thyroxine replacement therapy is to achieve a TSH value in the normal range, since overreplacement of thyroxine, suppressing TSH values to the subnormal range, may induce osteoporosis and cause cardiac dysfunction (Surks et al., 2004). In noncompliant young patients, the cumulative weekly doses of levothyroxine may be given as a single weekly dose, which is safe, effective, and well tolerated (Grebe et al., 1997). In individuals over the age of 60, institution of therapy at a lower daily dose of levothyroxine sodium (25 to 50 μg per day) is indicated to avoid exacerbation of underlying and undiagnosed cardiac disease. Death due to arrhythmias has been reported during the initiation of thyroid hormone replacement therapy in hypothyroid patients. The dose can be increased at a rate of 25 μg per day every few months until the TSH is normalized. For individuals with pre-existing cardiac disease, an initial dose of 12.5 μg per day, with increases of 12.5 to 25 μg per day every 6 to 8 weeks, is indicated. Daily doses of thyroxine may be interrupted periodically because of intercurrent medical or surgical illnesses that prohibit taking medications by mouth. Because of the 7-day half-life of T₄, a lapse of several days of hormone replacement is unlikely to have any significant metabolic consequences. However, if more prolonged interruption in oral therapy is necessary, levothyroxine may be given parenterally at a dose 25% to 50% less than the patient’s daily oral requirements.

Subclinical hypothyroidism is a clinical state with few if any symptoms, characterized by elevated serum TSH concentrations (for review, see Surks et al., 2004). Population screening has shown that subclinical hypothyroidism is very common, with a prevalence of up to 15% in some populations and up to 25% in the elderly. The decision to use levothyroxine therapy in these patients to normalize the serum TSH must be made on an individual basis, as treatment may not be appropriate for all patients. Patients with subclinical hypothyroidism who may benefit from levothyroxine therapy include those with goiter, autoimmune thyroid disease, hypercholesterolemia, cognitive dysfunction, or pregnancy (see below), and those patients who have symptoms of hypothyroidism.

The dose of levothyroxine in the hypothyroid patient who becomes pregnant often needs to be increased, perhaps due to the
increased serum concentrations of TBG induced by estrogen and a small transplacental passage of levothyroxine from mother to fetus (Glinoer, 2005). In addition, pregnancy may “unmask” hypothyroidism in patients with pre-existing autoimmune thyroid disease or in those who reside in a region of iodine deficiency (Glinoer et al., 1994). Overt hypothyroidism during pregnancy is associated with fetal distress (Wasserstrum and Anaia, 1995) and impaired psychoneurological development in the progeny (Man et al., 1991). In addition, studies have suggested that subclinical hypothyroidism during pregnancy is associated with mildly impaired psychomotor development in the children (Haddow et al., 1999; Pop et al., 1999). These findings strongly suggest that any degree of hypothyroidism, as judged by an elevated serum TSH, should be treated during pregnancy. Thus, serum TSH values should be determined in the first trimester in all patients with pre-existing hypothyroidism, as well as in those at high risk for developing hypothyroidism. Therapy with levothyroxine should be administered to keep the serum TSH in the normal range. Any adjustment of the levothyroxine dose should be re-evaluated in 4 to 6 weeks to determine if further adjustments are necessary.

**Comparative Responses to Thyroid Preparations.** There is no significant difference in the qualitative response of the patient with myxedema to triiodothyronine, thyroxine, or desiccated thyroid. However, there are obvious quantitative differences. Following the subcutaneous administration of a large experimental dose of T₃, a metabolic response can be detected within 4 to 6 hours, at which time the skin becomes detectably warmer and the pulse rate and temperature increase. With this dose, a 40% decrease in metabolic rate can be restored to normal in 24 hours. The maximal response occurs in 2 days or less, and the effects subside with a half-life of about 8 days. The same single dose of T₄ exerts much less effect. However, if thyroxine is given in approximately 4 times the dose of triiodothyronine, a comparable elevation in metabolic rate can be achieved. The peak effect of a single dose is evident in about 9 days, and this declines to half the maximum in 11 to 15 days. In both cases the effects outlast the presence of detectable amounts of hormone; these disappear from the blood with mean half-lives of approximately 1 day for T₃ and 7 days for T₄.

**Myxedema Coma.** Myxedema coma is a rare syndrome that represents the extreme expression of severe, long-standing hypothyroidism (Emerson, 2003; Farwell, 2004). It is a medical emergency, and even with early diagnosis and treatment, the mortality rate can be as high as 60%. Myxedema coma occurs most often in elderly patients during the winter months. Common precipitating factors include pulmonary infections, cerebrovascular accidents, and congestive heart failure. The clinical course of lethargy proceeding to stupor and then coma is often hastened by drugs, especially sedatives, narcotics, antidepressants, and tranquilizers. Indeed, many cases of myxedema coma have occurred in hypothyroid patients who have been hospitalized for other medical problems.

Cardinal features of myxedema coma are: (1) hypothermia, which may be profound; (2) respiratory depression; and (3) unconsciousness. Other clinical features include bradycardia, macroclosia, delayed reflexes, and dry, rough skin. Dilutional hyponatremia is common and may be severe. Elevated plasma creatine kinase (CK) and lactate dehydrogenase (LDH) concentrations, acidosis, and anemia are common findings. Lumbar puncture reveals increased opening pressure and high protein content. Hypothyroidism is confirmed by measuring serum free thyroxine index and TSH values. Ultimately, myxedema coma is a clinical diagnosis.

The mainstay of therapy is supportive care, with ventilatory support, rewarming with blankets, correction of hyponatremia, and treatment of the precipitating incident. Because of a 5% to 10% incidence of coexisting decreased adrenal reserve in patients with myxedema coma, intravenous steroids are indicated before initiating thyroxine therapy (see Chapter 59). Parenteral administration of thyroid hormone is necessary due to uncertain absorption through the gut. With intravenous preparations of both levothyroxine and liothyronine now available, a reasonable approach is an initial intravenous loading dose of 200 to 300 μg of levothyroxine with a second dose of 100 μg given 24 hours later. Alternatively, a bolus of 500 μg levothyroxine given orally (by mouth or via nasogastric tube) may be administered to patients <50 years old without cardiac complications (Yamamoto et al., 1999). Some clinicians recommend adding liothyronine (at a dose of 10 μg intravenously every 8 hours) with the initial dose of levothyroxine, until the patient is stable and conscious. The dose of thyroid hormone should be adjusted on the basis of hemodynamic stability, the presence of coexisting cardiac disease, and the degree of electrolyte imbalance. Studies suggest that overaggressive treatment with either levothyroxine (>500 μg per day) or liothyronine (>75 μg) may be associated with an increased mortality rate (Yamamoto et al., 1999).

**Treatment of Cretinism.** Success in the treatment of cretinism depends upon the age at which therapy is started. Because of this, newborn screening for congenital hypothyroidism is routine in the United States, Canada, and many other countries around the world. In cases that do not come to the attention of physicians until retardation of development is clinically obvious, the detrimental effects of thyroid hormone deficiency on mental development will be irreversible. If, on the other hand, therapy is instituted within the first few weeks of life, normal physical and mental development is almost always achieved (Rovet, 2003; Rovet and Daneman, 2003). Prognosis also depends on the severity of the hypothyroidism at birth and may be worse for babies with thyroid agenesis. The most critical need for thyroid hormone is during the period of myelination of the central nervous system that occurs about the time of birth. To rapidly normalize the serum thyroxine concentration in the congenitally hypothyroid infant, an initial daily dose of levothyroxine of 10 to 15 μg/kg is recommended (Brown, 2005). This dose will increase the total serum thyroxine concentration to the upper half of the normal range in most infants within 1 to 2 weeks. Individual levothyroxine doses are adjusted at 4- to 6-week intervals during the first 6 months, at 2-month intervals during the 6- to 18-month period, and at 3- to 6-month intervals thereafter to maintain serum thyroxine concentrations in the 10- to 16-μg/dl range and serum TSH values in the normal range. The free thyroxine levels should be kept in the upper normal or elevated range. Assessments that are important guides for appropriate hormone replacement include physical growth, motor development, bone maturation, and developmental progress. Management of premature infants with hypothyroxinemia due to the sick euthyroid syndrome (~50% of those born at less than 30 weeks of gestation) remains a therapeutic dilemma. Despite impaired psychomotor development in these patients (Reuss et al., 1996; Den Ouden et al., 1996), levothyroxine therapy has not been shown to be beneficial and may be deleterious if overreplacement is administered (Den Ouden et al., 1996).

**Nodular Thyroid Disease.** Nodular thyroid disease is the most common endocrinopathy. The prevalence of clinically apparent nodules is 4% to 7% in the United States, with the frequency increasing throughout adult life. When ultrasound and autopsy data are included, the prevalence of thyroid nodules approaches 50% by age 60. As with other forms of thyroid disease, nodules are more frequent in women. Nodules have been estimated to develop at a rate of 0.1% per year.
individuals exposed to ionizing radiation, the rate of nodule development is 20 times higher. While the presence of a nodule raises the question of a malignancy, only 8% to 10% of patients with thyroid nodules have thyroid cancer. About 22,000 new cases of thyroid cancer are diagnosed annually, with about 1000 deaths from the disease per year. However, many more people have clinically silent thyroid cancer, as up to 35% of thyroids removed at autopsy or at surgery harbor a small (<1 cm) occult papillary cancer.

The evaluation of the patient with nodular thyroid disease includes a careful physical examination, biochemical analysis of thyroid function, and assessment of the malignant potential of the nodule. If the serum TSH is normal, the most efficacious diagnostic procedure is a fine-needle aspiration biopsy. Other diagnostic measures that may be useful in the evaluation of the nodule include radioisotope scanning and ultrasound.

TSH suppressive therapy with levothyroxine is an option for the patient diagnosed with a benign solitary nodule and a normal serum TSH. The rationale behind levothyroxine therapy is that the benign nodule will either stop growing or decrease in size after TSH stimulation of the thyroid gland has been suppressed. The success rate of such therapy varies widely (Papini et al., 1998; Zelmanovitz et al., 1998; Gharib and Mazzaferri, 1998). Identification of those patients who are most likely to benefit from thyroid hormone therapy can be achieved through measurement of the serum TSH concentration and radioisotope scanning. Suppression therapy will be of no value if thyroid nodule autonomy exists, as evidenced by a subnormal TSH value and all, or almost all, isotope uptake in the nodule. Functioning nodules are the most likely to respond to suppression therapy. However, once TSH concentrations are suppressed, a repeat radioisotope scan (suppression scan) should be obtained. If significant uptake persists on a suppression scan, the nodule is nonsuppressible and levothyroxine therapy should be discontinued. Suppression therapy needs to be considered carefully in older patients or in those with coronary artery disease; in general, such therapy should be avoided in these patients. Hypofunctioning nodules are much less likely to respond to suppression therapy. However, a 6- to 12-month trial of levothyroxine suppression is reasonable (Hermus and Huysmans, 1998). If levothyroxine is administered, therapy should be continued for as long as the nodule is decreasing in size. Once the size of a nodule remains stable for a 6- to 12-month period, therapy may be discontinued and the nodule observed for recurrent growth. Any nodule that grows while on suppression therapy should be rebiopsied and/or surgically excised.

**Thyroid Cancer.** Surgery is the primary treatment for all forms of thyroid cancer, followed by levothyroxine suppression therapy (Mazzaferri and Kloos, 2001). In most patients, RAI ablation follows surgery (see below).

**ANTITHYROID DRUGS AND OTHER THYROID INHIBITORS**

A large number of compounds are capable of interfering, directly or indirectly, with the synthesis, release, or action of thyroid hormones (Table 56–4). Several are of great clinical value for the temporary or extended control of hyperthyroid states. The major inhibitors may be classified into four categories: (1) antithyroid drugs, which interfere directly with the synthesis of thyroid hormones; (2) ionic inhibitors, which block the iodide transport mechanism; (3) high concentrations of iodine itself, which decrease release of thyroid hormones from the gland and also may decrease hormone synthesis; and (4) radioactive iodine, which damages the gland with ionizing radiation. Adjuvant therapy with drugs that have no specific effects on thyroid gland hormonogenesis is useful in controlling the peripheral manifesta-
ions of thyrotoxicosis. These drugs include inhibitors of the peripheral deiodination of thyroxine to the active hormone, triiodothyronine; β adrenergic receptor antagonists; and Ca\(^{2+}\) channel blockers. The antithyroid drugs have been reviewed by Cooper (2003). Adrenergic receptor antagonists are discussed more fully in Chapter 10 and Ca\(^{2+}\) channel blockers in Chapters 31 and 34.

## Antithyroid Drugs

The antithyroid drugs that have clinical utility are the thioureylenes, which belong to the family of thionamides. Propylthiouracil may be considered as the prototype.

### History

Studies on the mechanism of the development of goiter began with the observation that rabbits fed a diet composed largely of cabbage often developed goiters. This result was probably due to the presence of precursors of the thiocyanate ion in cabbage leaves (see below). Later, two pure compounds were shown to produce goiter: sulfaguanidine and phenylthiourea. Investigation of the effects of thiourea derivatives revealed that rats became hypothyroid despite hyperplastic changes in their thyroid glands that were characteristic of intense thyrotropic stimulation. After treatment was begun, no new hormone was made, and the goitrogen had no visible effect upon the thyroid gland following hypophysectomy or the administration of thyroid hormone. This suggested to Astwood that the goiter was a compensatory change resulting from the induced state of hypothyroidism and that the primary action of the compounds was to inhibit the formation of thyroid hormone. The therapeutic possibilities of such agents in hyperthyroidism were evident, and the substances so used became known as antithyroid drugs.

### Structure–Activity Relationship

The two goitrogens found in the early 1940s proved to be prototypes of two different classes of antithyroid drugs. These two, with one later addition, made up three general categories into which the majority of the agents can be assigned: (1) thiourelenes include all the compounds currently used clinically (Figure 56–9); (2) aniline derivatives, of which the sulfonamides make up the largest number, embrace a few substances that have been found to inhibit thyroid hormone synthesis; and (3) polyhydric phenols, such as resorcnil, which have caused goiter in human beings when applied to the abraded skin. A few other compounds, mentioned briefly below, do not fit into any of these categories.

Thiourea and its simpler aliphatic derivatives and heterocyclic compounds containing a thioureylene group make up the majority of the known antithyroid agents that are effective in human beings. Although most of them incorporate the entire thioureylene group, in some a nitrogen atom is replaced by oxygen or sulfur so that only the thioamide group is common to all. Among the heterocyclic compounds, active representatives are the sulfur derivatives of imidazole, oxazole, hydantoin, thiazole, thiadiazole, uracil, and barbituric acid.

![Propylthiouracil, Methimazole, Carbimazole](image)

**Figure 56–9.** Antithyroid drugs of the thiamide type.

L-5-Vinyl-2-thiooxazolidone (goitrin) is responsible for the goiter that results from consuming turnips or the seeds or green parts of cruciferous plants. These plants are eaten by cows, and the compound is found in cow’s milk in areas of endemic goiter in Finland; it is about as active as propylthiouracil in humans.

As the result of industrial exposure, toxicological studies, or clinical trials for various purposes, several other compounds have been noted to possess antithyroid activity (DeRosa et al., 1998). Thiopental and oral hypoglycemic drugs of the sulfonylurea class have weak antithyroid action in experimental animals. This is not significant at usual doses in humans. However, antithyroid effects in human beings have been observed from dimercaprol, aminoglutethimide, and lithium salts. Polychlorinated biphenyls bear a striking structural resemblance to the thyroid hormones and may function as either agonists or antagonists of thyroid hormone action (DeRosa et al., 1998; Zoeller et al., 2000; Gauger et al., 2004). Amiodarone, the iodine-rich drug used in the management of cardiac arrhythmias, has complex effects on thyroid function (Harjai and Licata, 1997). In areas of iodine sufficiency, amiodarone-induced hypothyroidism due to the excess iodine is not uncommon, whereas in iodine-deficient regions, amiodarone-induced thyrotoxicosis predominates, whether because of the excess iodine or the thyroiditis induced by the drug. Amiodarone and its major metabolite, desethylamiodarone, are potent inhibitors of iodothyronine deiodination, resulting in decreased conversion of thyroxine to triiodothyronine. In addition, desethylamiodarone decreases binding of triiodothyronine to its nuclear receptors. Recommendations have been made as to screening methods to identify chemicals that may alter thyroid hormone action or homeostasis (DeVito et al., 1999).

### Mechanism of Action

The mechanism of action of the thioureylenes drugs has been thoroughly discussed by Taurog (2000). Antithyroid drugs inhibit the formation of thyroid hormones by interfering with the incorporation of iodine into tyrosyl residues of thyroglobulin; they also inhibit the coupling of these iodotyrosyl residues to form iodothyronines. This implies that they interfere with the oxidation of iodide ion and iodotyrosyl groups. Taurog (2000) proposed that the drugs inhibit the peroxidase enzyme, thereby preventing oxidation of iodide or iodotyrosyl groups to the required active state. The antithyroid drugs bind to and inactivate the peroxidase only when the heme of the enzyme is in the oxidized state. Over a period of time, the inhibition of hormone synthesis results in the depletion of stores of iodinated thyroglobulin as the protein is hydrolyzed and the hormones are released into the circulation. Only when the preformed hormone is deplet-
ed and the concentrations of circulating thyroid hormones begin to decline do clinical effects become noticeable.

There is some evidence that the coupling reaction may be more sensitive to an antithyroid drug, such as propylthiouracil, than is the iodination reaction (Taurog, 2000). This may explain why patients with hyperthyroidism respond well to doses of the drug that only partially suppress organification.

When Graves’ disease is treated with antithyroid drugs, the concentration of thyroid-stimulating immunoglobulins in the circulation often decreases, prompting some to propose that these agents act as immunosuppressants. Perchlorate, which acts by an entirely different mechanism, also decreases thyroid-stimulating immunoglobulins, suggesting that improvement in hyperthyroidism may itself favorably affect the abnormal humoral immune state.

In addition to blocking hormone synthesis, propylthiouracil partially inhibits the peripheral deiodination of $T_4$ to $T_3$. Methimazole does not have this effect; although the quantitative significance of this inhibition has not been established, it provides a rationale for the choice of propylthiouracil over other antithyroid drugs in the treatment of severe hyperthyroid states or of thyroid storm, where a decreased rate of $T_4 \rightarrow T_3$ conversion would be beneficial.

**Absorption, Metabolism, and Excretion.** The antithyroid compounds currently used in the United States are propylthiouracil (6-n-propylthiouracil) and methimazole (1-methyl-2-mercaptoimidazole; TAPAZOLE). In Great Britain and Europe, carbimazole (NEO-MERCZOILE), a carbethoxy derivative of methimazole, is available, and its antithyroid action is due to its conversion to methimazole after absorption. Some pharmacological properties of propylthiouracil and methimazole are shown in Table 56–5. Measurements of the course of organification of radioactive iodine by the thyroid show that absorption of effective amounts of propylthiouracil follows within 20 to 30 minutes of an oral dose and that the duration of action of the compounds used clinically is brief. The effect of a dose of 100 mg of propylthiouracil begins to wane in 2 to 3 hours, and even a 500-mg dose is completely inhibitory for only 6 to 8 hours. As little as 0.5 mg of methimazole similarly decreases the organification of radioactive iodine in the thyroid gland, but a single dose of 10 to 25 mg is needed to extend the inhibition to 24 hours.

The half-life of propylthiouracil in plasma is about 75 minutes, whereas that of methimazole is 4 to 6 hours. The drugs are concentrated in the thyroid, and methimazole, derived from the metabolism of carbimazole, accumulates after carbimazole is administered. Drugs and metabolites appear largely in the urine.

Propylthiouracil and methimazole cross the placenta equally (Mortimer et al., 1997) and also can be found in milk. The use of these drugs during pregnancy is discussed below.

**Untoward Reactions.** The incidence of side effects from propylthiouracil and methimazole as currently used is relatively low. The overall incidence as compiled from published cases by early investigators was 3% for propylthiouracil and 7% for methimazole, with 0.44% and 0.12% of cases, respectively, developing the most serious reaction, agranulocytosis. The development of agranulocytosis with methimazole is probably dose-related, but no such relationship exists with propylthiouracil. Further observations have found little, if any, difference in side effects between these two agents and suggest that an incidence of agranulocytosis of approximately 1 in 500 is a maximal figure. Agranulocytosis usually occurs during the first few weeks or months of therapy but may occur later. Because agranulocytosis can develop rapidly, periodic white cell counts usually are of little help. Patients should immediately report the development of sore throat or fever, which usually heralds the onset of this reaction. Agranulocytosis is reversible upon discontinuation of the
offending drug, and the administration of recombinant human granulocyte colony-stimulating factor may hasten recovery (Magnier and Snyder, 1994). Mild granulocytopenia, if noted, may be due to thyrotoxicosis or may be the first sign of this dangerous drug reaction. Caution and frequent leukocyte counts are then required.

The most common reaction is a mild, occasionally purpuric, urticarial papular rash. It often subsides spontaneously without interrupting treatment, but it sometimes calls for the administration of an antihistamine, corticosteroids, or changing to another drug (cross-sensitivity to propylthiouracil and methimazole is uncommon). Other less frequent complications are pain and stiffness in the joints, paresthesias, headache, nausea, skin pigmentation, and loss of hair. Drug fever, hepatitis, and nephritis are rare, although abnormal liver function tests are not infrequent with higher doses of propylthiouracil. While vasculitis was previously thought to be a rare complication, antineutrophilic cytoplasmic antibodies (ANCA)s have been reported to occur in about 50% of patients receiving propylthiouracil and rarely with methimazole (Sera et al., 2000; Sato et al., 2000).

**Therapeutic Uses.** The antithyroid drugs are used in the treatment of hyperthyroidism in the following three ways: (1) as definitive treatment, to control the disorder in anticipation of a spontaneous remission in Graves’ disease; (2) in conjunction with radioactive iodine, to hasten recovery while awaiting the effects of radiation; and (3) to control the disorder in preparation for surgical treatment.

The usual starting dose for propylthiouracil is 100 mg every 8 hours or 150 mg every 12 hours. When doses larger than 300 mg daily are needed, further subdivision of the time of administration to every 4 to 6 hours is occasionally helpful. Methimazole is effective when given as a single daily dose because of its relatively long plasma and intrathyroidal half-life, as well as its long duration of action. Failures of response to daily treatment with 300 to 400 mg of propylthiouracil or 30 to 40 mg of methimazole are most commonly due to noncompliance. Delayed responses also are noted in patients with very large goiters or those in whom iodine in any form has been given beforehand. Once euthyroidism is achieved, usually within 12 weeks, the dose of antithyroid drug can be reduced, but not stopped, lest an enhanced recurrence of Graves’ disease occur (see Remissions, below).

**Response to Treatment.** The thyrotoxic state usually improves within 3 to 6 weeks after the initiation of antithyroid drugs. The clinical response is related to the dose of antithyroid drug, the size of the goiter, and pretreatment serum T3 concentrations. The rate of response is determined by the quantity of stored hormone, the rate of turnover of hormone in the thyroid, the half-life of the hormone in the periphery, and the completeness of the block in synthesis imposed by the dosage given. When large doses are continued, and sometimes with the usual dose, hypothyroidism may develop as a result of overtreatment. The earliest signs of hypothyroidism call for a reduction in dose; if they have advanced to the point of discomfort, thyroid hormone in full replacement doses can be given to hasten recovery; then the lower maintenance dose of antithyroid drug discussed above is instituted for continued therapy. Despite initial suggestions to the contrary, there is no benefit of combination levothyroxine and methimazole therapy on either remission rates (Rittmaster et al., 1998) or on changes in serum concentrations of thyroid-stimulating immunoglobulins (Rittmaster et al., 1996). After treatment is initiated, patients should be examined and thyroid function tests (serum free thyroxine index and total triiodothyronine concentrations) measured every 2 to 4 months. Once euthyroidism is established, follow-up every 4 to 6 months is reasonable.

Control of the hyperthyroidism usually is associated with a decrease in goiter size, but if the thyroid enlarges, hypothyroidism probably has been induced. When this occurs, the dose of the antithyroid drug should be significantly decreased and/or levothyroxine can be added once hypothyroidism is confirmed by laboratory testing.

**Remissions.** The antithyroid drugs have been used in many patients to control the hyperthyroidism of Graves’ disease until a remission occurs. Early investigators reported that 50% of patients so treated for 1 year remained well without further therapy for long periods, perhaps indefinitely. More recent reports have indicated that a much smaller percentage of patients sustain remissions after such treatment (Maugendre et al., 1999; Benker et al., 1998). Increased dietary iodine has been implicated in the latter, less favorable rates.

Unfortunately, there is no way of predicting before treatment is begun which patients will eventually achieve a lasting remission and who will relapse. It is clear that a favorable outcome is unlikely when the disorder is of long standing, the thyroid is quite large, or various forms of treatment have failed. To complicate the issue further, remission and eventual hypothyroidism may represent the natural history of Graves’ disease.

During treatment, a positive sign that a remission may have taken place is reduced size of the goiter. The persistence of goiter often indicates failure, unless the patient becomes hypothyroid. Another favorable indication is continued freedom from all signs of hyperthyroidism when the maintenance dose is small. Finally, a decrease in thyroid-stimulating immunoglobulins, suppression of 121I thyroid uptake when thyroxine or triiodothyronine is given, and a normal serum TSH response to TRH may be helpful in predicting a remission in some patients, although these tests are not routinely performed.

**The Therapeutic Choice.** Because antithyroid drug therapy, radioactive iodine, and subtotal thyroidectomy all are effective treatments for Graves’ disease, there is no worldwide consensus among endocrinologists as to the best approach to therapy. Prolonged drug therapy of Graves’ disease in anticipation of a remission is most successful in patients with small goiters or mild hyperthyroidism. Those with large goiters or severe disease usually require definitive therapy with either surgery or radioactive iodine (121I). Radioactive iodine remains the treatment of choice of many endocrinologists in the United States. Many investigators consider coexisting ophthalmopathy to be a relative contraindication for radioactive iodine therapy, since worsening of ophthalmopathy has been reported after radioactive iodine (Bartalena et al., 1998a), although this remains controversial. Others suggest that development of hypothyroidism, regardless of the treatment, is the strongest risk factor for progression of ophthalmopathy (Manos et al., 1998). Smoking may also be a risk factor for worsening ophthalmopathy (Bartalena et al., 1998b). In older patients, depleting the thyroid gland of preformed hormone by treatment with antithyroid drugs is advisable prior to therapy with radioactive iodine, thus preventing a severe exacerbation of the hyperthyroid state during the subsequent
development of radiation thyroiditis. Subtotal thyroidectomy is advocated for Graves’ disease in young patients with large goiters, children who are allergic to antithyroid drugs, pregnant women (usually in the second trimester) who are allergic to antithyroid drugs, and patients who prefer surgery over antithyroid drugs or radioactive iodine. Radioactive iodine or surgery is indicated for definitive therapy in toxic nodular goiter, since remissions following antithyroid drug therapy do not occur.

**Thyrotoxicosis in Pregnancy.** Thyrotoxicosis occurs in about 0.2% of pregnancies and is caused most frequently by Graves’ disease. Antithyroid drugs are the treatment of choice; radioactive iodine is clearly contraindicated. Historically, propylthiouracil has been preferred over methimazole because transplacental passage was thought to be lower; however, as noted above, both propylthiouracil and methimazole cross the placenta equally (Mortimer, 1997). Current data suggest that either may be used safely in the pregnant patient (Momotani et al., 1997; Mortimer et al., 1997). Recent reports from Scandinavia, where carbimazole is used more frequently than propylthiouracil, have suggested that carbimazole administration is rarely associated with congenital gut abnormalities (Barwell et al., 2002; Diav-Citrin and Ornry, 2002). The antithyroid drug dosage should be minimized in order to keep the serum free thyroxine index in the upper half of the normal range or slightly elevated. As pregnancy progresses, Graves’ disease often improves, and it is not uncommon for patients either to be on very low doses or off antithyroid drugs completely by the end of pregnancy. Therefore the antithyroid drug dose should be reduced, and maternal thyroid function should be frequently monitored in order to decrease chances of fetal hypothyroidism. Relapse or worsening of Graves’ disease is common after delivery, and patients should be monitored closely. Propylthiouracil is the drug of choice in nursing women, since very small amounts of the drug appear in breast milk and do not appear to affect thyroid function in the sucking baby. However, doses of methimazole up to 20 mg daily in nursing mothers have been shown to have no effect on thyroid function in the baby (Azizi et al., 2003).

**Adjuvant Therapy.** Several drugs that have no intrinsic antithyroid activity are useful in the symptomatic treatment of thyrotoxicosis. **β Adrenergic receptor antagonists** (see Chapter 10) are effective in antagonizing the sympathetically/adrenergic effects of thyrotoxicosis, thereby reducing the tachycardia, tremor, and stare, and relieving palpitations, anxiety, and tension. Either propranolol, 20 to 40 mg four times daily, or atenolol, 50 to 100 mg daily, is usually given initially. Propranolol or esmolol can be given intravenously if needed. Propranolol, in addition to its β adrenergic receptor antagonist action, has weak inhibitory effects on peripheral T₄ → T₃ conversion. Calcium channel blockers (diltiazem, 60 to 120 mg four times daily) can be used to control tachycardia and decrease the incidence of supraventricular tachyarrhythmias (see Chapter 34). These drugs should be discontinued once the patient is euthyroid.

Other drugs that are useful in the rapid treatment of the severely thyrotoxic patient are agents that inhibit the peripheral conversion of thyroxine to triiodothyronine. Dexamethasone (0.5 to 1 mg intravenously every 6 hours) is recommended both as an inhibitor of conversion of thyroxine to triiodothyronine and as supportive therapy of possible relative adrenal insufficiency. Finally, **treatment of the underlying precipitating illness is essential.**

**Preoperative Preparation.** To reduce operative morbidity and mortality, patients must be rendered euthyroid prior to subtotal thyroidectomy as definitive treatment for hyperthyroidism. It is possible to bring virtually 100% of patients to a euthyroid state; the operative mortality in these patients in the hands of an experienced thyroid surgeon is extremely low. Prior treatment with antithyroid drugs usually is successful in rendering the patient euthyroid for surgery. Iodide is added to the regimen for 7 to 10 days prior to surgery to decrease the vascularity of the gland, making it less friable and decreasing the difficulties for the surgeon. In the patient who is either allergic to antithyroid drugs or is noncompliant, a euthyroid state usually can be achieved by treatment with iopanoic acid, dexamethasone, and propranolol for 5 to 7 days prior to surgery. All of these drugs should be discontinued after surgery.

**Thyroid Storm.** Thyroid storm is an uncommon but life-threatening complication of thyrotoxicosis in which a severe form of the disease is usually precipitated by an intercurrent medical problem (Safyan et al., 2003; Farwell, 2004). It occurs in untreated or partially treated thyrotoxic patients. Precipitating factors associated with thyrotoxic crisis include infections, stress, trauma, thyroidal or nonthyroidal surgery, diabetic ketoacidosis, labor, heart disease, and rarely, radioactive iodine treatment.

Clinical features are similar to those of thyrotoxicosis, but more exaggerated. Cardinal features include fever (temperature usually over 38.5°C) and tachycardia out of proportion to the fever. Nausea, vomiting, diarrhea, agitation, and confusion are frequent presentations. Coma and death may ensue in up to 20% of patients. Thyroid function abnormalities are similar to those found in uncomplicated hyperthyroidism. Therefore thyroid storm is primarily a clinical diagnosis.

Treatment includes supportive measures such as intravenous fluids, antipyretics, cooling blankets, and sedation. Antithyroid drugs are given in large doses. Propylthiouracil is preferred over methimazole because it also impairs peripheral conversion of T₄ → T₃. The recommended initial dose of propylthiouracil is 200 to 400 mg every 4 hours. Propylthiouracil and methimazole can be administered by nasogastric tube or rectally if necessary. Neither of these preparations is available for parenteral administration in the United States.

Oral iodides are used after the first dose of an antithyroid drug has been administered (see below). The agents mentioned above as adjuvant therapies of thyrotoxicosis may be usefully applied. Dexamethasone (0.5 to 1 mg intravenously every 6 hours) is recommended both as an inhibitor of conversion of thyroxine to triiodothyronine and as supportive therapy of possible relative adrenal insufficiency. Finally, **treatment of the underlying precipitating illness is essential.**

**Ionic Inhibitors**

The term ionic inhibitors designates substances that interfere with the concentration of iodide by the thyroid gland. The effective agents are anions that resemble iodide: They are all monovalent, hydrated anions of a size similar to that of iodide. The most studied example, thiocyanate, differs from the others qualitatively; it is not concentrated by the thyroid gland, but in large amounts may inhibit the organification of iodine. Thiocyanate is produced following the enzymatic hydrolysis of certain plant glycosides. Thus, certain foods (e.g., cabbage) and cigarette smoking result in an increased concentration of thiocyanate in the blood and urine, as does the administration of sodium nitroprusside. Indeed, cigarette smoking has been reported to worsen both subclinical hypothyroidism (Müller et al., 1995) and Graves’ opthalmopathy (Bartalena et al., 1996).
has been mentioned above. Acute inhibition of the synthesis of ioddotyrosines and iodothyronines by iodide also is well known (the Wolff-Chaihoff effect). This transient, 2-day inhibition is observed only above critical concentrations of intracellular rather than extracellular concentrations of iodide. With time, “escape” from this inhibition is associated with an adaptive decrease in iodide transport and a lowered intracellular iodide concentration, most likely due to a decrease in NIS mRNA and protein (Eng et al., 1999). The mechanism of the acute Wolff-Chaihoff effect remains elusive and has been postulated to be due to the generation of organic iodo-compounds within the thyroid (Pisarev and Gärnert, 2000).

An important clinical effect of high [I\(^{-}\)]\(_{\text{plasma}}\) is inhibition of the release of thyroid hormone. This action is rapid and efficacious in severe thyrotoxicosis. The effect is exerted directly on the thyroid gland and can be demonstrated in the euthyroid subject as well as in the hyperthyroid patient. Studies in a cultured thyroid cell line suggest that some of the inhibitory effects of iodide on thyrocyte proliferation may be mediated by actions of iodide on crucial regulatory points in the cell cycle (Smerdely et al., 1993).

In euthyroid individuals, the administration of doses of iodide from 1.5 to 150 mg daily results in small decreases in plasma thyroxine and triiodothyronine concentrations and small compensatory increases in serum TSH values, with all values remaining in the normal range. However, euthyroid patients with a history of a wide variety of underlying thyroid disorders may develop iodine-induced hypothyroidism when exposed to large amounts of iodine present in many commonly prescribed drugs (Table 56–6), and these patients do not escape from the acute Wolff-Chaihoff effect (Roti et al., 1997). Among the disorders that predispose patients to iodine-induced hypothyroidism are treated Graves’ disease, Hashimoto’s thyroiditis, postpartum lymphocytic thyroiditis, subacute painful thyroiditis, and lobectomy for benign nodules. The most commonly prescribed iodine-containing drugs are certain expectorants, topical antiseptics, and radiological contrast agents.

**Response to Iodide in Hyperthyroidism.** The response to iodides in patients with hyperthyroidism is often striking and rapid. The effect usually is discernible within 24 hours, and the basal metabolic rate may fall at a rate comparable to that following thyroidectomy. This provides evidence that the release of hormone into the circulation is rapidly blocked. Furthermore, thyroid hormone synthesis also is mildly decreased. In the thyroid gland vascularity is reduced, the gland becomes much firmer, the cells become smaller, colloid reaccumulates in the follicles, and the quantity of bound iodine increases, as though an excessive stimulus to the gland has been removed or antagonized. The maximal effect is attained after 10 to 15 days of continuous therapy, when the signs and symptoms of hyperthyroidism may have greatly improved.

**Chapter 56  /  Thyroid and Antithyroid Drugs**

1998b). Dietary precursors of thiocyanate may be a contributing factor in endemic goiter in certain parts of the world, especially in Central Africa, where the intake of iodine is very low.

Among other anions, perchlorate (ClO\(_{4}^{-}\)) is ten times as active as thiocyanate (Wolff, 1998). Perchlorate blocks the entrance of iodide into the thyroid by competitively inhibiting the NIS (Carrasco, 2005). Although perchlorate can be used to control hyperthyroidism, it has caused fatal aplastic anemia when given in excessive amounts (2 to 3 g daily). Over the past few years, however, perchlorate in doses of 750 mg daily has been used in the treatment of Graves’ disease and amiodarone-iodine–induced thyrotoxicosis. Perchlorate can be used to “discharge” inorganic iodide from the thyroid gland in a diagnostic test of iodide organification. Other ions, selected on the basis of their size, also have been found to be active: fluoborate (BF\(_{4}^{-}\) is as effective as perchlorate.

Over the past few years, concern has been raised in several western states over the potential antithyroid effects of trace amounts of perchlorate contaminating the drinking water. Ammonium perchlorate is an essential oxidizer in the production of rocket fuel, and water supplies have been contaminated with perchlorate derived from these sites. However, the minute amounts detected in drinking water are far below the levels (e.g., 500 μg daily for 2 weeks) that had no effect on thyroid 1\(^{231}\)I uptake and thyroid function tests in normal volunteers (Greer et al., 2002). Perchlorate levels in drinking water are almost always below 10 μg/L or 20 μg perchlorate daily, assuming a maximum intake of 2 L. Epidemiological studies around Redlands, California, where perchlorate has been detected in the water supply, have not found any increase in thyroid cancer (Morgan and Cassady, 2002) or elevations in neonatal serum TSH values (Kelsch et al., 2003). However, one study from Arizona has reported an increase in neonatal serum TSH values in neonates in Yuma City (perchlorate found in the water supply) compared to Flagstaff (perchlorate not found) (Brechner et al., 2000). The latter report has been refuted when socioeconomic factors, altitude, time of neonatal sampling, and length of stay in the hospital are accounted for by comparing neonatal serum TSH values in Yuma City with a nearby city in Yuma County where perchlorate is not detected in the water supply (Lamm, 2003). The Environmental Protection Agency and a National Academy of Sciences Committee are currently determining an allowable concentration of perchlorate in drinking water that unequivocally does not affect thyroid function.

Lithium has a multitude of effects on thyroid function; its principal effect is decreased secretion of thyroxine and triiodothyronine (Takami, 1994), which can cause overt hypothyroidism in some patients taking lithium for the treatment of mania (see Chapter 18).

**Iodide**

Iodide is the oldest remedy for disorders of the thyroid gland. Before the antithyroid drugs were used, it was the only substance available for control of the signs and symptoms of hyperthyroidism. Its use in this way is indeed paradoxical, and the explanation for this paradox is still incomplete.

**Mechanism of Action.** High concentrations of iodide appear to influence almost all important aspects of iodine metabolism by the thyroid gland (Roti and Vagenakis, 2005). The capacity of iodide to limit its own transport into the thyroid gland in a diagnostic test of iodide organification. Other ions, selected on the basis of their size, also have been found to be active: fluoborate (BF\(_{4}^{-}\) is as effective as perchlorate.

Over the past few years, concern has been raised in several western states over the potential antithyroid effects of trace amounts of perchlorate contaminating the drinking water. **Iodide**

Iodide is the oldest remedy for disorders of the thyroid gland. Before the antithyroid drugs were used, it was the only substance available for control of the signs and symptoms of hyperthyroidism. Its use in this way is indeed paradoxical, and the explanation for this paradox is still incomplete.

**Mechanism of Action.** High concentrations of iodide appear to influence almost all important aspects of iodine metabolism by the thyroid gland (Roti and Vagenakis, 2005). The capacity of iodide to limit its own transport...
The uses of iodide in the treatment of hyperthyroidism are in the preoperative period in preparation for thyroidectomy, and in conjunction with antithyroid drugs and propranolol, in the treatment of thyrotoxic crisis. Prior to surgery, iodide is sometimes employed alone, but more frequently it is used after the hyperthyroidism has been controlled by an antithyroid drug. It is then given for 7 to 10 days immediately preceding the operation. Optimal control of hyperthyroidism is achieved if antithyroid drugs are first given alone. If iodine also is given from the beginning, variable responses are observed; sometimes the effect of iodide predominates, storage of hormone is promoted, and prolonged antithyroid treatment is required before the hyperthyroidism is controlled. These clinical observations may be explained by the capacity of iodide to prevent the inactivation of thyroid peroxidase by antithyroid drugs (Taurog, 2000).

Another use of iodide is to protect the thyroid from radioactive iodine fallout following a nuclear accident. Because the uptake of radioactive iodine is inversely proportional to the serum concentration of stable iodine, the administration of 30 to 100 mg of iodide daily will markedly decrease the thyroid uptake of radioisotopes of iodine. Following the Chernobyl nuclear reactor accident in 1986, approximately 10 million children and adults in Poland were given stable iodide to block the thyroid exposure to radioactive iodine from the atmosphere and from dairy products from cows that ate contaminated grass (Nauman and Wolff, 1993). This prevented the occurrence of radiation-induced thyroid cancer, as observed in children residing near Chernobyl.

The dosage or form in which iodide is administered bears little relationship to the response achieved in hyperthyroidism, provided that not less than the minimal effective amount is given; this dosage is 6 mg of iodide per day in most, but not all, patients. Strong iodine solution (Lugol’s solution) is widely used and consists of 5% iodine and 10% potassium iodide, which yields a dose of 6.3 mg of iodine per drop. The iodine is reduced to iodide in the intestine before absorption. Saturated solution of potassium iodide (SSKI) also is available, containing 38 mg per drop. Typical doses include 3 to 5 drops of Lugol’s solution or 1 to 3 drops of SSKI three times a day. These doses have been determined empirically and are far in excess of that needed.

Untoward Reactions. Occasional individuals show marked sensitivity to iodide or to organic preparations that contain iodine when they are administered intravenously. The onset of an acute reaction may occur immediately or several hours after administration. Angioedema is the outstanding symptom, and laryngeal edema may lead to suffocation. Multiple cutaneous hemorrhages may be present. Also, manifestations of the serum-sickness type of hypersensitivity—such as fever, arthralgia, lymph node enlargement, and eosinophilia—may appear. Thrombotic thrombocytopenic purpura and fatal periarthritis nodosa attributed to hypersensitivity to iodide also have been described.

The severity of symptoms of chronic intoxication with iodide (iodism) is related to the dose. The symptoms start with an unpleasant brassy taste and burning in the mouth and throat as well as soreness of the teeth and gums. Increased salivation is noted. Coryza, sneezing, and irritation of the eyes with swelling of the eyelids are commonly observed. Mild iodism simulates a “head cold.” The patient often complains of a severe headache that originates in the frontal sinuses. Irritation of the mucous glands of the respiratory tract causes a productive cough. Excess transudation into the bronchial tree may lead to pulmonary edema. In addition, the parotid and submaxillary glands may become enlarged and tender, and the syndrome may be mistaken for mumps parotitis. There also may be

**Source:** Adapted from Roti et al., 1997.
inflammation of the pharynx, larynx, and tonsils. Skin lesions are common and vary in type and intensity. They usually are mildly acniform and distributed in the seborrheic areas. Rarely, severe and sometimes fatal eruptions (ioderma) may occur after the prolonged use of iodides. The lesions are bizarre; they resemble those caused by bromism, a rare problem, and as a rule involve quickly when iodide is withdrawn. Symptoms of gastric irritation are common, and diarrhea, which is sometimes bloody, may occur. Fever is occasionally observed, and anorexia and depression may be present.

Fortunately, the symptoms of iodism disappear spontaneously within a few days after stopping the administration of iodide. The renal excretion of I− can be increased by procedures that promote Cl− excretion (e.g., osmotic diuresis, chloruretic diuretics, and salt loading). These procedures may be useful when the symptoms of iodism are severe.

Radioactive Iodine

Chemical and Physical Properties. Although iodine has several radioactive isotopes, greatest use has been made of 131I. It has a half-life of 8 days; therefore, more than 99% of its radiation is expended within 56 days. Its radioactive emissions include both γ rays and β particles. The short-lived radionuclide of iodine, 123I, is primarily a γ-emitter with a half-life of only 13 hours. This permits a relatively brief exposure to radiation during thyroid scans.

Effects on the Thyroid Gland. The chemical behavior of the radioactive isotopes of iodine is identical to that of the stable isotope, 127I. 131I is rapidly and efficiently trapped by the thyroid, incorporated into the iodoamino acids, and deposited in the colloid of the follicles, from which it is slowly liberated. Thus, the destructive β particles originate within the follicle and act almost exclusively upon the parenchymal cells of the thyroid, with little or no damage to surrounding tissue. The γ radiation passes through the tissue and can be quantified by external detection. The effects of the radiation depend on the dosage. When small tracer doses of 131I are administered, thyroid function is not disturbed. However, when large amounts of radioactive iodine gain access to the gland, the characteristic cytotoxic actions of ionizing radiation are observed. Pyknosis and necrosis of the follicular cells are followed by disappearance of colloid and fibrosis of the gland. With properly selected doses of 131I, it is possible to destroy the thyroid gland completely without detectable injury to adjacent tissues. After smaller doses, some of the follicles, usually in the periphery of the gland, retain their function.

Therapeutic Uses. Radioactive iodine finds its widest use in the treatment of hyperthyroidism and in the diagnosis of disorders of thyroid function. Sodium iodide 123I (IODOTOPE THERAPEUTIC) is available as a solution or in capsules containing essentially carrier-free 131I suitable for oral administration. Sodium iodide 123I is available for scanning procedures. Discussion here is limited to the uses of 131I.

Hyperthyroidism. Radioactive iodine is highly useful in the treatment of hyperthyroidism; in many circumstances it is regarded as the therapeutic procedure of choice for this condition (Leslie et al., 2003). The use of stable iodide as treatment for hyperthyroidism, however, may preclude treatment and certain imaging studies with radioactive iodine for weeks after the iodide has been discontinued.

Dosage and Technique. 131I, 7000 to 10,000 rads per gram of thyroid tissue, is administered orally. The effective dose for a given patient depends primarily upon the size of the thyroid, the iodine uptake of the gland, and the rate of release of radioactive iodine from the gland subsequent to the nuclei’s deposition in the colloid. Comparison studies have shown little advantage of a standard individualized dose, based on gland weight and radioactive iodine uptake, over a fixed dose (Jarløv et al., 1995; de Bruin et al., 1994; Leslie et al., 2003). For these reasons, the optimal dose of 131I, expressed in terms of microcuries taken up per gram of thyroid tissue, varies in different laboratories from 80 to 150 μCi. The usual total dose is 4 to 15 mCi. The incidence of hypothyroidism in the early years after doses on the lower side is reduced; however, many patients with late hypothyroidism may go undetected. Therefore, the ultimate incidence of hypothyroidism is probably no less than with the larger doses. In addition, relapse of the hyperthyroid state, or initial failure to alleviate the hyperthyroid state, is increased in patients receiving lower doses of 131I. Thus, many endocrinologists recommend initial treatment with thyroid ablative doses of 131I, with subsequent treatment for hypothyroidism. There also is evidence that pretreatment with propylthiouracil reduces the therapeutic efficacy of 131I, necessitating a higher dose for a desired effect (Imseis et al., 1998; Tuttle et al., 1995). Methimazole appears not to share this effect of propylthiouracil (Imseis et al., 1998).

Course of Disease. The course of hyperthyroidism in a patient who has received an optimal dose of 131I is characterized by progressive recovery. Beginning a few weeks after treatment, the symptoms of hyperthyroidism gradually abate over a period of 2 to 3 months. If therapy has been inadequate, the necessity for further treatment is apparent within 6 months. It is not uncommon, however, for the serum TSH to remain low for several months after 131I therapy, especially if the patient was not rendered euthyroid prior to receiving the radioactive iodine (Uy et al., 1995). Occasionally, this delayed recovery of the hypothalamic-pituitary-thyroid axis results in a picture of central hypothyroidism, with low circulating thyroid hormones. Thus, assessing radioactive iodine failure based on TSH concentrations alone may be misleading and should always be accompanied by determination of free T₄ and serum T₃ concentrations. Furthermore, transient hypothyroidism, lasting up to 6 months, may occur in up to 50% of patients receiving a dose of 131I calculated to result in euthyroidism (Aizawa et al., 1997). This is less of a problem if the patient receives a higher, ablative dose of 131I, since hypothyroidism occurs far more frequently and persists.

Depending to some extent upon the dosage schedule adopted, one-half to two-thirds of patients are cured by a single dose, one-third to one-fifth require two doses, and the remainder require three or more doses before the disorder is controlled. Patients treated with larger doses of 131I almost always develop hypothyroidism within a few months.

β Adrenergic antagonists, antithyroid drugs, or both, or stable iodide, can be used to hasten the control of hyperthyroidism while awaiting the full effects of the radioactive iodine. However, the anti-
thyroid drugs should be withheld for a few days before and after the therapeutic dose of $^{131}$I.

**Advantages.** The advantages of radioactive iodine in the treatment of Graves’ disease are many. No death as a direct result of the use of the isotope has been reported. There have been reports of increased mortality from cardiovascular and cerebrovascular disease in the first year after radioactive iodine therapy (Franklyn et al., 1998); however, there is no evidence that the increased mortality was related to the radioactive iodine itself, and long-term follow-up of radioactive iodine therapy for Graves’ disease has demonstrated no increase in overall cancer mortality in patients treated with $^{131}$I (Ron et al., 1998). In the nonpregnant patient, no tissue other than the thyroid is exposed to sufficient ionizing radiation to be detectably altered. Nevertheless, continuing concern about potential effects of radiation on germ cells prompts some endocrinologists to advocate antithyroid drugs or surgery in younger patients who are acceptable operative risks. Hypoparathyroidism is a small risk of surgery. With radioactive iodine treatment, the patient is spared the risks and discomfort of surgery. The cost is low, hospitalization is not required in the United States, and patients can indulge in their customary activities during the entire procedure.

**Disadvantages.** The chief disadvantage of the use of radioactive iodine is the high incidence of delayed hypothyroidism that is induced. Even when elaborate procedures are used to estimate iodine uptake and gland size, a certain percentage of patients will be overtreated. A distressing feature of this complication is its rising prevalence with the passage of time; the longer the interval after treatment, the higher the incidence. Several analyses of groups of patients treated 10 or more years previously suggest that the eventual rate may exceed 80%. However, it now appears that the incidence of hypothyroidism also increases progressively after subtotal thyroidectomy or after antithyroid drug therapy, and such failure of glandular function is probably part of the natural progression of Graves’ disease, no matter what the therapy.

Although it is often said that hypothyroidism is not a serious complication because it can be treated so easily with thyroid hormone, its onset may be insidious and overlooked for some time. Also, once diagnosed, it is difficult to ensure that patients who need the hormone actually take it. Since the health risks of untreated subclinical hypothyroidism are becoming increasingly evident (Surks et al., 2004), hypothyroidism, either subclinical or overt, requires long-term follow-up to ensure that optimal replacement therapy is provided.

Another disadvantage of radioactive iodine therapy is the long period of time that is sometimes required before the hyperthyroidism is controlled. When a single dose is effective, the response is most satisfactory; however, when multiple doses are needed, it may be many months or a year or more before the patient is well. This disadvantage can be largely overcome if the initial dose is sufficiently large. Other disadvantages include possible worsening of ophthalmopathy after treatment, although this is controversial (DeGroot et al., 1995). Although extremely rare, thyroid storm has occurred after therapy with $^{131}$I, usually in patients who did not receive pretreatment with antithyroid drugs. Finally, salivary gland dysfunction may be seen, especially after the higher doses used for the treatment of thyroid cancer (see below) (Caglar et al., 2002).

**Indications.** The clearest indication for this form of treatment is hyperthyroidism in older patients and in those with heart disease. Radioactive iodine also is the best form of treatment when Graves’ disease has persisted or recurred after subtotal thyroidectomy and when prolonged treatment with antithyroid drugs has not led to remission. Finally, radioactive iodine is indicated in patients with toxic nodular goiter, since the disease does not go into spontaneous remission. The risk of inducing hypothyroidism is less in nodular goiter than in Graves’ disease, perhaps because of the normal progression of the latter and the preservation of nonautonomous thyroid tissue in the former. Usually, larger doses of radioactive iodine are required in the treatment of toxic nodular goiter than in the treatment of Graves’ disease. Radioactive iodine has been used to decrease the size of large, nontoxic, multinodular goiters that are causing compressive symptoms in patients who are otherwise poor operative risks. While surgery remains the treatment of choice for the young patient with compressive multinodular goiters, radioactive iodine therapy may benefit elderly patients, especially those with cardiopulmonary disease.

**Contraindications.** The main contraindication for the use of $^{131}$I therapy is pregnancy. After the first trimester, the fetal thyroid will concentrate the isotope and thus suffer damage; even during the first trimester, radioactive iodine is best avoided because there may be adverse effects of radiation on fetal tissues. The risk of causing neoplastic changes in the thyroid gland has been an ongoing concern since radioactive iodine was first introduced, and only small numbers of children have been treated in this way. Indeed, many clinics have declined to treat younger patients for fear of causing cancer and have reserved radioactive iodine for patients over some arbitrary age, such as 25 or 30 years. Since experience with $^{131}$I is now vast, these age limits are lower than they were in the past. The most recent report by the Cooperative Thyrotoxicosis Therapy Follow-up Study Group shows no increase in total cancer mortality following $^{131}$I treatment for Graves’ disease (Ron et al., 1998). Furthermore, there was no increase in the occurrence of leukemia following large-dose $^{131}$I therapy for thyroid cancer, although there was an increase in colorectal cancers in this population (de Vathaire et al., 1997). These data strongly suggest that laxatives be given to all patients receiving $^{131}$I therapy for treatment of thyroid cancer to decrease the risk of future digestive tract malignancies. Transient abnormalities in testicular function have been reported following $^{131}$I therapy for treatment of thyroid cancer, but no long-term effects on fertility in either men or women have been demonstrated (Pacini et al., 1994b; Dottorini et al., 1995).

**Thyroid Carcinoma.** While most well-differentiated thyroid carcinomas accumulate very little iodine, stimulation of iodine uptake with TSH often is used effectively to treat metastases. Follicular carcinomas, which account for 10% to 15% of thyroid malignancies, are especially amenable to this treatment. Currently, endogenous TSH stimulation is evoked by withdrawal of thyroid hormone replacement therapy in patients previously treated with near-total thyroidectomy with or without radioactive ablation of residual thyroid tissue. Total body $^{131}$I scanning and measurement of serum thyroglobulin when the patient is hypothyroid (TSH >35 milliunits/L) should be performed to identify metastatic disease or residual thyroid bed tissue. Depending upon the residual uptake or the presence of metastatic disease, an ablative dose of $^{131}$I ranging from 30 to 150 mCi is administered, and a repeat total body scan is obtained 1 week later. The precise amount of $^{131}$I needed to treat residual tissue and metastases is controversial. Recombinant human TSH (THYROGEN) is now available to test the ability of thyroid tissue, both normal and malignant, to take up radioactive iodine and to secrete thyroglobulin (Haugen et al., 1999). The major advantage to the use of this medication is that patients do not have to stop their suppressive levothyroxine therapy and become clinically hypothyroid for the presence of persistent or metastatic disease to be assessed. While recombi-
nant human TSH is not yet approved for treatment prior to therapeutic administration of $^{131}$I, trials are ongoing to assess this therapeutic indication (Robbins et al., 2002; Robbins and Robbins, 2003).

TSH-suppressive therapy with levothyroxine is indicated in all patients after treatment for thyroid cancer. The goal of therapy usually is to keep serum TSH levels in the subnormal range (Burmeister et al., 1992). Follow-up evaluation every 6 months is reasonable, along with determination of serum thyroglobulin concentrations. A rise in serum thyroglobulin concentration is often the first indication of recurrent disease. Prognosis in patients with thyroid cancer depends upon the pathology and size of the tumor and is generally worse in the elderly. Overall, the vast majority of patients with thyroid cancer will not die of their disease. Papillary cancer is not aggressive; the 10-year survival rate exceeds 40%. Follicular cancer is more aggressive and can metastasize via the bloodstream. Still, prognosis is fair and long-term survival is common. Even in patients with metastatic, differentiated thyroid cancer, $^{131}$I therapy is very effective and may be even curative (Pacini et al., 1994a). Anaplastic cancer is the exception, as it is highly malignant with survival usually less than 1 year. Medullary thyroid carcinomas do not accumulate I$^{-}$ and cannot usually be treated with $^{131}$I.

**Diagnostic Uses.** Measurement of the thyroidal accumulation of a tracer dose is helpful in the differential diagnosis of thyrotoxicosis and nodular goiter. The response of the thyroid to TSH-suppressive doses of thyroid hormone can be evaluated in this way. Following the administration of a tracer dose, the pattern of localization in the thyroid gland can be depicted by a special scanning apparatus, and this technique is sometimes useful in defining thyroid nodules as functional (“hot”) or nonfunctional (“cold”) and in finding ectopic thyroid tissue and occasionally metastatic thyroid tumors.

**CLINICAL SUMMARY**

Replacement therapy for hypothyroidism typically uses oral l-thyroxine given once daily, with the goal of restoring the serum TSH concentrations to the mid-normal or low-normal range. This usually is possible and most patients are treated successfully. Based on the prolonged half-life of thyroxine, at least 6 to 8 weeks are required before a new steady-state level is reached following initiation of therapy or adjustment of dose. Special cases of hypothyroidism include patients following surgical resection of differentiated thyroid carcinoma and pregnancy. In the former setting, the goal is to suppress the TSH level to below normal, thereby removing the potential effect of TSH to stimulate proliferation of the cancer cells. In pregnant patients, the standard replacement dose generally must be increased due to higher levels of TBG and small amounts of thyroxine crossing the placenta to reach the fetus. Realizing the effects of even relatively mild hypothyroidism on neurological development of the fetus, it is especially important to carefully monitor thyroid function tests during pregnancy.

Options available for treating hyperthyroid patients include antithyroid drugs (e.g., propylthiouracil and methimazole), radioactive iodine ablation, and surgery. The preferred therapy differs among endocrinologists and regions. Special circumstances such as the presence of coexisting ophthalmopathy in patients with Graves’ disease also may influence the choice of therapy; radioactive iodine may aggravate the ophthalmopathy. Although younger patients with hyperthyroidism often can be treated effectively with radioactive iodine, medical therapy with antithyroid drugs to reduce the levels of thyroid hormone may be preferred. In younger patients with very large goiters, thyroidectomy is a viable alternative. In older patients or those with cardiac disease, radioactive iodine usually is recommended after the patient has been rendered euthyroid with antithyroid medication. Recombinant human TSH is available for stimulation of radioactive iodine uptake and release of thyroglobulin in patients with thyroid cancer after thyroidectomy. It essentially has replaced induced hypothyroidism after thyroid hormone withdrawal for most patients who are having a total body scan and serum thyroglobulin measurement to determine the presence of residual tissue.

Greer, M.A., Goodman, G., Pleus, R.C. and Greer, S.E. Health effects assessment for environmental perchlorate contamination: The dose

Estrogens and progestins are endogenous hormones that produce numerous physiological actions. In women, these include developmental effects, neuroendocrine actions involved in the control of ovulation, the cyclical preparation of the reproductive tract for fertilization and implantation, and major actions on mineral, carbohydrate, protein, and lipid metabolism. Estrogens also have important actions in males, including effects on bone, spermatogenesis, and behavior.

The biosynthesis, biotransformation, and disposition of estrogens and progestins are well established. Two well-characterized nuclear receptors are present for each hormone. This knowledge provides a firm conceptual basis for understanding the actions of both steroids.

The therapeutic use of estrogens and progestins largely reflects extensions of their physiological activities. The most common uses of these agents are menopausal hormone therapy and contraception in women, but the specific compounds and dosages used in these two settings differ substantially.

Estrogen- and progesterone-receptor antagonists also are available. The main uses of anti-estrogens are treatment of hormone-responsive breast cancer and infertility. Selective estrogen receptor modulators (SERMs) that display tissue-selective agonist or antagonist activities are increasing in number. The main use of anti-progestins has been for medical abortion, but other uses are theoretically possible.

A number of naturally occurring and synthetic environmental chemicals mimic, antagonize, or otherwise affect the actions of estrogens in experimental test systems. The precise effect of these agents on humans is unknown, but this is an area of active investigation. Cancer chemotherapeutic strategies based on blockade of estrogen- and/or progesterone-receptor functions are considered in further detail in Chapter 51. Complementary therapeutic strategies based on suppression of gonadotropin secretion by long-acting gonadotropin-releasing hormone agonists are discussed in Chapter 55.

History. The hormonal nature of the ovarian control of the female reproductive system was firmly established in 1900 by Knauer when he found that ovarian transplants prevented the symptoms of gonadectomy, and by Halban, who showed that normal sexual development and function occurred when glands were transplanted. In 1923, Allen and Doisy devised a bioassay for ovarian extracts based upon the vaginal smear of the rat. Frank and associates in 1925 detected an active sex principle in the blood of sows in estrus, and Loewe and Lange discovered in 1926 that a female sex hormone varied in the urine of women throughout the menstrual cycle. The excretion of estrogen in the urine during pregnancy also was reported by Zondek in 1928 and enabled Butenandt and Doisy in 1929 to crystallize an active substance.

Early investigations indicated that the ovary secretes two substances. Beard had postulated in 1897 that the corpus luteum serves a necessary function during pregnancy, and Fraenkel showed in 1903 that destruction of the corpora lutea in pregnant rabbits caused abortion. Several groups then isolated progesterone from mammalian corpora lutea in the 1930s.

In the early 1960s, pioneering studies by Jensen and colleagues suggested the presence of intracellular receptors for estrogens in target tissues. This was the first demonstration of receptors of the steroid/thyroid superfamily and provided techniques to identify receptors for the other steroid hormones. A second estrogen receptor was identified in 1996 and termed estrogen receptor β (ER β) to distinguish it from the receptor identified by Jensen and others, termed estrogen receptor α (ER α). Two protein isoforms, A and B, of the progesterone receptor arise from a single gene by transcription initiation from different promoters. (Note: For the primary literature references about the history of this subject, consult the ninth and tenth editions of this volume.)
both ER α- and β-mediated actions, is 17β-estradiol, followed by estrone and estriol. Each contains a phenolic A ring with a hydroxyl group at carbon 3, and a β-OH or ketone in position 17 of ring D.

The phenolic A ring is the principal structural feature responsible for selective, high-affinity binding to both receptors. Most alkyl substitutions on the A ring impair binding, but substitutions on ring C or D may be tolerated. Ethynyl substitutions at the C17 position greatly increase oral potency by inhibiting first-pass hepatic metabolism. Models for the ligand-binding sites of both estrogen receptors have been determined from structure–activity relationships (Harrington et al., 2003) and structural analysis (Pike et al., 2000).

Diethylstilbestrol (DES), which is structurally similar to estradiol when viewed in the trans conformation, binds with high affinity to both estrogen receptors and is as potent as estradiol in most assays, but has a much longer half-life. DES no longer has widespread use, but it was important historically as an inexpensive, orally active estrogen.

Selective ligands for ER α and ER β are available for experimental studies but are not yet used therapeutically (Harrington et al., 2003).

Nonsteroidal compounds with estrogenic or anti-estrogenic activity—including flavones, isoflavones (e.g., genistein), and coumestan derivatives—occur in plants and fungi. Synthetic agents—including pesticides (e.g., p,p′-DDT), plasticizers (e.g., bisphenol A), and a variety of other industrial chemicals (e.g., polychlorinated biphenyls)—also have hormonal or antihormonal activity. While their affinity is relatively weak, their large number, bioaccumulation, and persistence in the environment have raised concerns about their potential toxicity in humans and wildlife (Mäkelä et al., 1999). Over-the-counter and prescription preparations containing naturally occurring, estrogenlike compounds from plants (i.e., phytoestrogens) now are available (Fitzpatrick, 2003).

**Biosynthesis.** Steroidal estrogens arise from androstenedione or testosterone (Figure 57–1) by aromatization of the A ring. The reaction is catalyzed by a cytochrome P450 monoxygenase enzyme complex (aromatase or CYP19) that uses NADPH and molecular oxygen as co-substrates. A ubiquitous flavoprotein, NADPH–cytochrome P450 reductase, also is essential. Both proteins are localized in the endoplasmic reticulum of ovarian granulosa cells, testicular Sertoli and Leydig cells, adipose stroma, placental syncytiotrophoblasts, preimplantation blastocysts, bone, various brain regions, and many other tissues (Simpson et al., 2002).

The ovaries are the principal source of circulating estrogen in premenopausal women, with estradiol being the main secretory product. Gonadotropins, acting via receptors that couple to the Gs-
adenylyl cyclase–cyclic AMP pathway, increase the activities of aromatase and the cholesterol side-chain cleavage enzyme and facilitate the transport of cholesterol (the precursor of all steroids) into the mitochondria of cells that synthesize steroids. The ovary contains a form of 17β-hydroxysteroid dehydrogenase (type I) that favors the production of testosterone and estradiol from androstenedione and estrone, respectively. However, in the liver, another form of this enzyme (type II) favors oxidation of circulating estradiol to estrone (Peltoketo et al., 1999), and both of these steroids are then converted to estriol (Figure 57–1). All three of these estrogens are excreted in the urine along with their glucuronide and sulfate conjugates.

In postmenopausal women, the principal source of circulating estrogen is adipose tissue stroma, where estrone is synthesized from dehydroepiandrosterone secreted by the adrenals. In men, estrogens are produced by the testes, but extragonadal production by aromatization of circulating C19 steroids (e.g., androstenedione and dehydroepiandrosterone) accounts for most circulating estrogens. Thus, the level of estrogens is regulated in part by the availability of androgenic precursors (Simpson, 2003).

Estrogenic effects most often have been attributed to circulating hormones, but locally produced estrogens also may have important actions (Simpson et al., 2002). For example, estrogens may be produced from androgens by the actions of aromatase or from estrogen conjugates by hydrolysis. Such local production of estrogens could play a causal role in the development of certain diseases such as breast cancer, since mammary tumors contain both aromatase and hydrolytic enzymes. Estrogens also may be produced from androgens via aromatase in the central nervous system (CNS) and other tissues and exert local effects near their production site (e.g., in bone they affect bone mineral density).

The placenta uses fetal dehydroepiandrosterone and its 16α-hydroxy derivative to produce large amounts of estrone and estriol. Human urine during pregnancy is thus an abundant source of natural estrogens, and pregnant mare’s urine is the source of conjugated equine estrogens, which have been widely used therapeutically for many years.

**Physiological and Pharmacological Actions**

**Developmental Actions.** Estrogens are largely responsible for pubertal changes in girls and secondary sexual characteristics. They cause growth and development of the vagina, uterus, and fallopian tubes, and contribute to breast enlargement. They also contribute to molding the body contours, shaping the skeleton, and causing the pubertal growth spurt of the long bones and epiphyseal closure. Growth of axillary and pubic hair, pigmentation of the genital region, and the regional pigmentation of the nipples and areolae that occur after the first trimester of pregnancy are also estrogenic actions. Androgens may also play a secondary role in female sexual development (see Chapter 58).

Estrogens appear to play important developmental roles in males. In boys, estrogen deficiency diminishes the puber-
growth spurt and delays skeletal maturation and epiphy-
seal closure so that linear growth continues into adulthood. Estrogen deficiency in men leads to elevated gonadotropins, macroorchidism, and increased testosterone levels and also may affect carbohydrate and lipid metabolism and fertility in some individuals (Grumbach and Auchus, 1999).

**Figure 57–2. Neuroendocrine control of gonadotropin secretion in females.** The hypothalamic pulse generator located in the arcuate nucleus of the hypothalamus functions as a neuronal “clock” that fires at regular hourly intervals (A). This results in the periodic release of gonadotropin-releasing hormone (GnRH) from GnRH-containing neurons into the hypothalamic-pituitary portal vasculature (B). GnRH neurons (B) receive inhibitory input from opioid, dopamine, and GABA neurons and stimulatory input from noradrenergic neurons (NE, norepinephrine). The pulses of GnRH trigger the intermittent release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from pituitary gonadotropes (C), resulting in the pulsatile plasma profile (D). FSH and LH regulate ovarian production of estrogen and progesterone, which exert feedback controls (E). (See text and Figure 57–3 for additional details.)

**Neuroendocrine Control of the Menstrual Cycle.** A neuroendocrine cascade involving the hypothalamus, pituitary, and ovaries controls the menstrual cycle (Figure 57–2). A neuronal oscillator or “clock” in the hypothalamus fires at intervals that coincide with bursts of gonadotropin-releasing hormone (GnRH) release into the hypothalamic-pituitary portal vasculature (see Chapter 55). GnRH interacts with its cognate receptor on pituitary gonadotropes to cause release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH). The frequency of the GnRH pulses, which varies in the different phases of the menstrual cycle (see below), controls the relative synthesis of the unique β subunits of FSH and LH.

The gonadotropins (LH and FSH) regulate the growth and maturation of the graafian follicle in the ovary and the ovar-
ian production of estrogen and progesterone, which exert feedback regulation on the pituitary and hypothalamus.

Because the release of GnRH is intermittent, LH and FSH secretion is pulsatile. The pulse frequency is determined by the neural “clock” (Figure 57–2), termed the hypothalamic GnRH pulse generator (Knobil, 1981), but the amount of gonadotropin released in each pulse (i.e., the pulse amplitude) is largely controlled by the actions of estrogens and progesterone on the pituitary. The intermittent, pulsatile nature of hormone release is essential for the maintenance of normal ovulatory menstrual cycles, since constant infusion of GnRH results in a cessation of gonadotropin release and ovarian steroid production (see Chapter 55). The pulse generator resides in the arcuate nucleus of the hypothalamus, which also contains the highest concentration of GnRH neurons; considerable evidence suggests that these GnRH neurons collectively form the pulse generator.

The precise mechanism that regulates the timing of GnRH release (i.e., pulse frequency) is unclear, but these cells appear to have an intrinsic ability to release GnRH episodically. The overall pattern of GnRH release likely is regulated by the interplay of intrinsic mechanism(s) and extrinsic synaptic inputs from opioid, catecholamine, and GABAergic neurons (Figure 57–2). Ovarian steroids, primarily progesterone, regulate the frequency of GnRH release, but the cellular and molecular mechanisms of this regulation are not well established. Some GnRH cells appear to contain immunoreactive steroid receptors. Some nerve cells that synapse with GnRH neurons contain steroid receptors, and neighboring glial cells also may contain estrogen and progesterone receptors. Steroids may thus directly and indirectly modulate GnRH neuronal function.

At puberty the pulse generator is activated and establishes cyclic profiles of pituitary and ovarian hormones. While the mechanism of activation is not entirely established, it may involve increases in circulating IGF-1 and leptin levels, the latter acting to inhibit neuropeptide Y (NPY) in the arcuate nucleus to relieve an inhibitory effect on GnRH neurons.

Figure 57–3 provides a schematic diagram of the profiles of gonadotropin and gonadal steroid levels in the menstrual cycle. The “average” plasma levels of LH throughout the cycle are shown in panel A of Figure 57–3; inserts illustrate the pulsatile patterns of LH during the proliferative and secretory phases in more detail. The average LH levels are similar throughout the early (follicular) and late (luteal) phases of the cycle, but the frequency and amplitude of the LH pulses are quite different in the two phases. This characteristic pattern of hormone secretions results from complex positive and negative feedback mechanisms (Hotchkiss and Knobil, 1994).

In the early follicular phase of the cycle: (1) the pulse generator produces bursts of neuronal activity with a frequency of about one per hour that correspond with pulses of GnRH secretion; (2) these cause a corresponding pulsatile release of LH and FSH from pituitary gonadotropes; and (3) FSH in particular causes the graafian follicle to mature and secrete estrogen. The effects of estrogens on the pituitary are inhibitory at this time and cause the amount of LH and FSH released from the pituitary to decline (i.e., the amplitude of the LH pulse decreases), so gonadotropin levels gradually fall, as seen in Figure 57–3. Inhibin, produced by the ovary, also exerts a negative feedback to selectively decrease serum FSH at this time (see Chapter 55). Activin and follistatin, two other peptides released from the ovary, may also regulate FSH production and secretion to a lesser extent, although their levels do not vary appreciably during the menstrual cycle.

At mid-cycle, serum estradiol rises above a threshold level of 150 to 200 pg/ml for approximately 36 hours. This sustained elevation of estrogen no longer inhibits gonadotropin release but exerts a brief positive feedback effect on the pituitary to trigger the preovulatory surge of LH and FSH. This effect primarily involves a change in pituitary responsiveness to GnRH. In some species, estrogens may also exert a positive effect on hypothalamic neurons that contributes to a mid-cycle “surge” of GnRH release; this is not yet established in humans. Progesterone may contribute to the mid-cycle LH surge.

The mid-cycle surge in gonadotropins stimulates follicular rupture and ovulation within 1 to 2 days. The ruptured follicle then develops into the corpus luteum, which produces large amounts of progesterone and lesser amounts of estrogen under the influence of LH during the second half of the cycle. In the absence of pregnancy, the corpus luteum ceases to function, steroid levels drop, and menstruation occurs. When steroid levels drop, the pulse generator reverts to a firing pattern characteristic of the follicular phase, the entire system then resets, and a new ovarian cycle occurs.

Regulation of the frequency and amplitude of gonadotropin secretions by steroids may be summarized as follows: Estrogens act primarily on the pituitary to control the amplitude of gonadotropin pulses, and may also contribute to the amplitude of GnRH pulses secreted by the hypothalamus.

In the follicular phase of the cycle, estrogens inhibit gonadotropin release, but then have a brief mid-cycle stimulatory action that increases the amount released and causes the LH surge. Progesterone, acting on the hypothalamus, exerts the predominant control of the frequency of LH release. It decreases the firing rate of the hypothalamic pulse generator, an action thought to be mediated largely via inhibitory opioid neurons (containing progesterone receptors) that synapse with GnRH neurons. Progesterone also exerts a direct effect on the pituitary to oppose the inhibitory actions of estrogens and thus enhance the amount of LH released (i.e., to increase the amplitude of the LH pulses). These steroid feedback effects, coupled with the intrinsic activity of the hypothalamic GnRH pulse generator, lead to relatively frequent LH pulses of small amplitude in the follicular phase of the cycle, and less frequent pulses of larger amplitude in the luteal phase. Studies in knockout mice indicate that ER α (Hewitt and Korach, 2003) and the progesterone receptor PR-A (Conneely et al., 2002) mediate the major actions of estrogens and progestins, respectively, on the hypothalamic-pituitary axis.

In males, testosterone regulates the hypothalamic-pituitary-gonadal axis at both the hypothalamic and pituitary levels, and its negative feedback effect is mediated to a substantial degree by estrogen formed via aromatization. Thus, exogenous estrogen administration decreases LH and testosterone levels in men, and anti-estrogens such as clomiphene cause an elevation of serum LH, which can be used to evaluate the male reproductive axis.
When the ovaries are removed or cease to function, there is overproduction of FSH and LH, which are excreted in the urine. Measurement of urinary or plasma LH is valuable to assess pituitary function and the effectiveness of therapeutic doses of estrogen. Although FSH levels will also decline upon estrogen administration, they do not return to normal, secondary to production of inhibin (see Chapter 55). Consequently, the measurement of FSH levels as a means to monitor the effectiveness of hormone therapy is not clinically useful. Additional features of the regulation of gonadotropin secretion and actions are discussed in Chapters 55 and 58.

**Effects of Cyclical Gonadal Steroids on the Reproductive Tract.**
The cyclical changes in estrogen and progesterone production by the ovaries regulate corresponding events in the fallopian tubes, uterus, cervix, and vagina. Physiologically, these changes prepare the uterus for implantation, and the proper timing of events in these tissues is essential for pregnancy. If pregnancy does not occur, the endometrium is shed as the menstrual discharge.

The uterus is composed of an endometrium and a myometrium. The endometrium contains an epithelium lining the uterine cavity and an underlying stroma; the myometrium is the smooth muscle component responsible for uterine contractions. These cell layers, the fallopian tubes, cervix, and vagina display a characteristic set of responses to both estrogens and progestins. The changes typically associated with menstruation occur largely in the endometrium (Figure 57–3).
The luminal surface of the endometrium is a layer of simple columnar epithelial secretory and ciliated cells that is continuous with the openings of numerous glands that extend through the underlying stroma to the myometrial border. Fertilization normally occurs in the fallopian tubes, so ovulation, transport of the fertilized ovum through the fallopian tube, and preparation of the endometrial surface must be temporally coordinated for successful implantation.

The endometrial stroma is a highly cellular connective-tissue layer containing a variety of blood vessels that undergo cyclic changes associated with menstruation. The predominant cells are fibroblasts, but macrophages, lymphocytes, and other resident and migratory cell types also are present.

Menstruation marks the start of the menstrual cycle. During the follicular (or proliferative) phase of the cycle, estrogen begins the rebuilding of the endometrium by stimulating proliferation and differentiation. Numerous mitoses become visible, the thickness of the layer increases, and characteristic changes occur in the glands and blood vessels. In rodent models, ER _α_ mediates the uterotrophic effects of estrogens (Hewitt and Korach, 2003). The overall endometrial response involves estrogen- and progesterone-mediated expression of peptide growth factors and receptors, cell cycle genes, and other regulatory signals. An important response to estrogen in the endometrium and other tissues is induction of the progesterone receptor (PR), which enables cells to respond to this hormone during the second half of the cycle.

In the luteal (or secretory) phase of the cycle, elevated progesterone limits the proliferative effect of estrogens on the endometrium by stimulating differentiation. Major effects include stimulation of epithelial secretions important for implantation of the blastocyst and the characteristic growth of the endometrial blood vessels seen at this time. These effects are mediated by PR-A in animal models (Conneely _et al._, 2002). Progesterone is thus important in preparation for implantation and for the changes that take place in the uterus at the implantation site (i.e., the decidual response). There is a narrow “window of implantation,” spanning days 19 to 24 of the endometrial cycle, when the epithelial cells of the endometrium are receptive to blastocyst implantation. Since endometrial status is regulated by estrogens and progestins, the efficacy of some contraceptives may be due in part to production of an endometrial surface that is not receptive to implantation. If pregnancy does not occur, the corpus luteum regresses due to lack of continued LH secretion, estrogen and progesterone levels fall, and the endometrium is shed (Figure 57–3).

If implantation occurs, human chorionic gonadotropin (hCG) (see Chapter 55), produced initially by the trophoblast and later by the placenta, interacts with the LH receptor of the corpus luteum to maintain steroid hormone synthesis during the early stages of pregnancy. In later stages the placenta itself becomes the major site of estrogen and progesterone synthesis.

Estrogens and progesterone have important effects on the fallopian tube, myometrium, and cervix. In the fallopian tube, estrogens stimulate proliferation and differentiation, whereas progesterone inhibits these processes. Also, estrogens increase and progesterone decreases tubal muscular contractility, which affects transit time of the ovum to the uterus. Estrogens increase the amount of cervical mucus and its water content to facilitate sperm penetration of the cervix, whereas progesterone generally has opposite effects. Estrogens favor rhythmic contractions of the uterine myometrium, while progesterone diminishes contractions. These effects are physiologically important and may also play a role in the action of some contraceptives.

**Metabolic Effects.** Estrogens affect many tissues and have many metabolic actions in human beings and animals. It is not clear in all cases if effects result directly from hormone actions on the tissue in question or secondarily from actions at other sites. Many nonreproductive tissues, including bone, vascular endothelium, liver, CNS, immune system, gastrointestinal tract, and heart, express low levels of both estrogen receptors, and the ratio of ER _α_ to ER _β_ varies in a cell-specific manner. Many metabolic effects of estrogens result directly from receptor-mediated events in affected organs. The effects of estrogens on selected aspects of mineral, lipid, carbohydrate, and protein metabolism are particularly important for understanding their pharmacological actions.

It long has been recognized that estrogens have positive effects on bone mass (reviewed by Riggs _et al._, 2002). Bone is continuously remodeled at sites called “bone-remodeling units” by the resorptive action of osteoclasts and the bone-forming action of osteoblasts (see Chapter 61). Maintenance of total bone mass requires equal rates of formation and resorption as occurs in early adulthood (18 to 40 years); thereafter resorption predominates. Osteoclasts and osteoblasts express both ER _α_ and ER _β_, with the former apparently playing a greater role. Bone also expresses both androgen and progesterone receptors. Based on animal models, the actions of ER _α_ predominate in bone. Estrogens directly regulate osteoblasts and increase the synthesis of type I collagen, osteocalcin, osteopontin, osteonectin, alkaline phosphatase, and other markers of differentiated osteoblasts. Estrogens also increase osteocyte survival by inhibiting apoptosis. However, the major effect of estrogens is to decrease the number and activity of osteoclasts. Much of the action of estrogens on osteoclasts appears to be mediated by altering cytokine (both paracrine and autocrine) signals from osteoblasts. Estrogens decrease osteoblast and stromal cell production of the osteoclast-stimulating cytokines interleukin (IL)-1, IL-6, and tumor necrosis factor (TNF)-α and increase the production of insulin-like growth factor (IGF)-1, bone morphogenic protein (BMP)-6, and transforming growth factor (TGF)-β, which are anti-resorptive (reviewed by Spelsberg _et al._, 1999). Estrogens also increase osteoblast production of the cytokine osteoproteoglycan (OPG), a soluble non–membrane-bound member of the TNF superfamily (see Chapter 61). OPG acts as a “decoy” receptor that antagonizes the binding of OPG-ligand (OPG-L) to its receptor (termed RANK, or receptor activator of NF-κB) and prevents the differentiation of osteoclast precursors to mature osteoclasts. Estrogens increase osteoclast apoptosis, either directly or by increasing OPG. Estrogens have anti-apoptotic effects on both osteoblasts and osteocytes in animal models, and this
action may be mediated by nongenomic mechanisms (Kousteni et al., 2002). Estrogens affect bone growth and epiphyseal closure in both sexes. The importance of estrogen in the male skeleton is illustrated by a man with a completely defective ER who had osteoporosis, unfused epiphyses, increased bone turnover, and delayed bone age (Smith et al., 1994), and by the observation that male idiopathic osteoporosis is associated with reduced ER α expression in both osteocytes and osteoblasts (Braidman et al., 2000).

Estrogens have many effects on lipid metabolism; of major interest are their effects on serum lipoprotein and triglyceride levels (Walsh et al., 1994). In general, estrogens slightly elevate serum triglycerides and slightly reduce total serum cholesterol levels. More important, they increase HDL levels and decrease the levels of LDL and Lp(a) (see Chapter 35). This beneficial alteration of the ratio of HDL to LDL is an attractive effect of estrogen therapy in postmenopausal women; however, the conclusion from two large clinical trials—the Heart and Estrogen/progestin Replacement Study, or HERS (Hulley et al., 1998), and the Women’s Health Initiative or WHI (Rossouw et al., 2002; Anderson et al., 2004)—is that estrogen-progestin or estrogen-only regimens do not provide any protection from cardiovascular disease. The presence of estrogen receptors in the liver suggests that the beneficial effects of estrogen on lipoprotein metabolism are due partly to direct hepatic actions, but other sites of action cannot be excluded. Estrogens also alter bile composition by increasing bile acid secretion and decreasing bile acid secretion. This leads to increased saturation of bile with cholesterol and appears to be the basis for increased gallstone formation in some women receiving estrogens. The decline in bile acid biosynthesis may contribute to the decreased incidence of colon cancer in women receiving combined estrogen-progestin treatment.

Estrogen alone slightly decreases fasting levels of glucose and insulin but does not have major effects on carbohydrate metabolism. Some older studies of combined oral contraceptives (which contained higher levels of both estrogens and progestins than contraceptives do today) suggested that estrogens might impair glucose tolerance, but it is uncertain whether these effects were due to the progestin or the estrogen component of those oral contraceptives.

Estrogens affect many serum proteins, particularly those involved in hormone binding and clotting cascades. In general, estrogens increase plasma levels of cortisol-binding globulin, thyroxine-binding globulin, and sex hormone–binding globulin (SHBG), which binds both androgens and estrogens.

Estrogens alter a number of metabolic pathways that affect the cardiovascular system (Mendelsohn and Karas, 1999). Systemic effects include changes in lipoprotein metabolism and in hepatic production of plasma proteins. Estrogens cause a small increase in coagulation factors II, VII, IX, X, and XII, and decrease the anticoagulation factors protein C, protein S, and antithrombin III (see Chapter 54). Fibrinolytic pathways also are affected, and several studies of women treated with estrogen alone or estrogen with a progestin have demonstrated decreased levels of plasminogen-activator inhibitor protein-1 (PAI-1) with a concomitant increase in fibrinolysis (Koh et al., 1997). Thus, estrogens increase both coagulation and fibrinolytic pathways, and imbalance in these two opposing activities may cause adverse effects. At relatively high concentrations, estrogens have antioxidant activity and may inhibit the oxidation of LDL by affecting superoxide dismutase. Long-term administration of estrogen is associated with decreased plasma renin, angiotensin-converting enzyme, and endothelin-1; expression of the AT1 receptor for angiotensin II is also decreased. Estrogen actions on the vascular wall include increased production of NO, which occurs within minutes via a mechanism involving activation of Akt (also known as protein kinase B) (Simoncini et al., 2000), and induction of inducible NO synthase and increased production of prostacyclin. All of these changes promote vasodilation. Estrogens also promote endothelial cell growth while inhibiting the proliferation of vascular smooth muscle cells.

**Estrogen Receptors**

Estrogens exert their effects by interaction with receptors that are members of the superfamily of nuclear receptors. The two estrogen receptor genes are located on separate chromosomes: ESR1 encodes ER α, and ESR2 encodes ER β. Both ERs are estrogen-dependent nuclear transcription factors that have different tissue distributions and transcriptional regulatory effects on a wide number of target genes (reviewed by Hanstein et al., 2004). Ligands that discriminate between ER α and ER β have been developed (Harrington et al., 2003) but are not yet in clinical use. Both ER α and ER β exist as multiple mRNA isoforms due to differential promoter use and alternative splicing (reviewed by Kos et al., 2001; Lewandowski et al., 2002). The two human ERs are 44% identical in overall amino-acid sequence and share the domain structure common to members of this family. The estrogen receptor is divided into six functional domains: the NH2-terminal A/B domain contains the activation function-1 (AF-1) segment, which can activate transcription independently of ligand; the
highly conserved C domain comprises the DNA-binding domain, which contains 4 cysteines arranged in 2 zinc fingers; the D domain, frequently called the “hinge region,” contains the nuclear localization signal; and the E/F domain has multiple functions, including ligand binding, dimerization, and ligand-dependent transactivation, mediated by the AF-2 domain. There are significant differences between the two receptor isoforms in the ligand-binding domains and in both transactivation domains. Human ER β does not appear to contain a functional AF-1 domain. The receptors appear to have different biological functions and respond differently to various estrogenic compounds (Kuiper et al., 1997). However, their high homology in the DNA-binding domains suggests that both receptors recognize similar DNA sequences and hence regulate many of the same target genes.

ER α, the first discovered, is expressed most abundantly in the female reproductive tract—especially the uterus, vagina, and ovaries—as well as in the mammary gland, the hypothalamus, endothelial cells, and vascular smooth muscle. ER β is expressed most highly in the prostate and ovaries, with lower expression in lung, brain, bone, and vasculature. Many cells express both ER α and ER β, which can form either homo- or heterodimers. When co-expressed, in many cases ER β inhibits ER α-mediated transcriptional activation (Hall and McDonnell, 1999). Polymorphic variants of ER have been identified, but attempts to correlate specific polymorphisms with the frequency of breast cancer (Han et al., 1999; Kurabayashi et al., 2004), bone mass (Vandevyver et al., 1999; Kurabayashi et al., 2004), endometrial cancer (Weiderpass et al., 2000), or cardiovascular disease (Herrington and Howard, 2003) have led to contradictory results.

**Mechanism of Action**

Both estrogen receptors (ERs) are ligand-activated transcription factors that increase or decrease the transcription of target genes (Figure 57–4). After entering the cell by passive diffusion through the plasma membrane, the hormone binds to an ER in the nucleus. In the nucleus, the ER is present as an inactive monomer bound to heat-shock proteins, and upon binding estrogen, a change in ER conformation dissociates the heat-shock proteins and causes receptor dimerization, which increases the affinity and the rate of receptor binding to DNA (Cheskis et al., 1997). Homodimers of ER α or ER β and ER α/ER β heterodimers can be produced depending on the receptor complement in a given cell. The concept of ligand-mediated changes in ER conformation is central to understanding the mechanism of action of estrogen agonists and antagonists. The ER dimer binds to estrogen response elements (EREs), typically located in the promoter region of target genes with the consensus sequence GGTCANNNT-GACC, but several similar sequences can act as estrogen response elements in a promoter-specific context. The type of ERE with which ERs interact also regulates the three-dimensional structure of the activated receptor (Hall et al., 2002).

The ER/DNA complex recruits a cascade of co-activator and other proteins to the promoter region of target genes (Figure 57–4B). There are three families of proteins that interact with ERs. The first of these has the ability to modify nucleosome structure either in an ATP-dependent manner, like SWI/Snf, or by histone methyl-transferase (HMT) activity, as in proteins such as PRMT1. The second family comprises the p160/SRC proteins and includes SRC-1 (steroid-receptor co-activator-1), SRC-2, and SRC-3. The third family includes p300/CBP (cyclic AMP response-element binding protein), co-activators that are targets of several signal transduction cascades and may integrate function among diverse pathways and the basal transcriptional apparatus. Agonist-bound ERs appear initially to recruit SWI/Snf and HMT members that modify nucleosome structure and facilitate the subsequent recruitment of p160 members and p300 proteins (Metivier et al., 2003). The co-activators and p300 proteins have histone acetylase (HAT) activity. Acetylation of histones further alters chromatin structure in the promoter region of target genes and allows the proteins that make up the general transcription apparatus to assemble and initiate transcription.

Interaction of ERs with antagonists also promotes dimerization and DNA binding. However, an antagonist produces a conformation of ER that is different from the agonist-occupied receptor (Wijayaratne et al., 1999; Smith and O’Malley, 2004). The antagonist-induced conformation facilitates binding of co-repressors such as NcoR/SMRT (nuclear hormone receptor co-repressor/silencing mediator of retinoid and thyroid receptors) (Figure 57–4C). The co-repressor/ER complex then further recruits other proteins with histone deacetylase activity such as HDAC1. Deacetylation of histones alters chromatin conformation and reduces the ability of the general transcription apparatus to form initiation complexes.

Besides co-activators and co-repressors, both ER α and ER β can interact physically with other transcription factors such as Sp1 (Saville et al., 2000) or AP-1 (Paech et al., 1997), and these protein-protein interactions provide an alternate mechanism of action. In these circumstances, ER-ligand complexes interact with Sp1 or AP-1 that is already bound to its specific regulatory element, such that the ER complex does not interact directly with an ERE. This may explain how estrogens are able to regulate genes that lack a consensus ERE. Responses to agonists and antagonists mediated by these protein-protein interactions also are ER isoform- and promoter-specific. For example, 17β-estradiol induces transcription of a target gene controlled by an AP-1 site in the presence of an ER α/AP-1 complex, but inhibits transcription in the presence of an ER β/AP-1
complex. Conversely, anti-estrogens are potent activators of ER \(\beta/\)
AP-1 but not of ER \(\alpha/\)AP-1 complexes.

Other signaling systems may activate nuclear ER by ligand-independent mechanisms. Phosphorylation of ER \(\alpha\) at serine 118 by MAP kinase activates the receptor (Kato et al., 1995). Similarly, PI-
3-kinase–activated Akt directly phosphorylates ER \(\alpha\), causing ligand-independent activation of estrogen-target genes (Simoncini et al., 2000). This provides a means of cross-talk between membrane-bound receptor pathways (i.e., EGF/IGF-1) that activate MAPK and the nuclear ER. In a reciprocal fashion ER may interact directly with members of the Src-Shc/Erk signaling pathway. Activation of Erk by the novel ER and androgen receptor (AR) agonist estren is thought to be responsible for the anti-apoptotic action of this drug in bone (reviewed in Manolagas et al., 2002).

Several studies have suggested that some estrogen receptors are located on the plasma membrane of cells. It appears that this form of the ER is encoded by the same gene that encodes ER \(\alpha\), but it is transported to the plasma membrane, mainly in caveolae (reviewed by Zhu and Smart, 2003). These membrane-localized ERs mediate the rapid activation of some proteins such as MAPK, which is phosphorylated in several cell types within 5 to 10 minutes of 17\(\beta\)-estradiol addition (Endoh et al., 1997), or the rapid increase in cyclic AMP caused by the hormone (Aronica and Katzenellenbogen, 1993). The finding that MAPK is activated by estradiol provides an additional level of cross-talk with growth factors, such as IGF-1 and EGF, that activate this kinase pathway.

**Absorption, Fate, and Elimination**

Various estrogens are available for oral, parenteral, transdermal, or topical administration (Table 57–1). Given the lipophilic nature of estrogens, absorption generally is good with the appropriate preparation. Aqueous or oil-
based esters of estradiol and estrone are available for intramuscular injection, ranging in frequency from every several days to once per month. Transdermal patches that are changed once or twice weekly deliver estradiol continuously through the skin. Preparations are available for topical use in the vagina or creams applied to the skin. For many uses, preparations are available as an estrogen alone or in combination with a progestin.

Oral administration is common and may utilize estradiol, conjugated estrogens, esters of estrone and other estrogens, and ethinyl estradiol. A special micronized preparation of estradiol (ESTRACE, others) that yields a large surface for rapid absorption is required for oral administration, although high doses must be used because absolute bioavailability remains low due to first-pass hepatic metabolism (Fotherby, 1996). Ethinyl estradiol is used orally, as the ethinyl substitution in the C17 position inhibits first-pass hepatic metabolism. Other common oral preparations contain conjugated equine estrogens (PREMARIN), which are primarily the sulfate esters of estrone, equilin, and other naturally occurring compounds; estered esters; or mixtures of conjugated estrogens prepared from plant-derived sources (CESTENIN). These are hydrolyzed by enzymes present in the lower gut that remove the charged sulfate groups and allow absorption of estrogen across the intestinal epithelium. In another oral preparation, estropipate (ORTHO-EST, OGEN), estrone is solubilized as the sulfate and stabilized with piperazine. Due largely to differences in metabolism, the potencies of various oral preparations differ widely; ethinyl estradiol, for example, is much more potent than conjugated estrogens.

A number of foodstuffs and plant-derived products, largely from soy, are available as nonprescription items and often are touted as providing benefits similar to those from compounds with established estrogenic activity. These products may contain flavonoids such as genistein (Table 57–1), which display estrogenic activity in laboratory tests, albeit generally much less than that of estradiol. In theory, these preparations could produce appreciable estrogenic effects, but their efficacy at relevant doses has not been established in human trials (Mäkelä et al., 1999; Fitzpatrick, 2003).

Administration of estradiol via transdermal patches (ESTRADERM, VIVELLE, ALORA, CLIMARA, others) provides slow, sustained release of the hormone, systemic distribution, and more constant blood levels than oral dosing. Estradiol is also available as a topical cream (ESTRASORB) that is applied to the upper thigh and calf, or as a gel (ESTROGEL) that is applied once daily to the arm. The transdermal route does not lead to the high level of the drug that enters the liver via the portal circulation after oral administration, and is thus expected to minimize hepatic effects of estrogens (e.g., on hepatic protein synthesis, lipoprotein profiles, and triglyceride levels).

Other preparations are available for intramuscular injection. When dissolved in oil and injected, esters of estradiol are well absorbed. The aryl and alkyl esters of estradiol become less polar as the size of the substituents increases; correspondingly, the rate of absorption of oily preparations is progressively slowed, and the duration of action can be prolonged. A single therapeutic dose of compounds such as estradiol valerate (DELESTROGEN) or estradiol cypionate (DEPO-ESTRADIOL) may be absorbed over several weeks following a single intramuscular injection. Suspensions containing estrone or a combination of esters (primarily estrone and equilin sulfates) also may be given via intramuscular injection.

Preparations of estradiol and conjugated estrogen creams are available for topical administration to the vagina. These are effective locally, but systemic effects also are possible due to significant absorption. A 3-month vaginal ring (ESTRING, FEMRING) may be used for slow release of estradiol, and tablets are also available for vaginal use (VAGIFEM).

Estradiol, ethinyl estradiol, and other estrogens are extensively bound to plasma proteins. Estradiol and other naturally occurring estrogens are bound mainly to sex hormone–binding globulin (SHBG) and to a lesser degree to serum albumin. In contrast, ethinyl estradiol is bound extensively to serum albumin but not SHBG. Due to their size and lipophilic nature, unbound estrogens distribute rapidly and extensively.

Variations in estradiol metabolism occur and depend upon the stage of the menstrual cycle, menopausal status, and several genetic polymorphisms (Herrington and Klein, 2001). In general, the hormone undergoes rapid hepatic biotransformation, with a plasma half-life measured in minutes. Estradiol is converted primarily by 17β-hydroxysteroid dehydrogenase to estrone, which undergoes conversion by 16α-hydroxylation and 17-β-keto reduction to estriol, the major urinary metabolite. A variety of sulfate and glucuronide conjugates also are excreted in the urine. Lesser amounts of estrone or estradiol are oxidized to the 2-hydroxycatechols by CYP3A4 in the liver and by CYP1A in extrahepatic tissues or to 4-hydroxycatechols by CYP1B1 in extrahepatic sites, with the 2-hydroxycatechol being formed to a greater extent. The 2- and 4-hydroxycatechols are largely inactivated by catechol-O-methyltransferases (COMTs). However, smaller amounts may be converted by CYP- or peroxidase-catalyzed reactions to yield semiquinones or quinones that are capable of forming DNA adducts or of generating (via redox cycling) reactive oxygen species that could oxidize DNA bases (Yue et al., 2003).

Estrogens also undergo enterohepatic recirculation via (1) sulfation and glucuronide conjugation in the liver, (2) biliary secretion of the conjugates into the intestine, and (3) hydrolysis in the gut (largely by bacterial enzymes) followed by reabsorption.

Many other drugs and environmental agents (e.g., cigarette smoke) act as inducers or inhibitors of the various enzymes that metabolize estrogens, and thus have the potential to alter their clearance. Consideration of the impact of these factors on efficacy and untoward effects is increasingly important with the decreased doses of estrogens currently employed for both menopausal hormone therapy and contraception.

Ethinyl estradiol is cleared much more slowly than is estradiol due to decreased hepatic metabolism, and the elimination-phase half-life in various studies ranges from 13 to 27 hours. Unlike estradiol, the primary route of biotransformation of ethinyl estradiol is via 2-hydroxylation and subsequent formation of the corresponding 2- and 3-methyl ethers. Mestranol, another semisynthetic estrogen and a component of some combination oral contraceptives, is the 3-methyl ether of ethinyl estradiol. In the body it undergoes rapid hepatic demethylation to ethinyl estradiol, which is its active form (Fotherby, 1996).

Untoward Responses

Estrogens are highly efficacious, but they do carry a number of risks as well. Many concerns arose initially from studies of early oral contraceptives, which contained high doses of estrogens, but the amount of estrogens (and pro-
gestins) in oral contraceptives has been markedly decreased, which has significantly diminished the risks associated with their use. Nevertheless, major concerns about the use of estrogens remain today, especially regarding cancer, thromboembolic disease, increased risk of cardiovascular disease, altered cognition, changes in carbohydrate and lipid metabolism, hypertension, gallbladder disease, nausea, migraine, changes in mood, and several lesser side effects.

**Concern about Carcinogenic Actions.** The possibility of developing cancer is probably the major concern for the use of estrogens and oral contraceptives. Early studies established that estrogens can induce tumors of the breast, uterus, testis, bone, kidney, and several other tissues in various animal species. These early studies disseminated a fear of cancer resulting from estrogen use.

In later reports (Greenwald et al., 1971; Herbst et al., 1971), an increased incidence of vaginal and cervical adenocarcinoma in women who were exposed to DES during the first trimester of pregnancy. The incidence of clear-cell vaginal and cervical adenocarcinoma in women who were exposed to DES in utero was 0.01% to 0.1% (Food and Drug Administration, 1985); these findings established for the first time that developmental exposure to estrogens was associated with an increase in a human cancer. Estrogen use during pregnancy also can increase the incidence of nonmalignant genital abnormalities in both male and female offspring. Thus, pregnant patients should not be given estrogens because of the possibility of such reproductive tract toxicities.

Other studies established that the use of unopposed estrogen for hormone treatment in postmenopausal women increases the risk of endometrial carcinoma by five- to fifteenfold (Shapiro et al., 1985). This increased risk can be prevented if a progestin is co-administered with the estrogen (Pike et al., 1997), and this is now standard practice.

The association between estrogen and/or estrogen-progestin use and breast cancer continues to be of great concern and debate. The results of two very large, randomized, clinical trials of estrogen-progestin and estrogen-only (i.e., the two arms of The Women’s Health Initiative or WHI) use in postmenopausal women have clearly established a small but significant increase in the risk of breast cancer, apparently due to the medroxyprogesterone (Rossouw et al., 2002; Anderson et al., 2004). In the WHI study, an estrogen-progestin combination increased the total risk of breast cancer by 24%; the absolute increase in attributable cases of disease was 6 per 1000 women and required 3 or more years of treatment. In women without a uterus who received estrogen alone, the relative risk of breast cancer was actually decreased by 23%, and the decrease only narrowly missed reaching statistical significance.

The Million Women Study (MWS) in the United Kingdom was a cohort study rather than a clinical trial (Beral et al., 2003). It surveyed over one million women, about half receiving some type of hormone treatment and half had never used them. Those receiving an estrogen-progestin combination had an increased relative risk of invasive breast cancer of 2, and those receiving estrogen alone had an increased relative risk of 1.3, but the increase in actual attributable cases of the disease was again small.

Both the WHI and MWS data are thus consistent with earlier studies indicating that the progestin component (e.g., medroxyprogesterone) in hormone-replacement therapy plays a major role in this increased risk of breast cancer (Schairer et al., 2000; Ross et al., 2000). Importantly, although long-term data have not accumulated for the WHI trials, the available data suggest that the excess risk of breast cancer associated with menopausal hormone use appears to abate 5 years after discontinuing therapy.

Historically, the carcinogenic actions of estrogens were thought to be related to their trophic effects. An increase in cell proliferation would be expected to cause an increase in spontaneous errors associated with DNA replication, and estrogens would then enhance the growth of clones with mutations introduced by this or other mechanisms (e.g., chemical carcinogens). More recently, another mechanism has been proposed. If catechol estrogens, especially the 4-hydroxycatechols, are converted to semiquinones or quinones prior to “inactivation” by COMT, these products, or reactive oxygen species generated during subsequent biotransformations, may cause direct chemical damage to DNA bases (Yue et al., 2003). In this regard, CYP1B1, which has specific estrogen-4-hydroxylase activity, is present in tissues such as uterus, breast, ovary, and prostate, which often give rise to hormone-responsive cancers (Yue et al., 2003).

**Metabolic and Cardiovascular Effects.** Although they may slightly elevate plasma triglycerides, estrogens themselves generally have favorable overall effects on plasma lipoprotein profiles. However, as noted in a later section dealing with hormone-replacement regimens, progestins may reduce the favorable actions of estrogens. In contrast, estrogens do increase cholesterol levels in bile and cause a relative two- to threefold increase in gallbladder disease. Currently prescribed doses of estrogens do not increase the risk of hypertension.

A number of observational studies, clinical trials using intermediate markers of cardiovascular disease, and numerous animal studies suggested that estrogen therapy in postmenopausal women would reduce the risk of cardiovascular disease by 35% to 50% ( Manson and Martin, 2001). However, two recent randomized clinical trials have not found such protection. The Heart and Estrogen/ progestin Replacement Study, or HERS (Hulley et al., 1998), followed women with established coronary heart disease (CHD) and found that estrogen plus a progestin increased the relative risk of nonfatal myocardial infarction or CHD death within 1 year of treatment, and found no overall change in 5 years. The HERS II follow-up (Grady et al., 2002) found no overall change in the incidence of CHD after 6.8 years of the treatment. A similar conclusion was reached in the WHI trials for women without existing CHD treated with an estrogen plus progestin (Rossouw et al., 2002). These studies establish unequivocally that the estrogen-progestin combination used does not protect against CHD. However, only conjugated equine estrogens (CEE) or CEE plus medroxyprogesterone acetate (MPA) were examined in these studies, and only a single dose was used in a relatively old patient population (e.g., average age approximately 60 years). It thus remains unclear whether these conclusions can be globally extended to other preparations, doses, and patient populations (e.g., women closer to age 50 who typically initiate hormone therapy for relief of vasomotor symptoms).

It is clear, however, that oral estrogens increase the risk of thromboembolic disease in healthy women and in women with pre-existing cardiovascular disease (Grady et al., 2000). The increase in absolute risk is small but significant. In the WHI, for example, an estrogen-progestin combination led to an increase in 8 attributable cases of stroke per 10,000 women and a similar increase in pulmonary embolism (Rossouw et al., 2002).

**Effects on Cognition.** Several retrospective studies had suggested that estrogens had beneficial effects on cognition and delayed the
onset of Alzheimer’s disease (Green and Simpkins, 2000). However, the Women’s Health Initiative Memory Study (WHIMS) of a group of women aged 65 or older (Shumaker et al., 2003) found that estrogen-progestin therapy was associated with a doubling in the number of women diagnosed with probable dementia, and no benefit of hormone treatment on global cognitive function was observed (Rapp et al., 2003). Women in the estrogen-only arm also showed a comparable decrease in cognitive function (Espeland et al., 2004), implicating estrogens in these cognitive changes.

**Other Potential Untoward Effects.** Nausea and vomiting are an initial reaction to estrogen therapy in some women, but these effects may disappear with time and may be minimized by taking estrogens with food or just prior to sleeping. Fullness and tenderness of the breasts and edema may occur but sometimes can be diminished by lowering the dose. A more serious concern is that estrogens may cause severe migraine in some women. Estrogens also may reactivate or exacerbate endometriosis.

**Therapeutic Uses**

The two major uses of estrogens are as components of combination oral contraceptives (see below) and for menopausal hormone therapy (MHT). The pharmacological considerations for their use and the specific drugs and doses used differ in these settings. Historically, conjugated estrogens have been the most common agents for postmenopausal use (0.625 mg/day most often used). In contrast, most combination oral contraceptives in current use employ 20 to 35 μg/day of ethinyl estradiol. These preparations differ widely in their oral potencies; e.g., a dose of 0.625 mg of conjugated estrogens generally is considered equivalent to 5 to 10 μg of ethinyl estradiol. Thus, the “effective” dose of estrogen used for MHT is less than that in oral contraceptives when one considers potency. Furthermore, in the last two decades the doses of estrogens employed in both settings have decreased substantially. The untoward effects of the 20- to 35-μg doses now commonly used thus have a lower incidence and severity than those reported in older studies (e.g., with oral contraceptives that contained 50 to 150 μg of ethinyl estradiol or mestranol).

**Menopausal Hormone Therapy.** The established benefits of estrogen therapy in postmenopausal women include amelioration of vasomotor symptoms and the prevention of bone fractures and urogenital atrophy.

**Vasomotor Symptoms.** The decline in ovarian function at menopause is associated with vasomotor symptoms in most women. The characteristic hot flashes may alternate with chilly sensations, inappropriate sweating, and (less commonly) paresthesias. Treatment with estrogen is specific and is the most efficacious pharmacotherapy for these symptoms (Belchetz, 1994). If estrogen is contraindicated or otherwise undesirable, other options may be considered. Medroxyprogesterone acetate (discussed in the later section on progestins) may provide some relief of vasomotor symptoms for certain patients, and the α2 adrenergic agonist clonidine diminishes vasomotor symptoms in some women, presumably by blocking the CNS outflow that regulates blood flow to cutaneous vessels. In many women, hot flashes diminish within several years; when prescribed for this purpose the dose and duration of estrogen use should thus be the minimum necessary to provide relief.

**Osteoporosis.** Osteoporosis is a disorder of the skeleton associated with the loss of bone mass (see Chapter 61). The result is thinning and weakening of the bones and an increased incidence of fractures, particularly compression fractures of the vertebrae and minimal-trauma fractures of the hip and wrist. The frequency and severity of these fractures and their associated complications (e.g., death and permanent disability) are a major public health problem, especially as the population continues to age. Osteoporosis is an indication for estrogen therapy, which clearly is efficacious in decreasing the incidence of fractures. However, because of the risks associated with estrogen use, first-line use of other drugs should be carefully considered (see Chapter 61). Nevertheless, it is important to note that the majority of fractures in the postmenopausal period occur in women without a prior history of osteoporosis, and estrogens are the most efficacious agents available for prevention of fractures at all sites in such women (Rossock et al., 2002; Anderson et al., 2004).

The primary mechanism by which estrogens act is to decrease bone resorption; consequently, estrogens are more effective at preventing rather than restoring bone loss (Prince et al., 1991; Belchetz, 1994). Estrogens are most effective if treatment is initiated before significant bone loss occurs, and their maximal beneficial effects require continuous use; bone loss resumes when treatment is discontinued. An appropriate diet with adequate intake of Ca and vitamin D and weight-bearing exercise enhance the effects of estrogen treatment. Public health efforts to improve diet and exercise patterns in girls and young women also are rational approaches to increase bone mass.

**Vaginal Dryness and Urogenital Atrophy.** Loss of tissue lining the vagina or bladder leads to a variety of symptoms in many postmenopausal women (Robinson and Cardozo, 2003). These include dryness and itching of the vagina, dyspareunia, swelling of tissues in the genital region, pain during urination, a need to urinate urgently or often, and sudden or unexpected urinary incontinence. When estrogens are being used solely for relief of vulvar and vaginal atrophy, local administration as a vaginal cream, ring device, or tablets may be considered.

**Cardiovascular Disease.** The incidence of cardiovascular disease is low in premenopausal women, rising rapidly after menopause, and epidemiological studies consistently showed an association between estrogen use and reduced cardiovascular disease in postmenopausal women. Furthermore, estrogens produce a favorable lipoprotein profile, promote vasodilation, inhibit the response to vascular injury, and reduce atherosclerosis. Studies such as these led to the widespread use of estrogen for prevention of cardiovascular disease in postmenopausal women (Mendelsohn and Karas, 1999). As discussed above, several randomized, prospective studies (Rossock et al., 2002; Grady et al., 2002) unexpectedly indicated that the incidence of heart disease and stroke in older postmenopausal women treated with conjugated estrogens and a progestin was initially increased, although the trend reversed with time. While it is not clear if similar results would occur with different drugs/doses or in different patient populations (Turgeon et al., 2004), estrogens (alone or in combination with a progestin) should not be used for the treatment or prevention of cardiovascular disease.
**Other Therapeutic Effects.** Many other changes occur in postmenopausal women, including a general thinning of the skin; changes in the urethra, vulva, and external genitalia; and a variety of changes including headache, fatigue, and difficulty concentrating, many of which may be due to the chronic lack of sleep created by hot flushes and other vasomotor symptoms. Estrogen replacement may help alleviate or lessen some of these direct actions (e.g., improvement of vasomotor symptoms) or secondary effects resulting in an improved feeling of well-being (Belchetz, 1994).

The Women's Health Initiative also demonstrated that a conjugated estrogen in combination with a progestin reduces the risk of colon cancer by roughly one-half in postmenopausal women (Rossouw et al., 2002).

**Menopausal Hormone Regimens.** In the 1960s and 1970s there was an increase in estrogen-replacement therapy, or ERT (i.e., estrogens alone), in postmenopausal women, primarily to reduce vasomotor symptoms, vaginitis, and osteoporosis. About 1980, epidemiological studies indicated that this treatment increased the incidence of endometrial carcinoma. This led to the use of hormone-replacement therapy, or HRT, that includes a progestin to limit estrogen-related endometrial hyperplasia. While the actions of progesterone on the endometrium are complex, its effects on estrogen-induced hyperplasia may involve a decrease in estrogen receptor content, increased local conversion of estradiol to the less potent estrone via the induction of 17β-hydroxysteroid dehydrogenase in the tissue, and/or the conversion of the endometrium from a proliferative to a secretory state. “Hormone-replacement” therapy (now generally referred to as “menopausal hormone” therapy) with both an estrogen and progestin now is recommended for postmenopausal women with a uterus (Belchetz, 1994). For women who have undergone a hysterectomy, endometrial carcinoma is not a concern, and estrogen alone avoids the possible deleterious effects of progestins previously discussed.

Conjugated estrogens and medroxyprogesterone acetate (MPA) historically have been used most commonly in menopausal hormone regimens, although estradiol, estrone, and estriol have been used as estrogens, and norethindrone, norgestimate, levonorgestrel, norethisterone, and progesterone also have been widely used (especially in Europe). Various “continuous” or “cyclic” regimens have been used; the latter regimens include drug-free days. An example of a cyclic regimen is as follows: (1) administration of an estrogen for 25 days; (2) the addition of MPA for the last 12 to 14 days of estrogen treatment; and (3) 5 to 6 days with no hormone treatment, during which withdrawal bleeding normally occurs due to breakdown and shedding of the endometrium. Continuous administration of combined estrogen plus progestin does not lead to regular, recurrent endometrial shedding, but may cause intermittent spotting or bleeding, especially in the first year of use. Other regimens include a progestin intermittently (e.g., every third month), but the long-term endometrial safety of these regimens remains to be firmly established. PREMPRO (conjugated estrogens plus MPA given as a fixed dose daily) and PREMPHASE (conjugated estrogens given for 28 days plus MPA given for 14 out of 28 days) are widely used combination formulations. Other combination products available in the United States are FEMHRT (ethinyl estradiol plus norethindrone acetate), ACTIVELLA (estradiol plus norethindrone), and PREFEEST (estradiol and norgestimate). Doses and regimens are usually adjusted empirically based on control of symptoms, patient acceptance of bleeding patterns, and/or other untoward effects.

Another pharmacological consideration is the route of estrogen administration. Oral administration exposes the liver to higher concentrations of estrogens than transdermal administration. Either route effectively relieves vasomotor symptoms and protects against bone loss. Oral but not transdermal estrogen may increase SHBG, other binding globulins, and angiotensinogen; the oral route might be expected to cause greater increases in the cholesterol content of the bile. Transdermal estrogen appears to cause smaller beneficial changes in LDL and HDL profiles (approximately 50% of those seen with the oral route) (Walsh et al., 1994), but may be preferred in women with hypertriglyceridemia.

**Tibolone** (LIVIAL) is widely used in Europe for treatment of vasomotor symptoms and prevention of osteoporosis but is not currently approved in the United States. The parent compound itself is devoid of activity, but it is metabolized in a tissue-selective manner to three metabolites that have predominantly estrogenic, progestogenic, and androgenic activities. The drug appears to increase bone mineral density and decrease vasomotor symptoms without stimulating the endometrium, but its effects on fractures, breast cancer, and long-term outcomes remain to be established (Modelska and Cummings, 2002).

Regardless of the specific agent or regimen, menopausal hormone therapy with estrogens should use the lowest dose and shortest duration necessary to achieve an appropriate therapeutic goal.

**Estrogen Treatment in the Failure of Ovarian Development.** In several conditions (e.g., Turner’s syndrome), the ovaries do not develop and puberty does not occur. Therapy with estrogen at the appropriate time replicates the events of puberty, and androgens (see Chapter 58) and/or growth hormone (see Chapter 55) may be used concomitantly to promote normal growth. While estrogens and androgens promote bone growth, they also accelerate epiphyseal fusion, and their premature use can thus result in a shorter ultimate height.

---

**SELECTIVE ESTROGEN RECEPTOR MODULATORS (SERMS) AND ANTI-ESTROGENS**

In the past, estrogen pharmacology was based on a simple model of an agonist binding to a single ER that subsequently affected transcription by the same molecular mechanism in all target tissues, and of antagonists that acted by simple competition with agonists for binding. This simple concept is no longer valid. By altering the conformation of the two different ERs and thereby changing interactions with coactivators and co-repressors in a cell- and promoter-specific context, ligands may have a broad spectrum of activities from purely anti-estrogenic in all tissues, to partially estrogenic in some tissues with anti-estrogenic or no activities in others, to purely estrogenic activities in all tissues. The elu-
cidation of these concepts has been a major breakthrough in estrogen pharmacology and should permit the rational design of drugs with very selective patterns of estrogenic activity (Smith and O’Malley, 2004).

**SERMs: Tamoxifen, Raloxifene, and Toremifene.** Selective estrogen receptor modulators, or SERMs, are compounds with tissue-selective actions. The pharmacological goal of these drugs is to produce beneficial estrogenic actions in certain tissues (e.g., bone, brain, and liver) during postmenopausal hormone therapy, but antagonist activity in tissues such as breast and endometrium, where estrogenic actions (e.g., carcinogenesis) might be deleterious. Currently approved drugs in the United States in this class are tamoxifen citrate (NOLVADEX, OTHERS), raloxifene hydrochloride (EVISTA), and toremifene (FARESTON), which is chemically related and has similar actions to tamoxifen. Tamoxifen and toremifene are used for treatment of breast cancer, and raloxifene is used primarily for prevention and treatment of osteoporosis.

**Anti-estrogens: Clomiphene and Fulvestrant.** These compounds are distinguished from the SERMs in that they are pure antagonists in all tissues studied. Clomiphene (CLOMID, SEROPHENE, others) is approved for the treatment of infertility in anovulatory women, and fulvestrant (FASLODEX, ICI 182,780) is used for the treatment of breast cancer in women with disease progression after tamoxifen.

**Chemistry.** The structures of the trans-isomer of tamoxifen, and of raloxifene, trans-clomiphene (enclomiphene), and fulvestrant are as follows:

Tamoxifen is a triphenylethylene with the same stilbene nucleus as diethylstilbestrol; compounds of this class display a variety of estrogenic and anti-estrogenic activities. In general, the trans conformations have anti-estrogenic activity, whereas the cis conformations display estrogenic activity. However, the pharmacological activity of the trans compound depends on the species, target tissue, and gene. Hepatic metabolism produces primarily N-desmethyltamoxifen, which has affinity for ER comparable to that of tamoxifen, and lesser amounts of the highly active 4-hydroxy metabolite, which has a 25 to 50 times higher affinity for both ER \( \alpha \) and ER \( \beta \) than does tamoxifen (Kuiper et al., 1997). Tamoxifen is marketed as the pure trans-isomer. Toremifene is a triphenylethylene with a chlorine substitution at the R2 position.

Raloxifene is a polyhydroxylated nonsteroidal compound with a benzothiophene core. Raloxifene binds with high affinity for both ER \( \alpha \) and ER \( \beta \) (Kuiper et al., 1997).

Clomiphene citrate is a triphenylethylene; its two isomers, zuclomiphene (cis-clomiphene) and enclomiphene (trans-clomiphene), are a weak estrogen agonist and a potent antagonist, respectively. Clomiphene binds to both ER \( \alpha \) and ER \( \beta \), but the individual isomers have not been examined (Kuiper et al., 1997).

Fulvestrant is a 7\( \alpha \)-alkylamide derivative of estradiol that interacts with both ER \( \alpha \) and ER \( \beta \) (Van Den Bemd et al., 1999).

**Pharmacological Effects**

Tamoxifen exhibits anti-estrogenic, estrogenic, or mixed activity depending on the species and target gene measured. In clinical tests or laboratory studies with human cells, the drug’s activity depends on the tissue and endpoint measured. For example, tamoxifen inhibits the proliferation of cultured human breast cancer cells and reduces tumor size and number in women (reviewed in Jaiyesimi et al., 1995), and yet it stimulates proliferation of endometrial cells and causes endometrial thickening (Lahti et al., 1993). The drug has an antiresorptive effect on bone, and in humans it decreases total cholesterol, LDL, and lipoprotein (a), but does not increase HDL and triglycerides (Love et al., 1994). Tamoxifen treatment causes a two- to threefold increase in the relative risk of deep vein thrombosis and pulmonary embolism and a roughly twofold increase in endometrial carcinoma (Smith, 2003). Tamoxifen produces hot flashes and other adverse effects, including cataracts and nausea. Due to its agonist activity in bone, it does not increase the incidence of fractures when used in this setting.
Raloxifene is an estrogen agonist in bone, where it exerts an antiresorptive effect. It reduces the number of vertebral fractures by up to 50% in a dose-dependent manner (Delmas et al., 1997; Ettinger et al., 1999). The drug also acts as an estrogen agonist in reducing total cholesterol and LDL, but it does not increase HDL or normalize plasminogen-activator inhibitor 1 in postmenopausal women (Walsh et al., 1998). Raloxifene does not cause proliferation or thickening of the endometrium. Preclinical studies indicate that raloxifene has an antiproliferative effect on ER-positive breast tumors and on proliferation of ER-positive breast cancer cell lines (Hol et al., 1997) and significantly reduces the risk of ER-positive but not ER-negative breast cancer (Cummings et al., 1999). Raloxifene does not alleviate the vasomotor symptoms associated with menopause. Adverse effects include hot flashes and leg cramps and a threefold increase in deep vein thrombosis and pulmonary embolism (Cummings et al., 1999).

Initial animal studies with clomiphene showed slight estrogenic activity and moderate anti-estrogenic activity, but the most striking effect was the inhibition of pituitary gonadotropes. In contrast, the most prominent effect in women was enlargement of the ovaries, and the drug induced ovulation in many patients with amenorrhea, polycystic ovarian syndrome, and dysfunctional bleeding with anovulatory cycles. This is the basis for clomiphene’s major pharmacological use: to induce ovulation in women with a functional hypothalamic-hypophyseal-ovarian system and adequate endogenous estrogen production. In some cases, clomiphene is used in conjunction with human gonadotropins (see Chapter 55) to induce ovulation.

Fulvestrant and its less potent forerunner ICI 164,384 have been purely anti-estrogenic in studies to date. In vitro, fulvestrant was more potent than 4-hydroxytamoxifen (DeFriend et al., 1994) in inhibiting proliferation of breast cancer cells, and in clinical trials it is efficacious in treating tamoxifen-resistant breast cancers (Robertson et al., 2003).

All of these agents bind to the ligand-binding pocket of both ER α and ER β and competitively block estradiol binding. However, the conformation of the ligand-bound ERs is different with different ligands (Smith and O’Malley, 2004), and this has two important mechanistic consequences. The distinct ER-ligand conformations recruit different co-activators and co-repressors onto the promoter of a target gene by differential protein-protein interactions at the receptor surface. The tissue-specific actions of SERMs thus can be explained in part by the distinct conformation of the ER when occupied by different ligands, in combination with different co-activator and co-repressor levels in different cell types that together affect the nature of ER complexes formed in a tissue-selective fashion.

The conformation of ERs, especially in the AF-2 domain, determines whether a co-activator or a co-repressor will be recruited to the ER-DNA complex (Smith and O’Malley, 2004). While 17β-estradiol induces a conformation that recruits co-activators to the receptor, tamoxifen induces a conformation that permits the recruitment of the co-repressor to both ER α and ER β. The agonist activity of tamoxifen seen in tissues such as the endometrium is mediated by the ligand-independent AF-1 transactivation domain of ER α; since ER β does not contain a functional AF-1 domain, tamoxifen does not activate ER β (McClerneny et al., 1998).

Raloxifene acts as a partial agonist in bone but does not stimulate endometrial proliferation in postmenopausal women. Presumably this is due to some combination of differential expression of transcription factors in the two tissues and the effects of this SERM on ER conformation. Raloxifene induces a configuration in ER α that is distinct from that of tamoxifen-ER β (Tamrazi et al., 2003), suggesting that a different set of co-activators/co-repressors may interact with ER-raloxifene compared to ER-tamoxifen.

Clomiphene increases gonadotropin secretion and stimulates ovulation. It increases the amplitude of LH and FSH pulses without changing pulse frequency (Kettel et al., 1993). This suggests that the drug is acting largely at the pituitary level to block inhibitory actions of estrogen on gonadotropin release from the gland, and/or is somehow causing the hypothalamus to release larger amounts of GnRH per pulse.

Fulvestrant binds to ER α and ER β with a high affinity comparable to estradiol, but represses transactivation. It also increases dramatically the intracellular proteolytic degradation of ER α, while apparently protecting ER β from degradation (Van Den Bemd et al., 1999). This effect on ER α protein levels may explain its efficacy in tamoxifen-resistant breast cancer.

**Absorption, Fate, and Excretion**

Tamoxifen is given orally, and peak plasma levels are reached within 4 to 7 hours after treatment. This drug displays two elimination phases with half-lives of 7 to 14 hours and 4 to 11 days. Due to the prolonged half-life, 3 to 4 weeks of treatment are required to reach steady-state plasma levels. The parent drug is converted largely to metabolites within 4 to 6 hours after oral administration. Tamoxifen is metabolized in humans by multiple hepatic CYPs, some of which it also induces (Sridar et al., 2002). In human beings and other species, 4-hydroxytamoxifen is produced via hepatic metabolism, and this compound is considerably more potent than the parent drug as an anti-estrogen. The major route of elimination from the body involves N-demethylation and deamination. The drug undergoes enterohepatic circulation, and excretion is primarily in the feces as conjugates of the deaminated metabolite.

Raloxifene is absorbed rapidly after oral administration and has an absolute bioavailability of about 2%. The drug has a half-life of about 28 hours and is eliminated primarily in the feces after hepatic glucuronidation; it does not appear to undergo significant biotransformation by CYPs.

Clomiphene is well absorbed following oral administration, and the drug and its metabolites are eliminated primarily in the feces and to a lesser extent in the urine. The long plasma half-life (5 to 7 days) is due largely to plasma-protein binding, enterohepatic circulation, and accumulation in fatty tissues. Other active metabolites with long half-lives also may be produced.

Fulvestrant is administered monthly by intramuscular depot injections. Plasma concentrations reach maximal levels in 7 days and are maintained for a month. Numerous metabolites are formed.
in vivo, possibly by pathways similar to endogenous estrogen metabolism, but the drug is eliminated primarily (90%) via the feces in humans.

**Therapeutic Uses**

**Breast Cancer.** Tamoxifen is highly efficacious in the treatment of breast cancer. It is used alone for palliation of advanced breast cancer in women with ER-positive tumors, and it is now indicated as the hormonal treatment of choice for both early and advanced breast cancer in women of all ages (Jaiesimi et al., 1995). Response rates are approximately 50% in women with ER-positive tumors and 70% for ER- and PR-positive tumors. Tamoxifen increases disease-free survival and overall survival; treatment for 5 years reduces cancer recurrence by 50% and death by 27% and is more efficacious than shorter 1- to 2-year treatment periods. Tamoxifen reduces the risk of developing contralateral breast cancer and is approved for primary prevention of breast cancer in women at high risk, in whom it causes a 50% decrease in the development of new tumors. Prophylactic treatment should be limited to 5 years, as effectiveness decreases thereafter. The most frequent side effect is hot flashes. Tamoxifen has estrogenic activity in the uterus, increases the risk of endometrial cancer by two- to threefold, and also causes a comparable increase in the risk of thromboembolic disease that leads to serious risks for women receiving anticoagulant therapy (Smith, 2003).

Toremifene has therapeutic actions similar to tamoxifen, and fulvestrant may be efficacious in women who become resistant to tamoxifen. Untoward effects of fulvestrant include hot flashes, GI symptoms, headache, back pain, and pharyngitis.

**Osteoporosis.**Raloxifene reduces the rate of bone loss and may increase bone mass at certain sites. In a large clinical trial, raloxifene increased spinal bone mineral density by more than 2% and reduced the rate of vertebral fractures by 30% to 50%, but did not significantly reduce nonvertebral fractures (Ettinger et al., 1999; Delmas et al., 2002). Raloxifene does not appear to increase the risk of developing endometrial cancer. The drug has beneficial actions on lipoprotein metabolism, reducing both total cholesterol and LDL; however, HDL is not increased. Adverse effects include hot flashes, deep vein thrombosis, and leg cramps.

**Infertility.** Clomiphene is used primarily for treatment of female infertility due to anovulation. By increasing gonadotropin levels, primarily FSH, it enhances follicular recruitment. It is relatively inexpensive, orally active, and requires less extensive monitoring than do other treatment protocols. However, the drug may exhibit untoward effects, including ovarian hyperstimulation, increased incidence of multiple births, ovarian cysts, hot flashes, and blurred vision. In addition, clomiphene-induced cycles have a relatively high incidence of luteal phase dysfunction due to inadequate progesterone production, and prolonged use (e.g., 12 or more cycles) may increase the risk of ovarian cancer. The drug should not be administered to pregnant women due to reports of teratogenicity in animals, but there is no evidence of this when the drug has been used to induce ovulation. Clomiphene also may be used to evaluate the male reproductive system, since testosterone feedback on the hypothalamus and pituitary is mediated to a large degree by estrogens formed from aromatization of the androgen.

**Experimental SERM-Estrogen Combinations.**There is considerable interest in menopausal hormone therapy using combinations of a pure estrogen agonist (e.g., estradiol) with a SERM that has predominantly antagonist activity in the breast and endometrium, but does not distribute to the CNS. The strategy is to obtain the beneficial actions of the agonist (e.g., prevention of hot flashes and bone loss), while the SERM blocks unwanted agonist action at peripheral sites (e.g., proliferative effects in breast and endometrium), but does not enter the brain to cause hot flashes. Animal studies have been encouraging (Labrie et al., 2003), but clinical efficacy and safety of this approach remain to be established.

**Estrogen-Synthesis Inhibitors**

Several agents can be used to block estrogen biosynthesis. Continual administration of GnRH agonists prevents ovarian synthesis of estrogens but not their peripheral synthesis from adrenal androgens (see Chapter 55). Aminoglutethimide inhibits aromatase activity, but its use is limited by lack of selectivity (see Chapters 51 and 59).

The recognition that locally produced, as well as circulating, estrogens may play a significant role in breast cancer has greatly stimulated interest in the use of aromatase inhibitors to selectively block production of estrogens (see Chapter 51). Both steroidal (e.g., formestane and exemestane [AROMASIN]) and nonsteroidal agents (e.g., anastrozole [ARIMIDEX], letrozole [FEMARA], and vorozole) are available. Steroidal, or type I, agents are substrate analogs that act as suicide inhibitors to irreversibly inactivate aromatase, while the nonsteroidal, or type II, agents interact reversibly with the heme groups of CYPs (Haynes et al., 2003). Exemestane, letrozole, and anastrozole are current-
ly approved in the United States for the treatment of breast cancer. The structures of exemestane and anastrozole are as follows:

As discussed in Chapter 51, these agents may be used as first-line treatment of breast cancer or as second-line drugs after tamoxifen. They are highly efficacious and actually superior to tamoxifen in some adjuvant settings (Coombes et al., 2004), but unlike tamoxifen, they do not increase the risk of uterine cancer or venous thromboembolism. Because they dramatically reduce circulating as well as local levels of estrogens, they produce hot flashes. Their potential long-term effects on bone and plasma lipids remain to be established.

There is also great interest in the potential use of aromatase inhibitors for the chemoprevention of breast cancer. These agents decrease estrogen levels and thus block hormonal effects as tumor promoters (i.e., by stimulating cell proliferation), but would also prevent actions of locally produced estrogens to initiate tumors (i.e., via formation of DNA-adducts). This would provide a theoretical advantage over tamoxifen, which would only be expected to decrease actions of estrogens as tumor promoters.

PROGESTINS

Compounds with biological activities similar to those of progesterone have been variously referred to in the literature as progestins, progestational agents, progestagens, progestogens, gestagens, or gestogens. The progestins (Figure 57–5) include the naturally occurring hormone progesterone, 17α-acetoxyprogesterone derivatives in the pregnane series, 19-nortestosterone derivatives (estranes), and norgestrel and related compounds in the gonane series. Medroxyprogesterone acetate (MPA) and megestrol acetate are C21 steroids with selective activity very similar to that of progesterone itself. MPA and oral micronized progesterone are widely used with estrogens for menopausal hormone therapy and other situations in which a selective progestational effect is desired, and a depot form of MPA is used as a long-acting injectable contraceptive. The 19-nortestosterone derivatives were developed for use as progestins in oral contraceptives, and while their predominant activity is progestational, they exhibit androgenic and other activities. The gonanes are a more recently developed series of “19-nor” compounds, containing an ethyl rather than a methyl substituent in the 13-position, and they have diminished androgenic activity. These two classes of 19-nortestosterone derivatives are the progestational components of all oral and some long-acting injectable contraceptives.

Figure 57–5. Structural features of various progestins.
History. Corner and Allen originally isolated a hormone in 1933 from the corpora lutea of sows and named it “progestin.” The next year, several European groups independently isolated the crystalline compound and called it “luteo-sterone,” unaware of the previous name. This difference in nomenclature was resolved in 1935 at a garden party in London given by Sir Henry Dale, who helped persuade all parties that the name “progesterone” was a suitable compromise.

Two major advances overcame the early difficulties and economical expense of obtaining progesterone from animal sources. The first was the synthesis of progesterone by Russell Marker from the plant product diosgenin in the 1940s, which provided relatively inexpensive and highly pure product. The second was the synthesis of 19-nor compounds, the first orally active progestins, in the early 1950s by Carl Djerassi, who synthesized norethindrone at Syntex, and Frank Colton, who synthesized the isomer norethynodrel at Searle. These advances led to the development of effective oral contraceptives.

Chemistry. Unlike the ER, which requires a phenolic A ring for high-affinity binding, the progesterone receptor (PR) favors a Δ^{4}-3-one A-ring structure in an inverted 1β, 2α-conformation (Duax et al., 1988). Other steroid hormone receptors also bind this nonphenolic A-ring structure, although the optimal conformation differs from that for the PR. Thus, some synthetic progestins (especially the 19-nor compounds) display limited binding to glucocorticoid, androgen, and mineralocorticoid receptors, a property that probably accounts for some of their nonprogestational activities. The spectrum of activities of these compounds is highly dependent upon specific substituent groups, especially the nature of the C17 substituent in the D ring, the presence of a C19 methyl group, and the presence of an ethyl group at position C13.

One major class of agents is similar to progesterone and its metabolite 17α-hydroxyprogesterone (Figure 57–5). Compounds such as hydroxyprogesterone caproate have progestational activity but must be used parenterally due to first-pass hepatic metabolism. However, further substitutions at the 6-position of the B ring yield orally active compounds such as medroxyprogesterone acetate and megestrol acetate with selective progestational activity.

The second major class of agents is 19-nor testosterone derivatives. These testosterone derivatives, lacking the C19 methyl group, display primarily progestational rather than androgenic activity. An ethynyl substituent at C17 decreases hepatic metabolism and yields orally active 19-nortestosterone analogs such as norethindrone, norethynodrel, ethynodiol diacetate. The activity of the latter three compounds is due primarily to their rapid in vivo conversion to norethindrone. These compounds are less selective than the 17α-hydroxyprogesterone derivatives mentioned above and have varying degrees of androgenic activity, and to a lesser extent, estrogenic and anti-estrogenic activities.

Replacement of the 13-methyl group of norethindrone with a 13-ethyl substituent yields the gonane norgestrel, which is a more potent progestin than the parent compound but has less androgenic activity. Norgestrel is a racemic mixture of an inactive dextrorotatory isomer and the active levorotatory isomer, levonorgestrel. Preparations containing half as much levonorgestrel as norgestrel thus prepared structures is changed to a scant, viscid material. As noted previously, these and other effects of progestins decrease penetration of the cervix by sperm.

Reproductive Tract. Progesterone decreases estrogen-driven endometrial proliferation and leads to the development of a secretory endometrium (Figure 57–3), and the abrupt decline in progesterone at the end of the cycle is the main determinant of the onset of menstruation. If the duration of the luteal phase is artificially lengthened, either by sustaining luteal function or by treatment with progesterone, decidual changes in the endometrial stroma similar to those seen in early pregnancy can be induced. Under normal circumstances, estrogen antecedes and accompanies progesterone in its action upon the endometrium and is essential to the development of the normal menstrual pattern.

Progesterone also influences the endocervical glands, and the abundant watery secretion of the estrogen-stimulated structures is changed to a scant, viscid material. As noted previously, these and other effects of progestins decrease penetration of the cervix by sperm.

The estrogen-induced maturation of the human vaginal epithelium is modified toward the condition of pregnancy by the action of progesterone, a change that can be detected in cytological alterations in the vaginal smear. If the quantity of estrogen concurrently acting is known to be adequate, or if it is assured by giving estrogen, the cytological response to a progestin can be used to evaluate its progestational potency.
Progesterone is very important for the maintenance of pregnancy. Progesterone suppresses menstruation and uterine contractility, but other effects also may be important. These effects to maintain pregnancy led to the historical use of progestins to prevent threatened abortion. However, such treatment is of questionable benefit, probably because spontaneous abortion infrequently results from diminished progesterone. Based on a recent report that premature labor in high-risk mothers was diminished by weekly intramuscular administration of 17-hydroxyprogesterone (DELALUTIN), this indication is being re-evaluated (Meis et al., 2003).

**Mammary Gland.** Development of the mammary gland requires both estrogen and progesterone. During pregnancy and to a minor degree during the luteal phase of the cycle, progesterone, acting with estrogen, brings about a proliferation of the acini of the mammary gland. Toward the end of pregnancy, the acini fill with secretions and the vasculature of the gland notably increases; however, only after the levels of estrogen and progesterone decrease at parturition does lactation begin.

During the normal menstrual cycle, mitotic activity in the breast epithelium is very low in the follicular phase and then peaks in the luteal phase. This pattern is due to progesterone, which triggers a single round of mitotic activity in the mammary epithelium. This effect is transient, however, and continued exposure to the hormone is rapidly followed by arrest of growth of the epithelial cells. As described above, progesterone may be responsible for the increased risk of breast cancer associated with estrogen-progestin use in postmenopausal women (Anderson et al., 2004; Ros sow et al., 2002).

**CNS Effects.** During a normal menstrual cycle, an increase in basal body temperature of about 0.6°C (1°F) may be noted at mid-cycle; this correlates with ovulation. This increase is due to progesterone, but the exact mechanism of this effect is unknown. Progesterone also increases the ventilatory response of the respiratory centers to carbon dioxide and leads to reduced arterial and alveolar P CO2 in the luteal phase of the menstrual cycle and during pregnancy. Progesterone also may have depressant and hypnotic actions in the CNS, possibly accounting for reports of drowsiness after hormone administration. This potential untoward effect may be abrogated by giving progesterone preparations at bedtime, which may even help some patients sleep.

**Metabolic Effects.** Progestins have numerous metabolic actions. Progesterone itself increases basal insulin levels and the rise in insulin after carbohydrate ingestion, but it does not normally alter glucose tolerance. However, long-term administration of more potent progestins, such as norgestrel, may decrease glucose tolerance. Progesterone stimulates lipoprotein lipase activity and seems to enhance fat deposition. Progesterone and analogs such as MPA have been reported to increase LDL and cause either no effects or modest reductions in serum HDL levels. The 19-norprogestins may have more pronounced effects on plasma lipids because of their androgenic activity. In this regard, a large prospective study has shown that MPA decreases the favorable HDL increase caused by conjugated estrogens during postmenopausal hormone replacement, but does not significantly affect the beneficial effect of estrogens to lower LDL. In contrast, micronized progesterone does not significantly affect beneficial estrogen effects on either HDL or LDL profiles (Writing Group for the PEPI Trial, 1995). Progesterone also may diminish the effects of aldosterone in the renal tubule and cause a decrease in sodium reabsorption that may increase mineralocorticoid secretion from the adrenal cortex.

**Mechanism of Action**

There is a single gene that encodes two isoforms of the progesterone receptor (PR): PR-A and PR-B. The first 164 N-terminal amino acids of PR-B are missing from PR-A; this occurs by use of two distinct estrogen-dependent promoters in the PR gene (Giangrande and McDonnell, 1999). The ratios of the individual isoforms vary in reproductive tissues as a consequence of tissue type, developmental status, and hormone levels. Both PR-A and PR-B have AF-1 and AF-2 transactivation domains, but the longer PR-B also contains an additional AF-3 that contributes to its cell- and promoter-specific activity. Since the ligand-binding domains of the two PR isoforms are identical, there is no difference in ligand binding. In the absence of ligand, PR is present in the nucleus in an inactive monomeric state bound to heat-shock proteins (HSP-90, HSP-70, and p59). Upon binding progesterone, the heat-shock proteins dissociate, and the receptors are phosphorylated and subsequently form dimers (homo- and heterodimers) that bind with high selectivity to PREs (progesterone response elements) located on target genes (Giangrande and McDonnell, 1999). Transcriptional activation by PR occurs primarily via recruitment of co-activators such as SRC-1, NcoA-1, or NcoA-2 (Collingwood et al., 1999). The receptor–co-activator complex then favors further interactions with additional proteins such as CBP and p300, which have histone acetylase activity. Histone acetylation causes a remodeling of chromatin that
increases the accessibility of general transcriptional proteins, including RNA polymerase II, to the target promoter. Progesterone antagonists also facilitate receptor dimerization and DNA binding, but, as with ER, the conformation of antagonist-bound PR is different from that of agonist-bound PR. This different conformation favors PR interaction with co-repressors such as NcoR/SMRT, which recruit histone deacetylases. Histone deacetylation increases DNA interaction with nucleosomes and renders a target promoter inaccessible to the general transcription apparatus.

The biological activities of PR-A and PR-B are distinct and depend on the target gene in question. In most cells, PR-B mediates the stimulatory activities of progesterone; PR-A strongly inhibits this action of PR-B (Vegeto et al., 1993) and is also a transcriptional inhibitor of other steroid receptors (McDonnell and Goldman, 1994). Current data suggest that co-activators and co-repressors interact differentially with PR-A and PR-B, e.g., the co-repressor SMRT binds much more tightly to PR-A than to PR-B (Giangrande et al., 2000), and this may account, at least in part, for the differential activities of the two isoforms. Female PR-A knockout mice are infertile, with impaired ovulation and defective decidualization and implantation. Several uterine genes appear to be regulated exclusively by PR-A, including calcitonin and amphiregulin (Mulac-Jericevic et al., 2000), and the antiproliferative effect of progesterone on the estrogen-stimulated endometrium is lost in PR-A knockout mice. In contrast, knockout studies suggest that PR-B is largely responsible for mediating hormone effects in the mammary gland (Mulac-Jericevic et al., 2003).

Certain effects of progesterone, such as increased Ca\(^{2+}\) mobilization in sperm, can be seen in as little as 3 minutes (Blackmore, 1999), and these effects are caused by nongenomic mechanisms involving membrane-bound progesterone receptors that are not derived from the gene encoding PR-A/PR-B (Losel et al., 2004). The pharmacological importance of these membrane-bound receptors has not been determined.

**Absorption, Fate, and Excretion**

Progesterone undergoes rapid first-pass metabolism, but high-dose (e.g., 100 to 200 mg) preparations of micronized progesterone (PROMETRIUM) are available for oral use. Although the absolute bioavailability of these preparations is low (Fotherby, 1996), efficacious plasma levels nevertheless may be obtained. Progesterone also is available in oil solution for injection, as a vaginal gel (CRINONE, PROCHIEVE), and as a slow-release intrauterine device (PROGESTASERT) for contraception.

Esters such as hydroxyprogesterone caproate (HYALUTIN) and MPA (DEPO-PROVERA) are available for intramuscular administration, and MPA (PROVERA, others) and megestrol acetate (MEGACE) may be used orally due to decreased hepatic metabolism. The 19-nor steroids have good oral activity because the ethinyl substituent at C17 significantly slows hepatic metabolism. Implants and depot preparations of synthetic progestins are available in many countries for release over very long periods of time (see later section on contraceptives).

In the plasma, progesterone is bound by albumin and corticosteroid-binding globulin, but is not appreciably bound to SHBG. 19-Nor compounds, such as norethindrone, norgestrel, and desogestrel, bind to SHBG and albumin, and esters such as MPA bind primarily to albumin. Total binding of all these synthetic compounds to plasma proteins is extensive, 90% or more, but the proteins involved are compound-specific.

The elimination half-life of progesterone is approximately 5 minutes, and the hormone is metabolized primarily in the liver to hydroxylated metabolites and their sulfate and glucuronide conjugates, which are eliminated in the urine. A major metabolite specific for progesterone is pregnane-3α, 20α-diol; its measurement in urine and plasma is used as an index of endogenous progesterone secretion. The synthetic progestins have much longer half-lives, e.g., approximately 7 hours for norethindrone, 16 hours for norgestrel, 12 hours for gestodene, and 24 hours for MPA. The metabolism of synthetic progestins is thought to be primarily hepatic, and elimination is generally via the urine as conjugates and various polar metabolites, although their metabolism is not as clearly defined as that of progesterone.

**Therapeutic Uses**

The two most frequent uses of progestins are for contraception, either alone or with an estrogen (see below), and in combination with estrogen for hormone therapy of postmenopausal women (see above).

Progestins also are used for secondary amenorrhea, abnormal uterine bleeding in patients without underlying organic pathology (e.g., fibroids or cancer), luteal-phase support to treat infertility, and premature labor. Among the oral progestins used besides MPA in these settings is norethindrone acetate (AYGESTIN). In general, these uses of oral progestins are extensions of the physiological actions of progesterone on the neuroendocrine control of ovarian function and on the endometrium.

Progesterone can be used diagnostically to test for estrogen secretion and for responsiveness of the endometrium. After administration of progesterone to amenorrheic women for 5 to 7 days, withdrawal bleeding will occur if the endometrium has been stimulated by endogenous estrogens. Combinations of estrogens and progestins also can be used to test endometrial responsiveness in patients with amenorrhea.

As described above, progestins are highly efficacious in decreasing the occurrence of endometrial hyperplasia and carcinoma caused by unopposed estrogens; when used in this setting, there appears to be less irregular uterine bleeding with sequential rather than continuous administration. When used to decrease estrogen-induced endometrial hyperplasia, local intrauterine application via a hormone-releasing IUD would be a rational approach to prevent untoward effects (e.g., unfavorable lipid profiles and incidence of breast cancer) of systemically administered progestins. Progestins are also used as a palliative measure for metastatic endometrial carcinoma, but adjuvant therapy after surgery does not significantly reduce cancer-related deaths; megestrol acetate is used as a second-line treatment for breast cancer. Megestrol acetate is also used off-label for AIDS-related wasting.

**ANTI-PROGESTINS AND PROGESTERONE-RECEPTOR MODULATORS**

The first report of an anti-progestin, RU 38486 (often referred to as RU-486) or mifepristone, appeared in 1981;
this drug is available for the termination of pregnancy (Christin-Maitre et al., 2000). Anti-progestins also have several other potential applications, including uses as contraceptives, to induce labor, and to treat uterine leiomomas, endometriosis, meningiomas, and breast cancer (Spitz and Chwalisz, 2000).

**Mifepristone**

**Chemistry.** Mifepristone is a derivative of the 19-norprogestin norethindrone containing a dimethyl-aminophenol substituent at the 11β-position. It effectively competes with both progesterone and glucocorticoids for binding to their respective receptors. Mifepristone was initially thought to be a pure anti-progestin; this is its predominant activity in most situations, but it also has some agonist activity. Thus it is now considered a progesterone-receptor modulator (PRM) due to its context-dependent activity.

Other PRMs and pure progesterone antagonists now have been synthesized, and most contain an 11β-aromatic group. Another widely studied anti-progestin is onapristone (or ZK 98299), which is similar in structure to mifepristone but contains a methyl substituent in the 13α rather than 13β orientation. More selective progesterone-receptor modulators, such as asoprisnil, are being studied experimentally (DeManno et al., 2003). Mifepristone and onapristone have the following structures:

Pharmacological Actions. In the presence of progestins, mifepristone acts as a competitive receptor antagonist for both progesterone receptors. While mifepristone acts primarily as an antagonist *in vivo*, it exhibits some agonist activity in certain *in vivo* and *in vitro* contexts. In contrast, onapristone appears to be a pure progesterone antagonist *both in vivo* and *in vitro*. PR complexes of both compounds antagonize the actions of progesterone-PR complexes and also appear to preferentially recruit co-repressors (Leonhardt and Edwards, 2002).

When administered in the early stages of pregnancy, mifepristone causes decidual breakdown by blockade of uterine progesterone receptors. This leads to detachment of the blastocyst, which decreases hCG production. This in turn causes a decrease in progesterone secretion from the corpus luteum, which further accentuates decidual breakdown. Decreased endogenous progesterone coupled with blockade of progesterone receptors in the uterus increases uterine prostaglandin levels and sensitizes the myometrium to their contractile actions. Mifepristone also causes cervical softening, which facilitates expulsion of the detached blastocyst.

Mifepristone can delay or prevent ovulation depending upon the timing and manner of administration. These effects are due largely to actions on the hypothalamus and pituitary rather than the ovary, although the mechanisms are unclear.

If administered for one or several days in the mid- to late luteal phase, mifepristone impairs the development of a secretory endometrium and produces menses. Progesterone-receptor blockade at this time is the pharmacological equivalent of progesterone withdrawal, and bleeding normally ensues within several days and lasts for 1 to 2 weeks after anti-progestin treatment.

Mifepristone also binds to glucocorticoid and androgen receptors and exerts anti-glucocorticoid and anti-androgenic actions. A predominant effect in humans is blockade of the feedback inhibition by cortisol of ACTH secretion from the pituitary, thus increasing both corticotropin and adrenal steroid levels in the plasma (see Chapter 59 for further discussion of effects on the hypothalamic-pituitary-adrenal axis). Onapristone also binds to both glucocorticoid and androgen receptors, but has less anti-glucocorticoid activity than does mifepristone.

**Absorption, Fate, and Excretion.** Mifepristone is orally active with good bioavailability. Peak plasma levels occur within several hours, and the drug is slowly cleared with a plasma half-life of 20 to 40 hours. In plasma, it is bound by α1-acid glycoprotein, which contributes to its long half-life. Metabolites are primarily the mono- and di-demethylated products (which are thought to have pharmacological activity) formed via CYP3A4-catalyzed reactions, and to a lesser extent, hydroxylated compounds. The drug undergoes hepatic metabolism and enterohepatic circulation, and metabolic products are found predominantly in the feces (Jang and Benet, 1997).

**Therapeutic Uses and Prospects.** Mifepristone (MIFEPREX), in combination with misoprostol or other prostaglandins (see below), is available for the termination of early pregnancy. When mifepristone is used to produce a medical abortion, a prostaglandin is given 48 hours after the anti-progestin to further increase myometrial contractions and ensure expulsion of the detached blastocyst. Intramuscular sulprostone, intravaginal gemeprost, and oral misoprostol have been used. The success rate with such regimens is >90% among women with pregnancies of 49 days’ duration or less. The most severe untoward effect is vaginal bleeding, which most often lasts from 8 to 17 days, but is only rarely (0.1% of patients) severe enough to require blood transfusions. High percentages of women also have experienced abdominal pain and uterine cramps, nausea, vomiting, and diarrhea due to the prostaglandin. Women receiving chronic glucocorticoid therapy should not be given mifepristone because of its anti-glucocorticoid activity, and the drug should be used very cautiously in women who are anemic or receiving anticoagulants. Women over 35 years old with cardiovascular risk factors
should not be given sulprostone because of possible heart failure (Christin-Maitre et al., 2000).

Other investigational or potential uses for mifepristone that are under development include the induction of labor after fetal death; the induction of labor at the end of the third trimester; treatment of endometriosis, leiomyomas, breast cancer, and meningiomas; and as a postcoital or luteal-phase contraceptive (Spitz and Chwalisz, 2000). A major concern about long-term use is the possibility of unopposed estrogenic effects, but this concern could be allayed by further development of selective progesterone-receptor modulators.

**HORMONAL CONTRACEPTIVES**

Oral contraceptives are among the most widely used agents in the United States and throughout the world and have had a revolutionary impact on global society. For the first time in history, they provided a convenient, affordable, and completely reliable means of contraception for family planning and the avoidance of unplanned pregnancies.

It is important to consider several key points as a prelude to the pharmacology of specific hormonal contraceptives: (1) A variety of agents with substantially different components, doses, and side effects are available and provide real therapeutic options; (2) In addition to contraceptive actions, these agents have substantial health benefits; (3) Because of differences in doses and specific compounds used, it is not appropriate to extrapolate directly untoward effects of hormonal contraceptives to menopausal hormone therapy, or vice versa. Oral contraceptives are now extremely effective and have a low incidence of untoward effects for most women.

**History.** Around the beginning of the twentieth century, a number of European scientists including Beard, Prenant, and Loeb developed the concept that secretions of the corpus luteum suppressed ovulation during pregnancy. The Austrian physiologist Haberlandt then produced temporary sterility in rodents in 1927 by feeding ovarian and placental extracts—a clear example of an oral contraceptive! In 1937 it was shown by Makepeace and colleagues that pure progesterone blocked ovulation in rabbits, and Astwood and Fenvold found a similar effect in rats in 1939.

In the 1950s, Pincus, Garcia, and Rock found that progesterone and 19-nor progestins prevented ovulation in women. Ironically, this finding grew out of their attempts to treat infertility with progestins or estrogen-progesterin combinations. The initial findings were that either treatment effectively blocked ovulation in the majority of women. However, concern about cancer and other possible side effects of the estrogen they used (i.e., diethylstilbestrol) led to the use of a progestin alone in their studies.

One of the compounds used was norethynodrel, and early batches of this compound were contaminated with a small amount of mestranol. When mestranol was removed, it was noted that treatment with pure norethynodrel led to increased breakthrough bleeding and less consistent inhibition of ovulation. Mestranol was thus re-incorporated into the preparation, and this combination was employed in the first large-scale clinical trial of combination oral contraceptives.

Clinical studies in the 1950s in Puerto Rico and Haiti established the virtually complete contraceptive success of the norethynodrel-mestranol combination. In late 1959, ENOVID (norethynodrel plus mestranol; no longer marketed in the United States) was the first “Pill” approved by the FDA for use as a contraceptive agent in the United States; this was followed in 1962 by approval for ORTHONOVUM (norethindrone plus mestranol). By 1966 numerous preparations utilizing either mestranol or ethinyl estradiol with a 19-nor progestin were available. In the 1960s, the progestin-only minipill and long-acting injectable preparations were developed and introduced.

Millions of women began using oral contraceptives, and frequent reports of untoward effects began appearing in the 1970s (Kols et al., 1982). The recognition that these side effects were dose-dependent and the realization that estrogens and progestins synergistically inhibited ovulation led to the reduction of doses and the development of so-called low-dose or second-generation contraceptives. The increasing use of biphasic and triphasic preparations throughout the 1980s further reduced steroid dosages; it may be that currently used doses are the lowest that will provide reliable contraception. In the 1990s, the “third-generation” oral contraceptives, containing progestins with reduced androgenic activity (e.g., norgestimate [CYCLEN, ORTHO TRI-CYCLEN LO] and desogestrel [DESOGEN]), became available in the United States after being used in Europe. Products containing gestodene as a progestin with reduced androgenic activity also are available in Europe. Another major development in the 1980s was the widespread realization that oral contraceptives have a number of substantial health benefits. More recently, a variety of contraceptive formulations have become available and now include pills, injections providing 1 or 3 months of contraceptive coverage, skin patches, subcutaneous implants, vaginal rings, and intrauterine devices that release hormones.

**Types of Hormonal Contraceptives**

**Combination Oral Contraceptives.** The most frequently used agents in the United States are combination oral contraceptives containing both an estrogen and a progestin. Their theoretical efficacy generally is considered to be 99.9%. Ethinyl estradiol and mestranol are the two estrogens used (with ethinyl estradiol being much more frequently used); several progestins currently are used, with levonorgestrel probably being the most common worldwide. The progestins are 19-nor compounds in the estrane or gonane series, and each has varying degrees of androgenic, estrogenic, and anti-estrogenic activities that may be responsible for some of their side effects. Compounds such as desogestrel and norgestimate are the most recently developed and have less androgenic activity than other 19-nor compounds.

Combination oral contraceptives are available in many formulations. Monophasic, biphasic, or triphasic pills are generally provided in 21-day packs. For the monophasic agents, fixed amounts of the estrogen and progestin are present in each pill, which is taken daily for 21 days, followed by a 7-day “pill-free” period. (Virtually all preparations
for postcoital contraception (the “morning-after pill”) but never received FDA approval for this indication. The FDA has now approved two preparations for postcoital contraception. PLAN-B is two doses of the “minipill” (0.75 mg levonorgestrel per pill) separated by 12 hours. PREVEN is two 2-pill doses of a high-dose oral contraceptive (0.25 mg of levonorgestrel and 0.05 mg of ethinyl estradiol per pill) separated by 12 hours. This is sometimes referred to as the “Yuzpe” method after the Canadian physician who pioneered its use. The FDA also has declared other products with the same or very similar composition safe and effective for use as emergency contraceptive pills.

The first dose of such preparations should be taken anytime within 72 hours after intercourse, and this should be followed 12 hours later by a second dose. This treatment reduces the risk of pregnancy following unprotected intercourse by approximately 60% for the Yuzpe method and 80% for levonorgestrel alone. With either preparation, effectiveness appears to increase the sooner after intercourse the pills are taken (Task Force on Postovulatory Methods of Fertility Regulation, 1998).

Mechanism of Action

Combination Oral Contraceptives. Combination oral contraceptives act by preventing ovulation (Lobo and Stanczyk, 1994). Direct measurements of plasma hormone levels indicate that LH and FSH levels are suppressed, a mid-cycle surge of LH is absent, endogenous steroid levels are diminished, and ovulation does not occur. While either component alone can be shown to exert these effects in certain situations, the combination synergistically decreases plasma gonadotropin levels and suppresses ovulation more consistently than either alone.

Given the multiple actions of estrogens and progestins on the hypothalamic-pituitary-ovarian axis during the menstrual cycle and the extraordinary efficacy of these agents, several effects probably contribute to the blockade of ovulation.

Hypothalamic actions of steroids play a major role in the mechanism of oral contraceptive action. Progestrone clearly diminishes the frequency of GnRH pulses. Since the proper frequency of LH pulses is essential for ovulation, this effect of progestrone likely plays a major role in the contraceptive action of these agents. In monkeys and women with normal menstrual cycles, estrogens do not affect the frequency of the pulse generator. However, in the prolonged absence of a menstrual cycle (e.g., in ovariectomized monkeys and postmenopausal women; Hotchkiss and Knobil, 1994), estrogens markedly diminish pulse-generator frequency, and progesterone enhances this effect. In theory, this hypothalamic effect of estrogens could come into play when oral contraceptives are used for extended time periods.

Multiple pituitary effects of both estrogen and progestin components are thus likely to contribute to oral contraceptive action. Oral
contraceptives seem likely to decrease pituitary responsiveness to GnRH. Estrogens also suppress FSH release from the pituitary during the follicular phase of the menstrual cycle, and this effect seems likely to contribute to the lack of follicular development in oral contraceptive users. Pharmacologically, the progestin component may also inhibit the estrogen-induced LH surge at mid-cycle. Other effects may contribute to a minor extent to the extraordinary efficacy of oral contraceptives. Transit of sperm, the egg, and fertilized ovum are important to establish pregnancy, and steroids are likely to affect transport in the fallopian tube. In the cervix, progestin effects also are likely to produce a thick, viscous mucus to reduce sperm penetration and in the endometrium to produce a state that is not receptive to implantation. However, it is difficult to assess quantitatively the contributions of these effects because the drugs block ovulation so effectively.

Progestin-Only Contraceptives. Progestin-only pills and levonorgestrel implants are highly efficacious but block ovulation in only 60% to 80% of cycles. Their effectiveness is thus thought to be due largely to a thickening of cervical mucus, which decreases sperm penetration, and to endometrial alterations that impair implantation; such local effects account for the efficacy of intrauterine devices that release progestins. Depot injections of MPA are thought to exert similar effects, but they also yield plasma levels of drug high enough to prevent ovulation in virtually all patients, presumably by decreasing the frequency of GnRH pulses.

Emergency Contraceptive Pills. Multiple mechanisms are likely to contribute to the efficacy of these agents, but their precise contributions are unknown (Glasier, 1997). Some studies have shown that ovulation is inhibited or delayed, but additional mechanisms thought to play a role include alterations in endometrial receptivity for implantation; interference with functions of the corpus luteum that maintain pregnancy; production of a cervical mucus that decreases sperm penetration; alterations in tubular transport of sperm, egg, or embryo; or effects on fertilization. However, emergency contraceptives do not interrupt pregnancy after implantation.

Untoward Effects

Combination Oral Contraceptives. Shortly after the introduction of oral contraceptives, reports of adverse side effects associated with their use began to appear. Many of the side effects were found to be dose dependent, and this led to the development of current low-dose preparations. Untoward effects of early hormonal contraceptives fell into several major categories: adverse cardiovascular effects, including hypertension, myocardial infarction, hemorrhagic or ischemic stroke, and venous thrombosis and embolism; breast, hepatocellular, and cervical cancers; and a number of endocrine and metabolic effects. The current consensus is that low-dose preparations pose minimal health risks in women who have no predisposing risk factors, and these drugs also provide many beneficial health effects (Burkman et al., 2004).

Cardiovascular Effects. The question of cardiovascular side effects has been re-examined for the newer low-dose oral contraceptives (Sherif, 1999; Burkman et al., 2004). For nonsmokers without other risk factors such as hypertension or diabetes, there is no significant increase in the risk of myocardial infarction or stroke. There is a 28% increase in relative risk for venous thromboembolism, but the estimated absolute increase is very small because the incidence of these events in women without other predisposing factors is low (e.g., roughly half that associated with the risk of venous thromboembolism in pregnancy). Nevertheless, the risk is significantly increased in women who smoke or have other factors that predispose to thrombosis or thromboembolism (Castelli, 1999). Early high-dose combination oral contraceptives caused hypertension in 4% to 5% of normotensive women and increased blood pressure in 10% to 15% of those with pre-existing hypertension. This incidence is much lower with newer, low-dose preparations, and most reported changes in blood pressure are not significant. The cardiovascular risk associated with oral contraceptive use does not appear to persist after use is discontinued. As noted previously, estrogens increase serum HDL and decrease LDL levels, and progestins tend to have the opposite effect. Recent studies of several low-dose preparations have not found significant change in total serum cholesterol or lipoprotein profiles, although slight increases in triglycerides have been reported.

Cancer. Given the growth-promoting effects of estrogens, there has been a long-standing concern that oral contraceptives might increase the incidence of endometrial, cervical, ovarian, breast, and other cancers. These concerns were further heightened in the late 1960s by reports of endometrial changes caused by sequential oral contraceptives, which have since been removed from the market in the United States. However, it is now clear that there is not a widespread association between oral contraceptive use and cancer (Westhoff, 1999; Burkman et al., 2004).

Recent epidemiological evidence suggests that combined oral contraceptive use may increase the risk of cervical cancer by about twofold, but only in long-term users (>5 years) with persistent human papilloma virus infection (Moodley, 2004).

There have been reports of increases in the incidence of hepatic adenoma and hepatocellular carcinoma in oral contraceptive users. Current estimates indicate that there is about a doubling in the risk of liver cancer after 4 to 8 years of use. However, these are rare cancers and the absolute increases are small.

The major present concern about the carcinogenic effects of oral contraceptives is focused on breast cancer. Numerous studies have dealt with this issue, and the following general picture has emerged. The risk of breast cancer in women of childbearing age is very low, and current oral contraceptive users in this group have only a very small increase in relative risk of 1.1 to 1.2, depending on other variables. This small increase is not substantially affected by duration of use, dose or type of component, age at first use, or parity. Importantly, 10 years after discontinuation of oral contraceptive use, there is no difference in breast cancer incidence between past users and never users. In addition, breast cancers diagnosed in women who have ever used oral contraceptives are more likely to be localized to the breast and thus easier to treat, i.e., are less likely to have spread to other sites (Westhoff, 1999). Thus, overall there is no significant difference in the cumulative risk of breast cancer between those...
who have ever used oral contraceptives and those who have never used them.

Combination oral contraceptives do not increase the incidence of endometrial cancer, but actually cause a 50% decrease in the incidence of this disease, which lasts 15 years after the pills are stopped. This is thought to be due to the inclusion of a progestin, which opposes estrogen-induced proliferation, throughout the entire 21-day cycle of administration. These agents also decrease the incidence of ovarian cancer, and decreased ovarian stimulation by gonadotropins provides a logical basis for this effect. There are accumulating data that oral contraceptive use decreases the risk of colorectal cancer (Fernandez et al., 2001).

Metabolic and Endocrine Effects. The effects of sex steroids on glucose metabolism and insulin sensitivity are complex (Goddard, 1996) and may differ among agents in the same class (e.g., the 19-nor progestins). Early studies with high-dose oral contraceptives generally reported impaired glucose tolerance as demonstrated by increases in fasting glucose and insulin levels and responses to glucose challenge. These effects have decreased as steroid dosages have been lowered, and current low-dose combination contraceptives may even improve insulin sensitivity. Similarly, the high-dose progestins in early oral contraceptives did raise LDL and reduce HDL levels, but modern low-dose preparations do not produce unfavorable lipid profiles (Sherif, 1999). There also have been periodic reports that oral contraceptives increase the incidence of gallbladder disease, but any such effect appears to be weak and limited to current or very long-term users (Burkman, 2004).

The estrogenic component of oral contraceptives may increase hepatic synthesis of a number of serum proteins, including those that bind thyroid hormones, glucocorticoids, and sex steroids. While physiological feedback mechanisms generally adjust hormone synthesis to maintain normal "free" hormone levels, these changes can affect the interpretation of endocrine function tests that measure total plasma hormone levels, and may necessitate dose adjustment in patients receiving thyroid-hormone replacement.

The ethinyl estradiol present in oral contraceptives appears to cause a dose-dependent increase in several serum factors known to increase coagulation. However, in healthy women who do not smoke, there also is an increase in fibrinolytic activity, which exerts a counter effect so that overall there is a minimal effect on hemostatic balance. In women who smoke, however, this compensatory effect is diminished, which may shift the hemostatic profile toward a hypercoagulable condition (Fruzzetti, 1999).

Miscellaneous Effects. Nausea, edema, and mild headache occur in some individuals, and more severe migraine headaches may be precipitated by oral contraceptive use in a smaller fraction of women. Some patients may experience breakthrough bleeding during the 21-day cycle when the active pills are being taken. Withdrawal bleeding may fail to occur in a small fraction of women during the 7-day "off" period, thus causing confusion about a possible pregnancy. Acne and hirsutism are thought to be mediated by the androgenic activity of the 19-nor progestins.

Progestin-Only Contraceptives. Episodes of irregular, unpredictable spotting and breakthrough bleeding are the most frequently encountered untoward effect and the major reason women discontinue use of all three types of progestin-only contraceptives. With time, the incidence of these bleeding episodes decreases, especially with the long-acting preparations, and amenorrhea becomes common after a year or more of use.

There is no evidence that the progestin-only minipill preparations increase thromboembolic events, which are thought to be related to the estrogenic component of combination preparations; blood pressure does not appear to be elevated, and nausea and breast tenderness do not occur. Acne may be a problem, however, because of the androgenic activity of norethindrone-containing preparations. These preparations may be attractive for nursing mothers because they do not decrease lactation as do products containing estrogens.

Aside from bleeding irregularities, headache is the most commonly reported untoward effect of depot MPA (medroxyprogesterone acetate). Mood changes and weight gain also have been reported, but controlled clinical studies of these effects are not available. It is of more concern that many studies have found decreases in HDL levels and increases in LDL levels and that there have been several reports of decreased bone density. These effects may be due to reduced endogenous estrogens because depot MPA is particularly effective in lowering gonadotropin levels. Numerous human studies have not found any increases in breast, endometrial, cervical, or ovarian cancer in women receiving MPA (Westhoff, 2003). Because of the time required to completely eliminate the drug, the contraceptive effect of this agent may remain for 6 to 12 months after the last injection.

Implants of norethindrone may be associated with infection, local irritation, pain at the insertion site, and rarely, expulsion of the inserts. Headache, weight gain, and mood changes have been reported, and acne is seen in some patients. A number of metabolic studies have been performed in NORPLANT (no longer marketed in the United States) users, and in most cases only minimal changes have been observed in lipid, carbohydrate, and protein metabolism. In women desiring pregnancy, ovulation occurs fairly soon after implant removal, reaching 50% in 3 months and almost 90% within 1 year.

Emergency Contraceptive Pills. Nausea and vomiting are the main untoward effects, with an incidence of roughly 50% and 20%, respectively, for combined estrogen-levonorgestrel combinations and 23% and 6% for levonorgestrel alone (Task Force on Postovulatory Methods of Fertility Regulation, 1998). No changes in clotting factors have been reported for the combined regimen, but based on concerns with combination oral contraceptives, levonorgestrel alone might be considered for women who smoke or have a history of blood clots. Emergency contraceptive pills are contraindicated in cases of confirmed pregnancy.

Contraindications

While the use of modern oral contraceptives is considered generally safe in most healthy women, these agents can contribute to the incidence and severity of certain diseases if other risk factors are present. The following conditions are thus considered absolute contraindications for combination oral contraceptive use: the presence or history of thromboembolic disease, cerebrovascular disease, myocardial infarction, coronary artery disease, or congenital hyperlipidemia; known or suspected carcinoma of the breast, carcinoma of the female reproductive tract, or other hormone-dependent/ responsive neoplasias; abnormal undiagnosed vaginal bleeding; known or suspected pregnancy; and past or present liver tumors or impaired liver function. The risk of serious cardiovascular side
effects is particularly marked in women over 35 years of age who smoke heavily (e.g., over 15 cigarettes per day); even low-dose oral contraceptives are contraindicated in such patients.

Several other conditions are relative contraindications and should be considered on an individual basis. These include migraine headaches, hypertension, diabetes mellitus, obstructive jaundice of pregnancy or prior oral contraceptive use, and gallbladder disease. If elective surgery is planned, many physicians recommend discontinuation of oral contraceptives for several weeks to a month to minimize the possibility of thromboembolism after surgery. These agents should be used with care in women with prior gestational diabetes or uterine fibroids, and low-dose pills should generally be used in such cases.

Progestin-only contraceptives are contraindicated in the presence of undiagnosed vaginal bleeding, benign or malignant liver disease, and known or suspected breast cancer. Depot medroxyprogesterone acetate and levonorgestrel inserts are contraindicated in women with a history or predisposition to thrombophlebitis or thromboembolic disorders.

Choice of Contraceptive Preparations

Many preparations that differ substantially in dose and specific components are available, providing the option to select the preparation best suited to each individual. Treatment should generally begin with preparations containing the minimum dose of steroids that provides effective contraceptive coverage. This is typically a pill with 30 to 35 μg of estrogen, but preparations with 20 μg may be adequate for lighter women or those over 40 with perimenopausal symptoms, while a preparation containing 50 μg of estrogen may be required for heavier women. Breakthrough bleeding may occur if the estrogen-to-progestin ratio is too low to produce a stable endometrium, and this may be prevented by switching to a pill with a higher ratio.

In women for whom estrogens are contraindicated or undesirable, progestin-only contraceptives may be an option. The progestin-only minipill may have enhanced effectiveness in several such types of women (e.g., nursing mothers and women over 40, in whom fertility may be decreased).

Another consideration is the concomitant administration of medications that may increase metabolism of estrogens (e.g., rifampicin, barbiturates, and phenytoin) or reduce their enterohepatic recycling (e.g., tetracyclines and ampicillin) or reduce their enterohepatic recycling that may increase metabolism of estrogens (e.g., rifampicin, barbiturates, and phenytoin) or reduce their enterohepatic recycling (e.g., tetracyclines and ampicillin) or reduce their enterohepatic recycling (e.g., tetracyclines and ampicillin) or reduce their enterohepatic recycling (e.g., tetracyclines and ampicillin). In these situations, a low-dose pill may not be 99.9% effective due to increased steroid metabolism.

The choice of a preparation also may be influenced by the specific 19-nor progestin component, since this component may have varying degrees of androgenic and other activities. The androgenic activity of this component may contribute to untoward effects such as weight gain, acne due to increased sebaceous gland secretions, and unfavorable lipoprotein profiles. These side effects are greatly reduced in newer, low-dose contraceptives, but any patients exhibiting such side effects may benefit by switching to pills that contain a progestin with less androgenic activity. Of the progestins commonly found in oral contraceptives, norgestrel is generally considered to have the most androgenic activity; norethindrone and ethynodiol diacetate to have more moderate androgenic activity; and desogestrel, norgestimate, and drospirenone to have the least androgenic activity.

The FDA has approved a triphasic, low-dose combination oral contraceptive (ORTHO TRI-CYCLEN) containing ethinyl estradiol and norgestimate for the treatment of moderate acne vulgaris. Similar preparations (DEMULEN 1/35, DESOGEN, others) also are effective. The mechanism appears to be a decrease in free plasma testosterone due to an increase in plasma SHBG, since total testosterone levels are unchanged (Redmond et al., 1997).

In summary, for a given individual, both the efficacy and side effects of hormonal contraceptives may vary considerably among preparations. A number of choices are available to counter the development of side effects and improve patient tolerance, both in terms of specific components and routes of administration, without decreasing contraceptive efficacy.

Noncontraceptive Health Benefits

It is generally accepted that combination oral contraceptives have substantial health benefits unrelated to their contraceptive use. Oral contraceptives significantly reduce the incidence of ovarian and endometrial cancer within 6 months of use, and the incidence is decreased 50% after 2 years of use. Depot MPA injections also reduce very substantially the incidence of uterine cancer. Furthermore, this protective effect persists for up to 15 years after oral contraceptive use is discontinued. These agents also decrease the incidence of ovarian cysts and benign fibrocystic breast disease.

Oral contraceptives have major benefits related to menstruation in many women. These include more regular menstruation, reduced menstrual blood loss and less iron-deficiency anemia, and decreased frequency of dysmenorrhea. There also is a decreased incidence of pelvic inflammatory disease and ectopic pregnancies, and endometriosis may be ameliorated. Some women also may obtain these benefits with progestin-only contraceptives. There are suggestions that MPA may improve hematological parameters in women with sickle-cell disease (Cullins, 1996).

There is now a consensus that combination oral contraceptives prevent thousands of deaths, episodes of various diseases, and cases of hospitalization each year in the United States alone. From a purely statistical perspective, fertility regulation by oral contraceptives is substantially safer than pregnancy or childbirth for most women, even without considering the additional health benefits of these agents.

CLINICAL SUMMARY

Estrogens are most commonly used to treat vasomotor disturbances (“hot flashes”) in postmenopausal women. Other important benefits are amelioration of the effects of urogenital atrophy, a decreased incidence of colon cancer, and prevention of bone loss. Estrogens have proven efficacy for prevention of bone fractures at all sites in normal women, although when used solely for this purpose they...
should not be considered first-line because of possible untoward side effects including breast cancer, stroke, and coronary heart disease (CHD). Estrogens should not be prescribed for treatment or prevention of CHD or other cardiovascular diseases, or to prevent neurodegenerative disease. A variety of preparations, including oral, transdermal, and vaginal, are available. Regardless of the specific drug(s) selected, treatment should use the minimum dose and duration for the desired therapeutic endpoint.

In postmenopausal women with an intact uterus, a progestin is included to prevent endometrial cancer. Medroxyprogesterone acetate is frequently used in the United States and micronized progesterone is available; norethindrone and norgestrel/levonorgestrel are also commonly used. As progestins may contribute to untoward effects, especially breast cancer and CHD, women without a uterus are administered estrogen alone. Postmenopausal hormone therapy and contraception are the most frequent uses of progestins.

Tamoxifen, a selective estrogen receptor modulator or SERM, is widely used for the adjuvant treatment of breast cancer and for prophylaxis of the disease in high-risk women, but treatment should be limited to 5 years. The drug is most effective in the treatment of estrogen-receptor positive disease, and untoward effects include hot flashes as well as an increase in blood clots and uterine cancer. Another SERM, raloxifene, is used to prevent osteoporosis and decreases the incidence of vertebral fractures in postmenopausal women. Raloxifene does not increase the risk of uterine cancer, but does increase the incidence of thromboembolic events and hot flashes.

The pure estrogen antagonist fulvestrant is also used to treat breast cancer, especially in patients who become refractory to tamoxifen. Another estrogen antagonist, clomiphene, is used to treat infertility in anovulatory women. Both compounds may cause hot flashes.

Aromatase inhibitors, including letrozole, anastrozole, and exemestane, are also highly effective for the adjuvant treatment of breast cancer, and their prophylactic use is being explored. Untoward effects include hot flashes; potential long-term effects of these agents on osteoporosis and bone fractures remain to be established.

Mifepristone is used therapeutically as an anti-progestin for medical abortion, and is administered with a prostaglandin for this purpose.

Estrogens and progestins are widely used as “combination” contraceptives and are 99% effective in preventing ovulation. These combinations are most often used orally, although transdermal preparations, once-monthly injections, and vaginal rings are available. Ethinyl estradiol (or mestranol) and 19-nor steroids such as norgestrel/levonorgestrel, norethindrone, or another synthetic progestin are commonly used. The greatest concern with these agents is the risk of stroke or other thromboembolic events; consequently, they should not be used in older women (over 35) who smoke or have other risk factors (e.g., hypertension) for cardiovascular disease.

Several progestin-only contraceptives are available, including low-dose pills, long-lasting (e.g., 3-month) depot injections, and subdermal implants (not available in the United States). These agents are also highly efficacious and exert a number of actions, including decreased frequency of ovulation, and effects on cervical mucus, ovum transport, and implantation. They may be used in nursing mothers and in some women with contraindications for combined estrogen-progestin combinations. The most common untoward effect is unpredictable vaginal bleeding.

A levonorgestrel-only pill and high-dose estrogen-progestin oral contraceptives are available and effective for postcoital or emergency contraception within 72 hours of unprotected intercourse. These preparations are ineffective in cases of established pregnancy and should not be used to terminate pregnancy.

TESTOSTERONE AND OTHER ANDROGENS

Synthesis of Testosterone. In men, testosterone is the principal secreted androgen. The Leydig cells synthesize the majority of testosterone by the pathways shown in Figure 58–1. In women, testosterone also is probably the principal androgen and is synthesized both in the corpus luteum and the adrenal cortex by similar pathways. The testosterone precursors androstenedione and dehydroepiandrosterone are weak androgens that can be converted peripherally to testosterone.

Secretion and Transport of Testosterone. The magnitude of testosterone secretion is greater in men than in women at almost all stages of life, a difference that explains almost all other differences between men and women. In the first trimester in utero, the fetal testes begin to secrete testosterone, which is the principal factor in male sexual differentiation, probably stimulated by human chorionic gonadotropin (hCG) from the placenta. By the beginning of the second trimester, the value is close to that of midpuberty, about 250 ng/dl (Figure 58–2) (Dawood and Saxena, 1977; Forest, 1975). Testosterone production then falls by the end of the second trimester, but by birth the value is again about 250 ng/dl (Dawood and Saxena, 1977; Forest, 1975), possibly due to stimulation of the fetal Leydig cells by luteinizing hormone (LH) from the fetal pituitary gland. The testosterone value falls again in the first few days after birth, but it rises and peaks again at about 250 ng/dl at 2 to 3 months after birth and falls to <50 ng/dl by 6 months, where it remains until puberty (Forest, 1975). During puberty, from about age 12 to 17 years, the serum testosterone concentration in males increases to a much greater degree than in females, so that by early adulthood the serum testosterone concentration is 500 to 700 ng/dl in men, compared to 30 to 50 ng/dl in women. The magnitude of the testosterone concentration in the male is responsible for the pubertal changes that further differentiate men from women. As men age, their serum testosterone concentrations gradually decrease, which may contribute to other effects of aging in men.

LH, secreted by the pituitary gonadotropes (see Chapter 55), is the principal stimulus of testosterone secretion in men, perhaps potentiated by follicle-stimulating hormone (FSH), also secreted by gonadotropes. The secretion of LH by gonadotropes is positively regulated by hypothalamic gonadotropin-releasing hormone (GnRH), while testosterone directly inhibits LH secretion in a negative feedback loop (see Chapter 55). LH is secreted in pulses, which occur approximately every 2 hours and are greater in magnitude in the morning. The pulsatility appears to result from pulsatile secretion of GnRH from the hypothalamus. Pulsatile administration of GnRH to men who are hypogonadal due to hypothalamic disease results in normal LH pulses and testosterone secretion, but continuous administration does not (Crowley et al., 1985). Testosterone secretion is likewise pulsatile and diurnal, with the highest plasma concentrations occurring at about 8 A.M. and the lowest at about 8 P.M. The morning peaks diminish as men age (Bremner et al., 1983).

In women, LH stimulates the corpus luteum (formed from the follicle after release of the ovum) to secrete testosterone. Under normal circumstances, however, estradiol and progesterone, not testosterone, are the principal inhibitors of LH secretion in women. Sex hormone–binding globulin (SHBG) binds about 40% of circulating testosterone with high affinity. Because of this high affinity, testosterone bound to SHBG is unavailable for biological effects.Albumin binds almost 60% of circulating testosterone with low affinity, leaving approximately 2% unbound or free. In some testosterone assays, the latter two components are considered as “bioavailable” testosterone.
Metabolism of Testosterone to Active and Inactive Compounds. Testosterone has many different effects in tissues. One of the mechanisms by which the varied effects are mediated is the metabolism of testosterone to two other active steroids, dihydrotestosterone and estradiol (Figure 58–3). Some effects of testosterone appear to be mediated by testosterone itself, some by dihydrotestosterone, and others by estradiol.

The enzyme 5α-reductase catalyzes the conversion of testosterone to dihydrotestosterone. Although both testosterone and dihydrotestosterone act via the androgen receptor, dihydrotestosterone binds with higher affinity (Wilbert et al., 1983) and activates gene expression more efficiently (Deslypere et al., 1992). As a result, testosterone, acting via dihydrotestosterone, is able to have effects in tissues that express 5α-reductase that it could not have if it were present only as testosterone. Two forms of 5α-reductase have been identified: type I, which is found predominantly in non-genital skin, liver, and bone, and type II, which is found predominantly in urogenital tissue in men and genital skin in men and women. The effects of dihydrotestosterone in these tissues are described below.

The enzyme complex aromatase (CYP19), which is present in many tissues, especially the liver and adipose tissue, catalyzes the conversion of testosterone to estradiol. This conversion results in approximately 85% of circulating estradiol in men; the remainder is secreted directly by the testes, probably the Leydig cells (MacDonald et al., 1979). The effects of testosterone thought to be mediated via estradiol are described below.

Testosterone is metabolized in the liver to androsterone and etiocholanolone (Figure 58–3), which are biologically inactive. Dihydrotestosterone is metabolized to androsterone, androstanedione, and androstanediol.
Physiological and Pharmacological Effects of Androgens

The biological effects of testosterone can be considered by the receptor it activates and by the tissues in which effects occur at various stages of life. Testosterone can act as an androgen either directly, by binding to the androgen receptor, or indirectly by conversion to dihydrotestosterone, which binds to the androgen receptor even more avidly than testosterone. Testosterone also can act as an estrogen by conversion to estradiol, which binds to the estrogen receptor (Figure 58–4).

Effects That Occur via the Androgen Receptor. Testosterone and dihydrotestosterone act as androgens via a single androgen receptor (Figure 58–5). The androgen receptor—officially designated NR3A—is a member of the nuclear receptor superfamily (steroid hormone receptors, thyroid hormone receptors, and orphan receptors). The androgen receptor is comprised of an amino-terminal domain, a DNA-binding domain, and a ligand-binding domain. Testosterone and dihydrotestosterone bind to the ligand-binding domain, causing a conformational change in the receptor that allows the ligand-receptor complex to translocate to the nucleus and bind via the DNA-binding domain to androgen response elements on certain responsive genes. The ligand-receptor complex acts as a transcription factor complex and stimulates expression of those genes (Brinkman and Trapman, 2000).

The mechanisms by which androgens have different actions in diverse tissues have become clearer in recent years. One mechanism is the higher affinity with which dihydrotestosterone binds to and activates the androgen

Figure 58–3. Metabolism of testosterone to its major active and inactive metabolites.

Figure 58–4. Direct effects of testosterone and effects mediated indirectly via dihydrotestosterone or estradiol.
receptor compared to testosterone (Deslypere et al., 1992; Wilbert et al., 1983). Another mechanism involves transcription co-factors, both co-activators and co-repressors, which are tissue-specific. At this time, the roles of co-factors are better described for other nuclear receptors than for the androgen receptor (Smith and O’Malley, 2004).

The importance of the androgen receptor is illustrated by the consequences of its mutations. Predictably, mutations that either alter the primary sequence of the protein or cause a single amino-acid substitution in the hormone- or DNA-binding domains result in resistance to the action of testosterone, beginning in utero (McPhaul and Griffin, 1999). Male sexual differentiation therefore is incomplete, as is pubertal development.

Another kind of mutation occurs in patients who have spinal and bulbar muscular atrophy, known as Kennedy’s disease. These patients have an expansion of the CAG repeat, which codes for glutamine, at the amino terminus of the molecule (Walcott and Merr, 2002). The result is very mild androgen resistance, manifest principally by gynecomastia (Dejager et al., 2002), but progressively severe motor neuron atrophy. The mechanism by which the neuron atrophy occurs is unknown, but similar trinucleotide repeats are associated with a number of other neurological disorders (Masino and Pastore, 2002).

Other kinds of androgen receptor mutations may explain why prostate cancer that is treated by androgen deprivation eventually becomes androgen-independent. Prostate cancer is initially at least partially androgen-sensitive, which is the basis for the initial treatment of metastatic prostate cancer by androgen deprivation. Metastatic prostate cancer often regresses initially in response to this treatment, but then becomes unresponsive to continued deprivation. The androgen receptor not only continues to be expressed in androgen-independent prostate cancer, but its signaling remains active, as indicated by expression of the androgen receptor–dependent prostate-specific antigen. It has been postulated that these observations can be explained by mutations in the androgen receptor gene or changes in androgen receptor co-regulatory proteins (Heinlein and Chang, 2004; Taplin and Balk, 2004).

**Effects That Occur via the Estrogen Receptor.** The effects of testosterone on at least one tissue are mediated by its conversion to estradiol, catalyzed by the CYP19 enzyme complex (Figures 58–3 and 58–4). In the rare cases in which a male does not express CYP19 (Carani et al., 1997; Morishima et al., 1995) or the estrogen receptor (Smith et al., 1994), the epiphyses do not fuse and long-bone growth continues indefinitely. In addition, the patients are osteoporotic. Administration of estradiol corrects the bone abnormalities in patients with CYP19 deficiency (Bilizekian et al., 1998), but not in those with an estrogen-receptor defect. Because men have larger bones than women, and bone cells express the androgen receptor (Colvard et al., 1989), testosterone also may have an effect on bone via the androgen receptor. Administration of estradiol to a man with CYP19 deficiency increased his libido (Carani et al., 1997), suggesting that the effect of testosterone on male libido may be mediated by conversion to estradiol.

**Effects of Androgens at Different Stages of Life. In Utero.** When the fetal testes, stimulated by human chorionic gonadotropin, begin to secrete testosterone at about the eighth week of gestation, the high local concentration of testosterone around the testes stimulates the nearby wolffian ducts to differentiate into the male internal genitalia: the epididymis, vas deferens, and seminal vesicles. Farther away, in the anlage of the external genitalia, testosterone is converted to dihydrotestosterone, which causes the development of the male external genitalia—the penis, scrotum—and the prostate. The increase in testosterone at the end of gestation may result in further phallic growth.

**Infancy.** The consequences of the increase in testosterone secretion by the testes during the first few months of life are not yet known.

**Puberty.** Puberty in the male begins at a mean age of 12 years with an increase in the secretion of FSH and LH from the gonadotropes, stimulated by increased secretion of GnRH from the hypothalamus. The increased secretion of FSH and LH stimulates the testes, so, not surprisingly, the first sign of puberty is an increase in testicular size. The increase in testosterone production by Leydig cells, along with the effect of FSH on the Sertoli cells, stimulates the development of the seminiferous tubules, which eventually produce mature sperm. Increased secretion of testosterone into the systemic circulation affects many tissues simultaneously, and the changes in most of them occur gradually during the course of several years. The phallus enlarges in length and width, the scrotum becomes rugated, and the prostate begins secreting the fluid it contributes to the semen. The skin becomes coarser and oilier due to increased sebum production, which contributes to the development of acne. Sexual hair begins to grow, initially pubic and axillary hair, then hair on the lower legs, and finally other body hair and facial hair. Full development of the latter two may not occur until 10 years after the start of puberty and marks the completion of puberty. Muscle mass and strength increase, especially of the shoulder girdle, and subcutaneous fat decreases. Epiphyseal bone growth accelerates, resulting in the pubertal growth spurt, but epiphyseal maturation leads eventually to a slowing and then cessation of growth. Bones also become thicker. The increase in the mass of muscle and bone results in a pronounced increase in body weight. Erythropoiesis increases, resulting in higher hematocrit and hemoglobin concentrations in men than boys or women. The larynx thickens, resulting in a lower voice. Libido develops.

Other changes may result from the increase in testosterone during puberty. Men tend to have a better sense of spatial relations than do women and to exhibit behavior that differs in some ways from that of women, including being more aggressive.

**Adulthood.** The serum testosterone concentration and the characteristics of the adult male are largely maintained during early
Chapter 58 / Androgens

1577

adulthood and midlife. One change during this time is the gradual
development of male pattern baldness, beginning with recession of
hair at the temples and the vertex.

Two changes that can occur in the prostate gland during adult-
hood are of much greater medical significance. One is the gradual
development of benign prostatic hyperplasia, which occurs to a vari-
able degree in almost all men, sometimes obstructing urine outflow
by compressing the urethra as it passes through the prostate. This
development is mediated by the conversion of testosterone to dihy-
drotestosterone by 5α-reductase II within prostatic cells (Wilson,
1980).

The other change that can occur in the prostate during adulthood
is the development of cancer. Although no direct evidence suggests
that testosterone causes the disease, prostate cancer is dependent on
testosterone, at least to some degree and at some time in its course.
This dependency is the basis of treating metastatic prostate cancer
by lowering the serum testosterone concentration (Iversen et al.,
1990) or by blocking its action.

Senescence. As men age, the serum testosterone concentration
gradually declines (Figure 58–2), and the sex hormone–binding
globulin concentration gradually increases, so that by age 80, the
total testosterone concentration is approximately 80% and the free
testosterone is approximately 40% of that present at age 20 (Harman
et al., 2001). This fall in serum testosterone could contribute to sev-
eral other changes that occur with increasing age in men, including
decreases in energy, libido, muscle mass (Forbes, 1976) and
strength (Murray et al., 1980), and bone mineral density (Riggs et
al., 1982). A causal role is suggested by the occurrence of similar
changes seen in men who develop hypogonadism due to disease at a
younger age, as discussed below.

Consequences of Androgen Deficiency

The consequences of androgen deficiency depend on the
stage of life during which the deficiency first occurs and
on the degree of the deficiency.

During Fetal Development. Testosterone deficiency in
a male fetus during the first trimester in utero causes
incomplete sexual differentiation. Testosterone deficiency
in the first trimester results only from testicular disease,
such as deficiency of CYP17 (17α-hydroxylase); deficien-
cy of LH secretion because of pituitary or hypothalamic
disease does not result in testosterone deficiency during the
first trimester, presumably because Leydig cell secretion of
testosterone at that time is regulated by placental hCG.
Complete deficiency of testosterone secretion results in
etirely female external genitalia; less severe testosterone
deficiency results in incomplete virilization of the external
genitalia proportionate to the degree of deficiency. Testos-
 terme deficiency at this stage of development also leads to
failure of the wolffian ducts to differentiate into the male
internal genitalia, such as the vas deferens and seminal ves-
icles, but the müllerian ducts do not differentiate into the
female internal genitalia as long as testes are present and
secrete müllerian inhibitory substance. Similar changes
occur if testosterone is secreted normally, but its action is
diminished because of an abnormality of the androgen
receptor or of 5α-reductase. Abnormalities of the androgen
receptor can have quite varied effects. The most severe
form results in complete absence of androgen action and a
female phenotype; moderately severe forms result in partial
virilization of the external genitalia; and the mildest forms
permit normal virilization in utero and result only in
impaired spermatogenesis in adulthood (McPhaul and Grif-
fin, 1999). Abnormal 5α-reductase results in incomplete
virilization of the external genitalia in utero but normal
development of the male internal genitalia, which requires
only testosterone (Wilson et al., 1993).

Testosterone deficiency during the third trimester,
caused either by a testicular disease or a deficiency of fetal
LH secretion, has two known consequences. First, the phal-
lus fails to grow normally. The result, called microphallus,
is a common occurrence in boys later discovered to be
unable to secrete LH due to abnormalities of GnRH synthe-
sis. Second, the testes fail to descend into the scrotum; this
condition, called cryptorchidism, occurs commonly in boys
whose LH secretion is subnormal (see Chapter 55).

Before Completion of Puberty. When a boy can secrete
testosterone normally in utero but loses the ability to do so
before the anticipated age of puberty, the result is failure to
complete puberty. All of the pubertal changes described
above, including those of the external genitalia, sexual hair,
muscle mass, voice, and behavior, are impaired to a degree propor-
tionate to the abnormality of testosterone secretion. In
addition, if growth hormone secretion is normal when testos-
 terme secretion is subnormal during the years of expected
puberty, the long bones continue to lengthen because the epi-
physes do not close. The result is longer arms and legs rela-
tive to the trunk; these proportions are referred to as eu-
nuchoïd. Another consequence of subnormal testosterone
secretion during the age of expected puberty is enlargement
of glandular breast tissue (gynecomastia).

After Completion of Puberty. When testosterone secre-
tion becomes impaired after puberty is completed, regres-
sion of the pubertal effects of testosterone depends on
both the degree and the duration of testosterone deficien-
cy. When the degree of testosterone deficiency is substan-
tial, libido and energy decrease within a week or two, but
other testosterone-dependent characteristics decline more
slowly. A clinically detectable decrease in muscle mass in
an individual does not occur for several years. A pro-
nounced decrease in hematocrit and hemoglobin will
occur within several months. A decrease in bone mineral
density probably can be detected by dual-energy x-ray
absorptiometry within 2 years, but an increase in fracture
incidence would not be likely to occur for many years. A
loss of sexual hair takes many years.
In Women. Loss of androgen secretion in women results in a decrease in sexual hair, but not for many years. Androgens may have other important effects in women, and the loss of androgens (especially with the severe loss of ovarian and adrenal androgens that occurs in panhypopituitarism) would result in the loss of these effects. Testosterone preparations that can yield serum testosterone concentrations in the physiological range in women currently are being developed. The availability of such preparations will allow clinical trials to determine if testosterone replacement in androgen-deficient women improves their libido, energy, muscle mass and strength, and bone mineral density.

Therapeutic Androgen Preparations

The need for a creative approach to pharmacotherapy with androgens arises from the fact that ingestion of testosterone is not an effective means of replacing testosterone deficiency. Even though ingested testosterone is readily absorbed into the hepatic circulation, rapid hepatic metabolism ensures that hypogonadal men generally cannot ingest testosterone in sufficient amounts and with sufficient frequency to maintain a normal serum concentration. Therefore most pharmaceutical preparations of androgens are designed to bypass hepatic metabolism of testosterone.

Testosterone Esters. Esterifying a fatty acid to the 17α-hydroxyl group of testosterone creates a compound that is even more lipophilic than testosterone itself. When an ester, such as testosterone enanthat (heptanoate) (Figure 58–6) or cypionate (cyclopentylpropionate) is dissolved in oil and administered intramuscularly every 2 weeks to hypogonadal men, the ester hydrolyzes in vivo and results in serum testosterone concentrations that range from higher-than-normal in the first few days after the injection to low-normal just before the next injection (Snyder and Lawrence, 1980) (Figure 58–7). Attempts to decrease the frequency of injections by increasing the amount of each injection result in wider fluctuations and poorer therapeutic outcomes. The undecanoate ester of testosterone (Figure 58–6), when dissolved in oil and ingested orally, is absorbed into the lymphatic circulation, thus bypassing initial hepatic metabolism. Testosterone undecanoate in oil also can be injected and produces stable serum testosterone concentrations for a month (Zhang et al., 1998). The undecanoate ester of testosterone is not currently marketed in the United States.

Alkylated Androgens. Adding an alkyl group to the 17α position of testosterone (Figure 58–6) retards hepatic metabolism of the compound. Consequently, 17α-alkylated androgens are androgenic when administered orally; however, they are less androgenic than testosterone itself, and they cause hepatotoxicity (Cabasso, 1994; Petera et al., 1962), whereas native testosterone does not.

Transdermal Delivery Systems. Recent attempts to avoid the first-pass inactivation of testosterone by the liver have employed novel delivery systems; chemicals called excipients are used to facilitate the absorption of native testosterone across the skin in a controlled fashion. These transdermal preparations provide more stable serum testosterone concentrations than do injections of testosterone esters. The first such preparations were patches, one of which (ANDRODERM) is still available (Dobs et al., 1999). Newer preparations include gels (ANDROGEL, TESTIM) (Marbury et al., 2003; Swerdloff et al., 2000) and a buccal tablet (STRIANT). These preparations produce mean serum testosterone concentrations within the normal range in hypogonadal men (Figure 58–7).

Attempts to Design Selective Androgens

Alkylated Androgens. Decades ago, investigators attempted to synthesize analogs of testosterone that possessed greater anabolic effects than androgenic effects compared to native testosterone. Several compounds appeared to have such differential effects, based on a greater effect on the levator ani muscle compared to the ventral prostate of the rat. These compounds were called anabolic steroids, and most are 17α-alkylated androgens. None of these compounds, however, has been convincingly demonstrated to have such a differential effect in human beings. Nonetheless, they have enjoyed popularity among athletes who seek to enhance their performance, as described below. Another alkylated androgen, 7α-methyl-19-nortestosterone, is poorly converted to dihydrotestosterone (Kumar et al., 1992).

Selective Androgen Receptor Modulators. Stimulated by the development of selective estrogen receptor modulators, which have estrogenic effects in some tissues but not others (see Chapter 57), investigators are attempting to develop selective androgen receptor modulators. Indeed, it would be desirable to produce effects of testosterone in some tissues, such as muscle and bone, while avoiding the undesirable effects in other tissues, such as the prostate. Nonsteroidal molecules have been developed that bind to the androgen receptor, and when administered to castrated rats, stimulate the growth of the levator ani more than the prostate (Hanada et al., 2003; Yin et al., 2003). One molecule also improved several properties of bone (Hanada et al., 2003). No human studies have yet been reported.

Therapeutic Uses of Androgens

Male Hypogonadism. The best-established indication for administration of androgens is for the treatment of
male hypogonadism (testosterone deficiency in men). Any of the transdermal testosterone preparations or testosterone esters described above can be used to treat testosterone deficiency. Monitoring treatment for beneficial and deleterious effects differs somewhat in adolescents and the elderly from that in other men.
Section XII / Hormones and Hormone Antagonists

Monitoring for Efficacy. The goal of testosterone therapy for a hypogonadal man is to mimic as closely as possible the normal serum concentration; therefore, serum testosterone concentration must be monitored during treatment. When the serum testosterone concentration is measured depends on the testosterone preparation used. With transdermal patches (e.g., ANDRODERM), the serum testosterone concentration fluctuates during the 24-hour wearing period, with a peak value 6 to 9 hours after application and a nadir (about 50% of the peak) just before the next patch is applied (Dobs et al., 1999). With testosterone gels, the mean serum testosterone concentration is relatively constant from one application to the next (Marbury et al., 2003; Swerdloff et al., 2000). Occasional random fluctuations can occur, however, so measurements should be repeated for any dose. When the enanthate or cypionate esters of testosterone are administered once every 2 weeks, the serum testosterone concentration measured midway between doses should be normal; if not, the dosage schedule should be adjusted accordingly. If testosterone deficiency results from testicular disease, as indicated by an elevated serum LH concentration, adequacy of testosterone treatment also can be judged indirectly by the normalization of LH within 2 months of treatment initiation (Findlay et al., 1989; Snyder and Lawrence, 1980).

Normalization of the serum testosterone concentration induces normal virilization in prepubertal boys and restores virilization in men who became hypogonadal as adults. Within a few months, and often sooner, libido, energy, and hematocrit return to normal. Within 6 months, muscle mass increases and fat mass decreases. Bone density, however, continues to increase for 2 years (Snyder et al., 2000).

Monitoring for Deleterious Effects. When testosterone itself is administered, as in one of the transdermal preparations or as an ester that is hydrolyzed to testosterone, it has no “side effects” (i.e., no effects that endogenously secreted testosterone does not have), as long as the dose is not excessive. Modified testosterone compounds, such as the 17α-alkylated androgens, do have undesirable effects even when dosages are targeted at physiologic replacement. Some of these undesirable effects occur shortly after testosterone administration is initiated, whereas others usually do not occur until administration has been continued for many years. Raising the serum testosterone concentration from prepubertal or midpubertal levels to that of an adult male at any age can result in undesirable effects similar to those that occur during puberty, including acne, gynecomastia, and more aggressive sexual behavior. Physiological amounts of testosterone do not appear to affect serum lipids or apolipoproteins. Replacement of physiological levels of testosterone may occasionally have undesirable effects in the presence of concomitant illnesses. For example, stimulation of erythropoiesis would increase the hematocrit from subnormal to normal in a healthy man, but would raise the hematocrit above normal in a man with a predisposition to erythrocytosis, such as in chronic pulmonary disease. Similarly, the mild degree of sodium and water retention seen with testosterone replacement would have no clinical effect in a healthy man, but would exacerbate pre-existing congestive heart failure. If the testosterone dose is excessive, erythrocytosis, and uncommonly, salt and water retention and peripheral edema occur, even in men who have no predisposition to these conditions. When a man’s serum testosterone concentration has been in the normal adult male range for many years, whether from endogenous secretion or exogenous administration, and he is older than 40, he is subject to certain testosterone-dependent diseases, including benign prostatic hyperplasia and prostate cancer.

Figure 58–7. Pharmacokinetic profiles of three testosterone preparations during their chronic administration to hypogonadal men. Doses of each were given at time 0. Dashed lines indicate range of normal levels. (A. Adapted from Snyder and Lawrence, 1980; B. Dobs et al., 1999; and C. Swerdloff et al., 2000.)

The principal side effects of the 17α-alkylated androgens are hepatic, including cholestasis, and uncommonly, peliosis hepati, blood-filled hepatic cysts. Hepatocellular cancer has been reported rarely. Case reports of cancer regression after androgen cessation suggest a possible causal role, but an etiologic link is unproven. The
Chapter 58  /  Androgens

17α-alkylated androgens, especially in large amounts, may lower serum HDL cholesterol.

Monitoring at the Anticipated Time of Puberty. Administration of testosterone to testosterone-deficient boys at the anticipated time of puberty should be guided by the considerations above, but also by the fact that testosterone accelerates epiphyseal maturation, leading initially to a growth spurt but then to epiphyseal closure and permanent cessation of linear growth. Consequently, the height and growth-hormone status of the boy must be considered. Boys who are short because of growth-hormone deficiency should be treated with growth hormone before their hypogonadism is treated with testosterone.

Male Senescence. Preliminary evidence suggests that increasing the serum testosterone concentration of men whose serum levels are subnormal for no reason other than their age will increase their bone mineral density and lean mass and decrease their fat mass (Amory et al., 2004; Kenny et al., 2001; Snyder et al., 1999a; Snyder et al., 1999b). However, it is entirely uncertain at this time if such treatment will worsen benign prostatic hyperplasia or increase the incidence of clinically detectable prostate cancer.

Female Hypogonadism. It remains to be determined if increasing the serum testosterone concentrations of women whose serum testosterone concentrations are below normal will improve their libido, energy, muscle mass and strength, or bone mineral density.

Enhancement of Athletic Performance. Some athletes take drugs, including androgens, to attempt to improve their performance. Because androgens taken for this purpose usually are taken surreptitiously, information about their possible effects is not as reliable as that for androgens taken for treatment of male hypogonadism.

Kinds of Androgens Used. Virtually all androgens produced for human or veterinary purposes have been taken by athletes. When use by athletes began more than two decades ago, the favored compounds were 17α-alkylated androgens and other compounds that were thought to have greater anabolic effects than androgen effects relative to testosterone (so-called “anabolic steroids”). Because these compounds can be detected readily by organizations that govern athletic competitions, preparations that increase the serum concentration of testosterone itself, such as the testosterone esters or human chorionic gonadotropin, have increased in popularity. Testosterone precursors, such as androstenedione and dehydroepiandrosterone (DHEA), also have increased in popularity recently because they are considered nutritional supplements and thus are not regulated by national governments or athletic organizations.

A new development in use of androgens by athletes is represented by tetrahydrogestrinone (THG), a potent androgen (Death et al., 2004) that appears to have been designed and synthesized in order to avoid detection by anti-doping laboratories on the basis of its novel structure (Figure 58–6) and rapid metabolism.

Efficacy. There have been few controlled studies of the effects of pharmacological doses of androgens on muscle strength. In one controlled study, 43 normal young men were randomized to one of four groups: strength training with either 600 mg of testosterone enanthate once a week (more than six times the replacement dose) or placebo; or no exercise with either testosterone or placebo. The men who received testosterone experienced an increase in muscle strength compared to those who received placebo, and the men who exercised simultaneously experienced even greater increases (Bhasin et al., 1996). In another study, normal young men were treated with a GnRH analog to reduce endogenous testosterone secretion severely and in a random, blinded fashion, weekly doses of testosterone enanthate from 25 mg to 600 mg. There was a dose-dependent effect of testosterone on muscle strength (Bhasin et al., 2001).

In a double-blind study of androstenedione, men who took 100 mg three times a day for 8 weeks did not experience an increase in muscle strength compared to men who took placebo. Failure of this treatment to increase muscle strength is not surprising, because it also did not increase the mean serum testosterone concentration (King et al., 1999).

Side Effects. All androgens suppress gonadotropin secretion when taken in high doses and thereby suppress endogenous testicular function. This decreases endogenous testosterone and sperm production, resulting in diminished fertility. If administration continues for many years, testicular size may diminish. Testosterone and sperm production usually return to normal within a few months of discontinuation but may take longer. High doses of androgens also cause erythrocytosis (Drinka et al., 1995).

When administered in high doses, androgens that can be converted to estrogens, such as testosterone, cause gynecomastia. Androgens whose A rings have been modified so that they cannot be aromatized, such as dihydrotestosterone, do not cause gynecomastia, even in high doses.

The 17α-alkylated androgens are the only androgens that cause hepatotoxicity. When administered at high doses, these androgens are more likely than others to affect serum lipid concentrations, specifically to decrease high-density lipoprotein (HDL) cholesterol and increase low-density lipoprotein (LDL) cholesterol. Other side effects have been suggested by many anecdotes but have not been confirmed, including psychological disorders and sudden death due to cardiac disease, possibly related to changes in lipids or to coagulation activation.

Certain side effects occur specifically in women and children. Both experience virilization, including facial and body hirsutism, temporal hair recession in a male pattern, and acne. Boys experience phallic enlargement, and women experience clitoral enlargement. Boys and girls whose epiphyses have not yet closed experience premature closure and stunting of linear growth.

Male Contraception. As discussed above, androgens inhibit LH secretion by the pituitary and thereby decrease endogenous testosterone production. Based on these observations, scientists have tried for more than a decade to use androgens—either alone or in combination with other drugs—as a male contraceptive. Because the concentration of testosterone within the testes, approximately one hundred times that in the peripheral circulation, is necessary for spermatogenesis, suppression of endogenous testosterone production greatly diminishes spermatogenesis. Initial use of testosterone alone, however, required supraphysiologic doses, and addition of GnRH agonists required daily injections. A more promising approach is the combination of a progestin with a physiologically dose of testosterone to suppress LH secretion and spermatogenesis,
but provide a normal serum testosterone concentration (Bebb et al., 1996). A recent trial employed injections of testosterone undecanoate with a depot progestin every 2 months (Gu et al., 2004). Another androgen being tested as part of a male contraceptive regimen is 7α-methyl-19-nortestosterone, a synthetic androgen that cannot be metabolized to dihydrotestosterone (Cummings et al., 1998).

Catabolic and Wasting States. Testosterone, because of its anabolic effects, has been used in attempts to ameliorate catabolic and muscle-wasting states, but this has not been generally effective. One exception is in the treatment of muscle wasting associated with acquired immunodeficiency syndrome (AIDS), which often is accompanied by hypogonadism. Treatment of men with AIDS-related muscle wasting and subnormal serum testosterone concentrations increases their muscle mass and strength (Bhasin et al., 2000).

Angioedema. Chronic androgen treatment of patients with angioedema effectively prevents attacks. The disease is caused by hereditary impairment of C1-esterase inhibitor or acquired development of antibodies against it (Cicardi et al., 1998). The 17α-alkylated androgens, such as stanozolol and danazol, stimulate the hepatic synthesis of the esterase inhibitor. In women, virilization is a potential side effect. In children, virilization and premature epiphyseal closure prevent chronic use of androgens for prophylaxis, although they are used occasionally to treat acute episodes.

Blood Dyscrasias. Androgens once were employed to attempt to stimulate erythropoiesis in patients with anemias of various etiologies, but the availability of erythropoietin has supplanted that use. Androgens such as danazol still are used occasionally as adjunctive treatment for hemolytic anemia and idiopathic thrombocytopenic purpura that are refractory to first-line agents.

### ANTI-ANDROGENS

Because some effects of androgens are undesirable, at least under certain circumstances, agents have been developed specifically to inhibit androgen synthesis or effects. Other drugs, originally developed for different purposes, have been accidentally found to be anti-androgens and now are used intentionally for this indication.

Inhibitors of Testosterone Secretion. Both agonists and antagonists of the GnRH receptor are used to reduce testosterone secretion. Analogs of GnRH effectively inhibit testosterone secretion by inhibiting LH secretion. GnRH “superactive” analogs, given repeatedly, down-regulate the GnRH receptor and are available for treatment of prostate cancer. An extended-release form of the GnRH antagonist abarelix (PLENAXIS) is approved for treating prostate cancer (Trachtenberg et al., 2002). Because abarelix does not transiently increase sex steroid production, this preparation may be especially useful in prostate cancer patients in whom any stimulus to tumor growth might have serious adverse consequences, such as patients with spinal cord metastases in whom increased tumor growth could cause paralysis (see Chapter 55).

Some antifungal drugs of the imidazole family, such as ketoconazole (see Chapter 48), inhibit CYPs and thereby block the synthesis of steroid hormones, including testosterone and cortisol. Because they may induce adrenal insufficiency and are associated with hepatotoxicity, these drugs generally are not used to inhibit androgen synthesis, but sometimes are employed in cases of glucocorticoid excess (see Chapter 59).

### Inhibitors of Androgen Action

These drugs inhibit the binding of androgens to the androgen receptor or inhibit 5α-reductase.

Androgen Receptor Antagonists. Flutamide, Bicalutamide, and Nilutamide. These relatively potent androgen receptor antagonists have limited efficacy when used alone because the increased LH secretion stimulates higher serum testosterone concentrations. They are used primarily in conjunction with a GnRH analog in the treatment of metastatic prostate cancer. In this situation, they block the action of adrenal androgens, which are not inhibited by GnRH analogs. Survival rates in groups of patients with metastatic prostate cancer treated with a combination of a GnRH agonist and flutamide (EULEXIN), bicalutamide (CASODEX), or nilutamide (NILANDRON) are similar to one another (Schellhammer et al., 1995) and to survival rates in those treated by castration (Iversen et al., 1990). Bicalutamide is replacing flutamide for this purpose because it appears to have less hepatotoxicity and is taken once a day instead of three times a day. Nilutamide appears to have worse side effects than flutamide and bicalutamide (Dole and Holdsworth, 1997). Flutamide also has been used to treat hirsutism in women, and it appears to be as effective as any other treatment for this purpose (Venturoli et al., 1999). However, the association with hepatotoxicity warrants caution against its use for this cosmetic purpose.
Spironolactone. Spironolactone (ALDACTONE) (see Chapter 28) is an inhibitor of aldosterone that also is a weak antagonist at the androgen receptor and a weak inhibitor of testosterone synthesis, apparently inhibiting CYP17. When used to treat fluid retention or hypertension in men, gynecomastia is a common side effect (Caminos-Torres et al., 1977). In part because of this adverse effect, the selective mineralocorticoid receptor antagonist eplerenone (INSPIRA) recently was launched in the United States. Spironolactone is approved by the FDA for treating hirsutism in women, for which it is moderately effective (Cumming et al., 1986), however, it may cause irregular menses.

Cyproterone Acetate. Cyproterone acetate is a progestin and a weak anti-androgen by virtue of binding to the androgen receptor. It is moderately effective in reducing hirsutism alone or in combination with an oral contraceptive (Venturoli et al., 1999), but it is not approved for use in the United States.

5α-Reductase Inhibitors. Finasteride (PROSCAR) is an antagonist of 5α-reductase, especially type II; dutasteride (AVODART) is an antagonist of types I and II; both drugs block the conversion of testosterone to dihydrotestosterone, especially in the male external genitalia. These agents were developed to treat benign prostatic hyperplasia, and they are approved in the United States and many other countries for this purpose. When they are administered to men with moderately severe symptoms due to obstruction of urinary tract outflow, serum and prostatic concentrations of dihydrotestosterone decrease, prostatic volume decreases, and urine flow rate increases (McConnell et al., 1998; Roehrborn et al., 2004; Clark et al., 2004). Impotence is a well-documented, albeit infrequent, side effect of this use, although the mechanism is not understood. Finasteride also is approved for use in the treatment of male pattern baldness under the trade name PROPECIA, even though that effect is presumably mediated via type I 5α-reductase. Finasteride appears to be as effective as flutamide and the combination of estrogen and cyproterone in the treatment of hirsutism (Venturoli et al., 1999).

BIBLIOGRAPHY

Adrenocorticotropic hormone (ACTH, also called corticotropin) and the steroid hormone products of the adrenal cortex are considered together because the major physiological and pharmacological effects of ACTH result from its action to increase the circulating levels of adrenocortical steroids. Synthetic derivatives of ACTH are used principally in the diagnostic assessment of adrenocortical function. Because all known therapeutic effects of ACTH can be achieved with corticosteroids, synthetic steroid hormones generally are used therapeutically instead of ACTH.

Corticosteroids and their biologically active synthetic derivatives differ in their metabolic (glucocorticoid) and electrolyte-regulating (mineralocorticoid) activities. These agents are employed at physiological doses for replacement therapy when endogenous production is impaired. In addition, glucocorticoids potently suppress inflammation, and their use in a variety of inflammatory and autoimmune diseases makes them among the most frequently prescribed classes of drugs. Because they exert effects on almost every organ system, the clinical use of and withdrawal from corticosteroids are complicated by a number of serious side effects, some of which are life-threatening. Therefore, the decision to institute therapy with corticosteroids always requires careful consideration of the relative risks and benefits in each patient.

Agents that inhibit steps in the steriodogenic pathway and thus alter the biosynthesis of adrenocortical steroids are discussed, as are synthetic steroids that inhibit glucocorticoid action. Agents that inhibit the action of aldosterone are presented in Chapter 28; agents used to inhibit growth of steroid-dependent tumors are discussed in Chapter 51.

History. Addison described fatal outcomes in patients with adrenal destruction in a presentation to the South London Medical Society in 1849. These studies were soon extended when Brown-Séquard demonstrated that bilateral adrenalectomy was fatal in laboratory animals. It later was shown that the adrenal cortex, rather than the medulla, was essential for survival in these experiments. Further studies demonstrated that the adrenal cortex regulated both carbohydrate metabolism and fluid and electrolyte balance. Studies of the factors that regulated carbohydrate metabolism (termed glucocorticoids) culminated with the synthesis of cortisone, the first pharmacologically effective glucocorticoid to become readily available. Subsequently, Tate and colleagues isolated and characterized a distinct corticosteroid, aldosterone, which potently affected fluid and electrolyte balance and therefore was termed a mineralocorticoid. The isolation of distinct corticosteroids that regulated carbohydrate metabolism or fluid and electrolyte balance led to the concept that the adrenal cortex comprises two largely independent units: an outer zone that produces mineralocorticoids and an inner region that synthesizes glucocorticoids and androgen precursors.

Studies of adrenocortical steroids also played a key part in delineating the role of the anterior pituitary in endocrine function. As early as 1912, Cushing described patients with hypercorticism, and later recognized that pituitary basophilism caused the adrenal overactivity, thus establishing the link between the anterior pituitary and adrenal function. These studies led to the purification of ACTH and the determination of its chemical structure. ACTH was further shown to be essential for maintaining the structural integrity and steriodogenic capacity of the inner cortical zones. Harris established the role of the hypothalamus in pituitary control and postulated that...
ADRENOCORTICOTROPIC HORMONE (ACTH; CORTICOTROPIN)

As summarized in Figure 59–1, ACTH is synthesized as part of a larger precursor protein, pro-opiomelanocortin (POMC), and is liberated from the precursor through proteolytic cleavage at dibasic residues by the enzyme prohormone convertase 1 (see Chapter 21). Impaired processing of POMC due to a mutation in prohormone convertase 1 has been implicated in the pathogenesis of a human disorder that presents with adrenal insufficiency, childhood obesity, hypogonadotropic hypogonadism, and diabetes. A number of other biologically important peptides, including endorphins, lipotropins, and the melanocyte-stimulating hormones (MSH), also are produced from the same POMC precursor.

Human ACTH is a peptide of 39 amino acids (Figure 59–1). Whereas removal of a single amino acid at the amino terminus considerably impairs biological activity, a number of amino acids can be removed from the carboxyl-terminal end without a marked effect. The structure–activity relationships of ACTH have been studied extensively, and it is believed that a stretch of four basic amino acids at positions 15 to 18 is an important determinant of high-affinity binding to the ACTH receptor, whereas amino acids 6 to 10 are important for receptor activation.

The actions of ACTH and the other melanocortins liberated from POMC are mediated by their specific interactions with five melanocortin receptor (MCR) subtypes comprising a distinct subfamily of G protein–coupled receptors. The well-known effects of MSH on pigmentation result from interactions with the MC1R on melanocytes. MC1Rs also are found on cells of the immune system and are thought to mediate the anti-inflammatory effects of α-MSH in experimental models of inflammation. ACTH, which is identical to α-MSH in its first 13 amino acids (Ser-Tyr-Ser-Met-Glu-His-Phe-Arg-Trp-Gly-Lys-Pro-Val), exerts its effects on the adrenal cortex through the MC2R. ACTH has a much higher affinity for the MC2R than for the MC1R; however, under pathological conditions in which ACTH levels are persistently elevated, such as primary adrenal insufficiency, ACTH can signal through the MC1R and cause hyperpigmentation. Recent studies have defined a key role for α-MSH acting via the MC3R and MC4R receptors in the hypothalamic regulation of appetite and body weight (Wardlaw, 2001), and they therefore are the subject of considerable investigation as possible targets for drugs that affect appetite. The role of MC5R is less well defined, but studies in rodents suggest that MSH stimulates LH secretion and triggers aggressive, pheromone-related behavior via the MC5R.

Actions on the Adrenal Cortex. Acting via MC2R, ACTH stimulates the adrenal cortex to secrete glucocorticoids, mineralocorticoids, and the androgen precursor dehydroepiandrosterone (DHEA) that can be converted peripherally into more potent androgens. The adrenal cortex histologically and functionally can be separated into three zones that produce different steroid products under different regulatory influences. The outer zona glomerulosa secretes the mineralocorticoid aldosterone, the middle zona fasciculata secretes the glucocorticoid cortisol, and the inner zona reticularis secretes DHEA and its sulfated derivative (Figure 59–2).
Cells of the outer zone have receptors for angiotensin II and express aldosterone synthase (CYP11B2), an enzyme that catalyzes the terminal reactions in mineralocorticoid biosynthesis. Although ACTH acutely stimulates mineralocorticoid production by the zona glomerulosa, this zone is regulated predominantly by angiotensin II and extracellular Na$^+$ (see Chapter 30) and does not undergo atrophy in the absence of ongoing stimulation by the pituitary gland. In the setting of persistently elevated ACTH, mineralocorticoid levels initially increase and then return to normal (a phenomenon termed ACTH escape).

In contrast, cells of the zona fasciculata have fewer receptors for angiotensin II and express 11β-hydroxylase (CYP11B1), which catalyzes the production of glucocorticoids. In the zona reticularis, CYP17 carries out a second C 17-20 lyase reaction that converts C 21 corticosteroids to C 19 androgen precursors.

In the absence of the anterior pituitary, the inner zones of the cortex atrophy, and the production of glucocorticoids and adrenal androgens is markedly impaired.

Persistently elevated levels of ACTH, due either to repeated administration of large doses of ACTH or to excessive endogenous production, induce hyperplasia and hyper trophy of the inner zones of the adrenal cortex, with overproduction of cortisol and adrenal androgens. Adrenal hyperplasia is most marked in congenital disorders of steroidogenesis, in which ACTH levels are continuously elevated as a secondary response to impaired cortisol biosynthesis. There is some debate regarding the relative roles of ACTH versus other POMC-derived peptides in stimulating adrenal growth, but the essential role of the anterior pituitary in maintaining the integrity of the zona fasciculata is indisputable.

**Mechanism of Action.** ACTH stimulates the synthesis and release of adrenocortical hormones. As specific mechanisms for steroid hormone secretion have not been defined and since steroids do not accumulate appreciably in the gland, it is believed that the actions of ACTH to increase steroid hormone production are mediated predominantly at the level of de novo biosynthesis.

ACTH, binding to MC2R, activates the G protein Go$, to stimulate adenyl cyclase, increase intracellular cyclic AMP content, and activate PKA. Cyclic AMP is an obligatory second messenger for most, if not all, effects of ACTH on steroidogenesis. Mutations in the ACTH receptor are one of the causes of the rare syndrome of familial resistance to ACTH (Clark and Weber, 1998).

Temporally, the response of adrenocortical cells to ACTH has two phases. The acute phase, which occurs within seconds to minutes, largely reflects increased supply of cholesterol substrate to the steroidogenic enzymes. The chronic phase, which occurs over hours to days, results largely from increased transcription of the steroidogenic enzymes. A summary of the pathways of adrenal steroid biosynthesis and the structures of the major steroid intermediates and products of the human adrenal cortex are shown in Figure 59–3. The rate-limiting step in steroid hormone production is the conversion of cholesterol to pregnenolone, a reaction catalyzed by CYP11A1, the cholesterol side-chain cleavage enzyme. Most of the enzymes required for steroid hormone biosynthesis, including CYP11A1, are members of the cytochrome P450 superfamily of mixed-function oxidases that play important roles in the metabolism of xenobiotics such as drugs and environmental pollutants, as well as in the biosynthesis of such endogenous compounds as steroid hormones, vitamin D, bile acids, fatty acids, prostaglandins, and biogenic amines (see Chapter 3). The rate-limiting components in this reaction regulate the mobilization of substrate cholesterol and its delivery to CYP11A1 in the inner mitochondrial matrix.

To ensure an adequate supply of substrate for steroidogenesis, the adrenal cortex uses multiple sources of cholesterol, including: (1) circulating cholesterol and cholesterol esters taken up via the low-density lipoprotein and high-density lipoprotein receptor pathways; (2) liberation of cholesterol from endogenous cholesterol ester stores via activation of cholesterol esterase; and (3) increased de novo biosynthesis.

The mechanisms by which ACTH stimulates the translocation of cholesterol to the inner mitochondrial matrix are not fully defined. A 30,000-dalton phosphoprotein—designated the steroidogenic...
Figure 59–3. Pathways of corticosteroid biosynthesis. The steroidogenic pathways used in the biosynthesis of the corticosteroids are shown, along with the structures of the intermediates and products. The pathways that are unique to the zona glomerulosa are shown in blue, whereas those that occur in the inner zona fasciculata and zona reticularis are shown in gray. The zona reticularis does not express 3β-HSD, and thus preferentially synthesizes DHEA. CYP11A1, cholesterol side-chain cleavage enzyme; 3β-HSD, 3β-hydroxysteroid dehydrogenase; CYP17, steroid 17α-hydroxylase; CYP21, steroid 21-hydroxylase; CYP11B2, aldosterone synthase; CYP11B1, steroid 11β-hydroxylase.
acute regulatory protein—clearly plays essential roles in cholesterol delivery. Mutations in the gene encoding this phosphoprotein are found in patients with congenital lipoid adrenal hyperplasia, a rare congenital disorder in which adrenal cells become engorged with cholesterol deposits secondary to an inability to synthesize any steroid hormones. An important component of the trophic effect of ACTH is the enhanced transcription of genes that encode the individual steroidogenic enzymes, with associated increases in the steroidogenic capacity of the gland. A variety of transcriptional regulators mediate the induction of steroid hydroxylases by ACTH, and concerted mechanisms that coordinate the expression of the different genes have not been defined.

**Extra-adrenal Effects of ACTH.** In large doses, ACTH causes a number of metabolic changes in adrenalectomized animals, including ketosis, lipolysis, hypoglycemia (immediately after treatment), and resistance to insulin (later after treatment). Because of the large doses of ACTH required, the physiological significance of these extra-adrenal effects is questionable. ACTH also improves learning in experimental animals; this latter effect appears to be non-endocrine and mediated via distinct receptors in the central nervous system.

**Regulation of ACTH Secretion.** **Hypothalamic-Pituitary-Adrenal Axis.** The rate of glucocorticoid secretion is determined by fluctuations in the release of ACTH by the pituitary corticotropes. These corticotropes, in turn, are regulated by corticotropin-releasing hormone (CRH), a peptide hormone released by CRH neurons of the endocrine hypothalamus. These three organs collectively are referred to as the hypothalamic-pituitary-adrenal (HPA) axis, an integrated system that maintains appropriate levels of glucocorticoids (see Figure 59–4 for a schematic overview). There are three characteristic modes of regulation of the HPA axis: diurnal rhythm in basal steroidogenesis, negative feedback regulation by adrenal corticosteroids, and marked increases in steroidogenesis in response to stress. The diurnal rhythm is entrained by higher neuronal centers in response to sleep-wake cycles, such that levels of ACTH peak in the early morning hours, causing the circulating glucocorticoid levels to peak at approximately 8 A.M. As discussed below, negative feedback regulation occurs at multiple levels of the HPA axis and is the major mechanism that maintains circulating glucocorticoid levels in the appropriate range. Stress can override the normal negative feedback control mechanisms, leading to marked increases in plasma concentrations of glucocorticoids.

**Central Nervous System.** The central nervous system integrates a number of positive and negative influences on ACTH secretion that are conveyed by several neurotransmitters (Figure 59–4). These signals converge on the CRH neurons, which are clustered largely in the paraventricular region of the paraventricular hypothalamic nucleus and make axonal connections to the median eminence of the hypothalamus (see Chapter 12). Following release into the hypophysial portal system, CRH is transported via this portal system to the anterior pituitary, where it binds to specific membrane receptors on corticotropes. Upon CRH binding, the CRH receptor activates the Gs-adenylyl cyclase–cyclic AMP pathway within corticotropes, ultimately stimulating both ACTH biosynthesis and secretion. CRH and CRH-related peptides called urocrins also are produced at other sites, including the amygdala and hindbrain, gut, skin, adrenal gland, adipose tissue, placenta, and other sites in the periphery (Bale and Vale, 2004). The classical CRH receptor, now designated CRF1 receptor, belongs to the class II family of G protein–coupled receptors that includes receptors for calcitonin, parathyroid hormone, growth hormone–releasing hormone, secretin, glucagon, and glucagon-like peptide. A second CRH receptor, designated CRF2 receptor, shares 70% homology at the amino-acid level. These two receptors differentially bind CRH and the urocrins, providing a highly complex neural network that modulates the adaptive response to stress. The complex relationships between stress and mood have stimulated considerable interest in the possible use of CRH antagonists in disorders such as anxiety and depression.

**Arginine Vasopressin.** Arginine vasopressin (AVP) also acts as a secretagogue for corticotropes, significantly potentiating the effects of CRH. Animal studies suggest that the potentiation of CRH action by AVP probably contributes to the full magnitude of the stress response in vivo. Like CRH, AVP is produced in the parvocellular neurons of the paraventricular nucleus and secreted into the pituitary gland.
A complex from the median eminence. After binding to V₁b receptors, AVP activates the G_{q}-PLC-IP_{3}-Ca^{2+} pathway to enhance the release of ACTH. In contrast to CRH, AVP apparently does not increase ACTH synthesis.

**Negative Feedback of Glucocorticoids.** Glucocorticoids inhibit ACTH secretion via direct and indirect actions on CRH neurons to decrease CRH mRNA levels and CRH release and via direct effects on corticotropes. The inhibition of CRH release may be mediated by specific corticosteroid receptors in the hippocampus. At lower cortisol levels, the mineralocorticoid receptor (MR), which has a higher affinity for glucocorticoids and is the predominant form found in the hippocampus, is the major receptor species occupied. As glucocorticoid concentrations rise and exceed the capacity of the MR, the glucocorticoid receptor (GR) also becomes occupied. Both classes of receptor apparently control the basal activity of the HPA axis, whereas feedback inhibition by glucocorticoids predominantly involves the GR.

In the pituitary, glucocorticoids act through the GR to inhibit the release of ACTH from corticotropes and the expression of POMC. These effects are both rapid (occurring within seconds to minutes and possibly mediated by glucocorticoid receptor-independent mechanisms) and delayed (requiring hours and involving changes in gene transcription mediated through the GR).

**The Stress Response.** Stress overcomes negative feedback regulation of the HPA axis, leading to a marked rise in corticosteroid production. Examples of stress signals include injury, hemorrhage, severe infection, major surgery, hypoglycemia, cold, pain, and fear. Although the precise mechanisms that underlie this stress response and the essential actions played by corticosteroids are not fully defined, it is clear that their increased secretion is vital to maintain homeostasis in these stressful settings. As discussed below, complex interactions between the HPA axis and the immune system may be a fundamental physiological component of this stress response (Sapolsky et al., 2000).

**Assays for ACTH.** Initially, ACTH levels were assessed by bioassays that measured induced steroid production or the depletion of adrenal ascorbic acid. Radioimmunoassays that subsequently were developed to quantitate ACTH levels in individual patients were not always reproducible and did not clearly differentiate between low and normal levels of ACTH. Immunochemical luminescent assays that use two separate antibodies directed at distinct epitopes on the ACTH molecule now are widely available. These assays increase considerably the ability to differentiate patients with primary hypoadrenalism due to intrinsic adrenal disease, who have high ACTH levels due to the loss of normal glucocorticoid feedback inhibition, from those with secondary forms of hypoadrenalism, due to low ACTH levels resulting from hypothalamic or pituitary disorders. The immunochemical luminescent ACTH assays also are useful in differentiating between ACTH-dependent and ACTH-independent forms of hypercorticism: High ACTH levels are seen when the hypercorticism results from pituitary adenomas (e.g., Cushing’s disease) or nonpituitary tumors that secrete ACTH (e.g., the syndrome of ectopic ACTH), whereas low ACTH levels are seen in patients with excessive glucocorticoid production due to primary adrenal disorders. Despite their considerable utility, one problem with the immunoassays for ACTH is that their specificity for intact ACTH can lead to falsely low values in patients with ectopic ACTH secretion; these tumors can secrete aberrantly processed forms of ACTH that have biological activity but do not react in the antibody assays.

**Therapeutic Uses and Diagnostic Applications of ACTH.** There are anecdotal reports that selected conditions respond better to ACTH than to corticosteroids (e.g., multiple sclerosis), and some clinicians continue to advocate therapy with ACTH. Despite this, ACTH currently has only limited utility as a therapeutic agent. Therapy with ACTH is less predictable and less convenient than therapy with corticosteroids. In addition, ACTH stimulates mineralocorticoid and adrenal androgen secretion and may therefore cause acute retention of salt and water, as well as virilization. While ACTH and the corticosteroids are not pharmacologically equivalent, all proven therapeutic effects of ACTH can be achieved with appropriate doses of corticosteroids with a lower risk of side effects.

**Testing the Integrity of the HPA Axis.** The major clinical use of ACTH is in testing the integrity of the HPA axis. Other tests used to assess the HPA axis include the insulin tolerance test (see Chapter 55) and the metyrapone test (discussed later in this chapter). Cosyntropin (CORTROSYN, SYNACTHEN) is a synthetic peptide that corresponds to residues 1 to 24 of human ACTH. At the considerably supraphysiologic dose of 250 μg, cosyntropin maximally stimulates adrenocortical steroidogenesis. In the standard cosyntropin stimulation test, 250 μg of cosyntropin is administered either intramuscularly or intravenously, with cortisol measured just before administration (baseline) and 30 to 60 minutes after cosyntropin administration. An increase in the circulating cortisol to a level greater than 18 to 20 μg/dl indicates a normal response. Others also have included an increase of 7 μg/dl over the baseline value as a positive response, although this is less widely accepted. In patients with pituitary or hypothalamic disease of recent onset or shortly after surgery for pituitary tumors, the standard cosyntropin stimulation test may be misleading, as the duration of ACTH deficiency may have been insufficient to cause significant adrenal atrophy with frank loss of steroidogenic capacity. For these patients, some experts advocate a “low-dose” cosyntropin stimulation test, in which 1 μg of cosyntropin is administered intravenously, and cortisol is measured just before and 30 minutes after cosyntropin administration; the cutoff for a normal response is the same as that for the standard test. Because cosyntropin is not generally available in a 1-μg dose, the standard ampule of cosyntropin (250 μg) is diluted to permit accurate delivery of the 1-μg challenge dose. Care must be taken to avoid adsorption of the cosyntropin to plastic tubing and to measure the plasma cortisol precisely at 30 minutes after the cosyntropin injection. Although some studies indicate that the low-dose test is more sensitive than the standard 250-μg test, others report that this test also may fail to detect secondary adrenal insufficiency.

As noted above, primary adrenocortical insufficiency and secondary adrenocortical insufficiency are reliably distinguished using avail-
able sensitive assays for ACTH. Thus, longer-course ACTH stimulation tests rarely are used to differentiate between these disorders.

**CRH Stimulation Test.** Ovine CRH (corticotropin [ACTHREL]) and human CRH are available for diagnostic testing of the HPA axis, with the former used in the United States and the latter preferred in Europe. In patients with documented ACTH-dependent hypercorticism, CRH testing may help differentiate between a pituitary source (i.e., Cush-ing’s disease) and an ectopic source of ACTH. After two baseline blood samples are obtained 15 minutes apart, CRH (1 μg/kg body weight) is administered intravenously over a 30- to 60-second interval, and peripheral blood samples are obtained at 15, 30, and 60 minutes for ACTH measurement. It is important that the blood samples be handled as recommended for the ACTH assay. At the recommended dose, CRH generally is well tolerated, although flushing may occur, particularly if the dose is administered as a bolus. Patients with Cushing’s disease respond to CRH with either a normal or an exaggerated increase in ACTH, whereas ACTH levels do not increase in patients with ectopic sources of ACTH. It should be noted that this test is not perfect: ACTH levels are induced by CRH in occasional patients with ectopic ACTH, whereas approximately 5% to 10% of patients with Cushing’s disease fail to respond.

To improve the diagnostic accuracy of the CRH stimulation test, many authorities advocate sampling of blood from the inferior petrosal sinuses and the peripheral circulation after peripheral administration of CRH as above. In this test, an inferior petrosal/peripheral ratio of >2.5 supports a pituitary source of ACTH. When performed by a skilled neuroradiologist, this procedure increases diagnostic accuracy with a tolerable risk of complications from the catheterization procedure (Arnaldi et al., 2003).

**Absorption and Fate.** ACTH is readily absorbed from parenteral sites. The hormone rapidly disappears from the circulation after intravenous administration; in humans, the half-life in plasma is about 15 minutes, primarily due to rapid enzymatic hydrolysis.

**Toxicity of ACTH.** Aside from rare hypersensitivity reactions, the toxicity of ACTH is primarily attributable to the increased secretion of corticosteroids. Cosyntropin generally is less antigenic than native ACTH; thus cosyntropin is the preferred agent for clinical use.

ADRENOCORTICAL STEROIDS

The adrenal cortex synthesizes two classes of steroids: the corticosteroids (glucocorticoids and mineralocorticoids), which have 21 carbon atoms, and the androgens, which have 19 (Figure 59–3). The actions of corticosteroids historically were described as glucocorticoid (carbohydrate metabolism–regulating) and mineralocorticoid (electrolyte balance–regulating), reflecting their preferential activities. In humans, cortisol (hydrocortisone) is the main glucocorticoid and aldosterone is the main mineralocorticoid. The mechanisms by which glucocorticoid biosynthesis is regulated by ACTH are discussed above, and the regulation of aldosterone production is described in Chapter 30. Table 59–1 shows typical rates of secretion of cortisol and aldosterone, as well as their normal circulat-

**Physiological Functions and Pharmacological Effects

**Physiological Actions.** The effects of corticosteroids are numerous and widespread, and include alterations in carbohydrate, protein, and lipid metabolism; maintenance of fluid and electrolyte balance; and preservation of normal function of the cardiovascular system, the immune system, the kidney, skeletal muscle, the endocrine system, and the nervous system. In addition, corticosteroids endow the organism with the capacity to resist such
stressful circumstances as noxious stimuli and environmental changes. In the absence of the adrenal cortex, survival is made possible only by maintaining an optimal environment, including adequate and regular feedings, ingestion of relatively large amounts of sodium chloride, and maintenance of an appropriate environmental temperature; stresses such as infection and trauma in this setting can be life-threatening.

Until recently, corticosteroid effects were viewed as physiological (reflecting actions of corticosteroids at doses corresponding to normal daily production levels) or pharmacological (representing effects seen only at doses exceeding the normal daily production of corticosteroids). More recent concepts suggest that the antiinflammatory and immunosuppressive actions of corticosteroids—one of the major “pharmacological” uses of this class of drugs—also provide a protective mechanism in the physiological setting. Many of the immune mediators associated with the inflammatory response decrease vascular tone and could lead to cardiovascular collapse if unopposed by the adrenal corticosteroids. This hypothesis is supported by the fact that the daily production rate of cortisol can rise at least tenfold in the setting of severe stress. In addition, as discussed below, the pharmacological actions of corticosteroids in different tissues and their physiological effects are mediated by the same receptor. Thus, the various glucocorticoid derivatives used as pharmacological agents generally have side effects on physiological processes that parallel their therapeutic effectiveness.

The actions of corticosteroids are interrelated to those of other hormones. For example, in the absence of lipolytic hormones, cortisol has virtually no effect on the rate of lipolysis by adipocytes. Likewise, in the absence of glucocorticoids, epinephrine and norepinephrine have only minor effects on lipolysis. Administration of a small dose of glucocorticoid, however, markedly potentiates the lipolytic action of these catecholamines. Those effects of corticosteroids that involve concerted actions with other hormonal regulators are termed permissive and most likely reflect steroid-induced changes in protein synthesis that, in turn, modify tissue responsiveness to other hormones.

Corticosteroids are grouped according to their relative potencies in Na⁺ retention, effects on carbohydrate metabolism (i.e., hepatic deposition of glycogen and gluconeogenesis), and antiinflammatory effects. In general, potencies of steroids as judged by their ability to sustain life in adrenalectomized animals closely parallel those determined for Na⁺ retention, while potencies based on effects on glucose metabolism closely parallel those for antiinflammatory effects. The effects on Na⁺ retention and the carbohydrate/antiinflammatory actions are not closely related and reflect selective actions at distinct receptors, as noted above.

Based on these differential potencies, the corticosteroids traditionally are divided into mineralocorticoids and glucocorticoids. Estimates of potencies of representative steroids in these actions are listed in Table 59–2. Some steroids that are classified predominantly as glucocorticoids (e.g., cortisol) also possess modest but significant mineralocorticoid activity and thus may affect fluid and electrolyte handling in the clinical setting. At doses used for replacement therapy in patients with primary adrenal insufficiency (see below), the mineralocorticoid effects of

*S, short (i.e., 8–12 hour biological half-life); I, intermediate (i.e., 12–36 hour biological half-life); L, long (i.e., 36–72 hour biological half-life).
†These dose relationships apply only to oral or intravenous administration, as glucocorticoid potencies may differ greatly following intramuscular or intraarticular administration.
‡This agent is not used for glucocorticoid effects.
these “glucocorticoids” are insufficient to replace that of aldosterone, and concurrent therapy with a more potent mineralocorticoid generally is needed. In contrast, aldosterone is exceedingly potent with respect to Na+ retention, but has only modest potency for effects on carbohydrate metabolism. At normal rates of secretion by the adrenal cortex or in doses that maximally affect electrolyte balance, aldosterone has no significant glucocorticoid activity and thus acts as a pure mineralocorticoid.

**General Mechanisms for Corticosteroid Effects.** Corticosteroids interact with specific receptor proteins in target tissues to regulate the expression of corticosteroid-responsive genes, thereby changing the levels and array of proteins synthesized by the various target tissues (Figure 59–5). As a consequence of the time required to modulate gene expression and protein synthesis, most effects of corticosteroids are not immediate but become apparent after several hours. This fact is of clinical significance, because a delay generally is seen before beneficial effects of corticosteroid therapy become manifest. Although corticosteroids predominantly act to increase expression of target genes, there are well-documented examples in which glucocorticoids decrease transcription of target genes (De Bosscher et al., 2003), as discussed below. In addition to these genomic effects, some immediate actions of corticosteroids may be mediated by membrane-bound receptors (Norman et al., 2004).

The receptors for corticosteroids are members of the nuclear receptor family of transcription factors that transduce the effects of a diverse array of small, hydrophobic ligands, including the steroid hormones, thyroid hormone, vitamin D, and retinoids. These receptors share two highly conserved domains: a region of approximately 70 amino acids forming two zinc-binding domains, called zinc fingers, that are essential for the interaction of the receptor with specific DNA sequences, and a region at the carboxyl terminus that interacts with ligand (the ligand-binding domain).

Although complete loss of glucocorticoid receptor (GR) function apparently is lethal, mutations leading to partial loss of GR function have been identified in rare patients with generalized glucocorticoid resistance (Bray and Cotton, 2003). These patients harbor mutations in the GR that impair glucocorticoid binding and decrease transcriptional activation. As a consequence of these mutations, cortisol levels that normally mediate feedback inhibition fail to suppress the HPA axis completely. In this setting of partial loss of GR function, the HPA axis resets to a higher level to provide compensatory increases in ACTH and cortisol secretion. Because the GR defect is partial, adequate compensation for the end-organ insensitivity can result from the elevated cortisol level, but the excess ACTH secretion also stimulates the production of mineralocorticoids and adrenal androgens. Because the mineralocorticoid receptor (MR) and the androgen receptor are intact, these subjects present with manifestations of mineralocorticoid excess (hypertension and hypokalemic alkalosis) and/or of increased androgen levels (acne, hirsutism, male pattern baldness, menstrual irregularities, anovulation, and infertility). In children, the excess adrenal androgens can cause precocious sexual development.

**Glucocorticoid Receptor.** The GR resides predominantly in the cytoplasm in an inactive form until it binds glucocorticoids (Figure 59–5). Steroid binding results in receptor activation and translocation to the nucleus. The inactive GR is complexed with other proteins, including heat-shock protein (HSP) 90, a member of the heat-shock family of stress-induced proteins; HSP70; and a 56,000-dalton immu-
nophilin, one of the group of intracellular proteins that bind the immunosuppressive agents cyclosporine and tacrolimus (see Chapter 52 for a discussion of these agents). HSP90, through interactions with the steroid-binding domain, may facilitate folding of the GR into an appropriate conformation that permits ligand binding.

**Regulation of Gene Expression by Glucocorticoids.** After ligand binding, the GR dissociates from its associated proteins and translocates to the nucleus. There, it interacts with specific DNA sequences within the regulatory regions of affected genes. The short DNA sequences that are recognized by the activated GR are called glucocorticoid responsive elements (GREs) and provide specificity to the induction of gene transcription by glucocorticoids. The consensus GRE sequence is an imperfect palindrome (GGTACAnnTGGTCT, where n is any nucleotide) to which the GR binds as a receptor dimer. The mechanisms by which GR activates transcription are complex and not completely understood, but they involve the interaction of the GR with transcriptional coactivators and with proteins that make up the basal transcription apparatus. Genes that are negatively regulated by glucocorticoids also have been identified. One well-characterized example is the pro-opiomelanocortin gene, whose negative regulation in corticotropes by glucocorticoids is an important part of the negative feedback regulation of the HPA axis. In this case, the GR appears to inhibit transcription by a direct interaction with a GRE in the POMC promoter. Other genes negatively regulated by glucocorticoids include genes for cyclooxygenase-2 (COX-2), inducible nitric oxide synthase (NOS2), and inflammatory cytokines.

Although glucocorticoids and the GR are essential for survival, interactions of the GR with specific GREs apparently are not. These conclusions are supported by the findings that genetically engineered mice completely lacking GR function die immediately after birth, whereas mice harboring a mutated GR incapable of binding to DNA are viable. These observations imply that the critical function of GR involves protein–protein interactions with other transcription factors. Indeed, protein–protein interactions have been observed between the GR and the transcription factors NF-κB and AP-1, which regulate the expression of a number of components of the immune system (De Bossche et al., 2003). Such interactions repress the expression of genes encoding a number of cytokines—regulatory molecules that play key roles in the immune and inflammatory networks—and enzymes, such as collagenase and stromelysin, that are proposed to play key roles in the joint destruction seen in inflammatory arthritis. Thus, these negative effects on gene expression appear to contribute significantly to the antiinflammatory and immunosuppressive effects of the glucocorticoids.

The recognition that the metabolic effects of glucocorticoids generally are mediated by transcriptional activation, while the antiinflammatory effects largely are mediated by transrepression, suggests that selective GR ligands may maintain the antiinflammatory actions while lessening the metabolic side effects (Coghlan et al., 2003). Recent reports describe steroid- and nonsteroidal compounds that exhibit antiinflammatory actions but have little effect on blood glucose, suggesting that such selective glucocorticoid agonists may emerge from ongoing research.

**Regulation of Gene Expression by Mineralocorticoids.** Like the GR, MR also is a ligand-activated transcription factor and binds to a very similar, if not identical, hormone-responsive element. Although its actions have been studied in less detail than the GR, the basic principles of action appear to be similar; in particular, the MR also associates with HSP90 and activates the transcription of discrete sets of genes within target tissues. Studies have not yet identified differences in the DNA recognition motifs for the GR and the MR that would explain their differential capacities to activate discrete sets of target genes. The GR and MR differ in their ability to inhibit AP-1–mediated gene activation, suggesting that differential interactions with other transcription factors may underlie their distinct effects on cell function. In addition, unlike the GR, the MR has a restricted expression: It is expressed principally in the kidney (distal cortical tubule and cortical collecting duct), colon, salivary glands, sweat glands, and hippocampus.

Aldosterone exerts its effects on Na⁺ and K⁺ homeostasis primarily via its actions on the principal cells of the distal renal tubules and collecting ducts, while the effects on H⁺ secretion largely are exerted in the intercalated cells. After binding to the MR, aldosterone initiates a sequence of events that includes the rapid induction of serum- and glucocorticoid-regulated kinase, which in turn phosphorylates and activates amiloride-sensitive epithelial Na⁺ channels in the apical membrane. Thereafter, increased Na⁺ influx stimulates the Na⁺,K⁺-ATPase in the basolateral membrane. In addition to these rapid actions, aldosterone also increases the synthesis of the individual components of these membrane proteins.

Further insights into the roles of the MR and its target genes in fluid and electrolyte balance have emerged from analyses of patients with rare genetic disorders of mineralocorticoid action, such as pseudohypoaldosteronism and pseudoaldosteronism. Despite elevated levels of mineralocorticoids, patients with pseudohypoaldosteronism present with clinical manifestations suggestive of deficient mineralocorticoid action (i.e., volume depletion, hypotension, hyperkalemia, and metabolic acidosis). Molecular analyses have defined discrete subpopulations of patients with this disorder. One form is an autosomal recessive disease resulting from loss-of-function mutations in genes encoding subunits of the amiloride-sensitive epithelial sodium channel. A second, autosomal dominant form of pseudohypoaldosteronism is caused by mutations in the MR that impair its activity. Pseudoaldosteronism, also termed Liddle’s syndrome, is an autosomal dominant disease that results from mutations in subunits of the amiloride-sensitive Na⁺ channel that interfere with its down-regulation. The constitutive activity of this channel leads to hypertension, hypokalemia, and metabolic alkalosis, despite low levels of plasma renin and aldosterone.

**Receptor-Independent Mechanism for Corticosteroid Specificity.** The availability of cloned genes encoding the GR and MR led to the surprising finding that aldosterone (a classic mineralocorticoid) and cortisol (generally viewed as predominantly glucocorticoid) binds the MR with equal affinity. This raised the question of how the apparent specificity of the MR for aldosterone was maintained in the face of much higher circulating levels of glucocorticoids. We now know that the type 2 isozyme of 11β-hydroxysteroid dehydrogenase (11βHSD2) plays a key role in corticosteroid specificity, particularly in the kidney, colon, and salivary glands (Sandep and Walker, 2001). This enzyme metabolizes glucocorticoids such as cortisol to receptor-inactive 11-keto derivatives such as cortisone (Figure 59–6). Because its predominant form in physiological settings is the hemiacetal derivative (Figure 59–7), which is resistant to 11βHSD action, aldosterone escapes this inactivation and maintains mineralocorticoid activity. In the absence of 11βHSD2, as occurs in an inherited disease called the syndrome of apparent mineralocorticoid excess, the MR is swamped by cortisol, leading to severe hypokalemia and mineralocorticoid-related hypertension. A state of mineralocorticoid excess also can be induced by inhibiting 11βHSD with glycyrrhizinic acid, a component of licorice implicated in licorice-induced hypertension.
Carbohydrate and Protein Metabolism. Corticosteroids profoundly affect carbohydrate and protein metabolism. Teleologically, these effects of glucocorticoids on intermediary metabolism can be viewed as protecting glucose-dependent tissues (e.g., the brain and heart) from starvation. They stimulate the liver to form glucose from amino acids and glycerol and to store glucose as liver glycogen. In the periphery, glucocorticoids diminish glucose utilization, increase protein breakdown and the synthesis of glutamine, and activate lipolysis, thereby providing amino acids and glycerol for gluconeogenesis. The net result is to increase blood glucose levels. Because of their effects on glucose metabolism, glucocorticoids can worsen glycemic control in patients with overt diabetes and can precipitate the onset of hyperglycemia in patients who are otherwise predisposed.

The mechanisms by which glucocorticoids inhibit glucose utilization in peripheral tissues are not fully understood. Glucocorticoids decrease glucose uptake in adipose tissue, skin, fibroblasts, thymocytes, and polymorphonuclear leukocytes; these effects are postulated to result from translocation of the glucose transporters from the plasma membrane to an intracellular location. These peripheral effects are associated with a number of catabolic actions, including atrophy of lymphoid tissue, decreased muscle mass, negative nitrogen balance, and thinning of the skin.

Similarly, the mechanisms by which the glucocorticoids promote gluconeogenesis are not fully defined. Amino acids mobilized from a number of tissues in response to glucocorticoids reach the liver and provide substrate for the production of glucose and glycogen. In the liver, glucocorticoids induce the transcription of a number of
enzymes involved in gluconeogenesis and amino acid metabolism, including phosphoenolpyruvate carboxykinase (PEPCK), glucose-6-phosphatase, and the bi-functional enzyme fructose-2,6-bisphosphatase. Analyses of the molecular basis for regulation of PEPCK gene expression have identified complex regulatory influences involving an interplay among glucocorticoids, insulin, glucagon, and catecholamines. The effects of these hormones and amines on PEPCK gene expression mirror the complex regulation of gluconeogenesis in the intact organism.

**Lipid Metabolism.** Two effects of corticosteroids on lipid metabolism are firmly established. The first is the dramatic redistribution of body fat that occurs in settings of endogenous or pharmacologically induced hypercorticism, such as Cushing’s syndrome. The other is the permissive facilitation of the lipolytic effect of other agents, such as growth hormone and β adrenergic receptor agonists, resulting in an increase in free fatty acids after glucocorticoid administration. With respect to fat distribution, there is increased fat in the back of the neck (“buffalo hump”), face (“moon facies”), and supraclavicular area, coupled with a loss of fat in the extremities.

One hypothesis for this redistribution is that peripheral and truncal adipocytes differ in their relative sensitivities to insulin and to glucocorticoid-facilitated lipolytic effects, that truncal adipocytes respond predominantly to elevated levels of insulin resulting from glucocorticoid-induced hyperglycemia, whereas peripheral adipocytes are less sensitive to insulin and respond mostly to the glucocorticoid-facilitated effects of other lipolytic hormones. This differential sensitivity may reflect differences in the expression of the type 1 isozyme of 11βHSD that converts inactive cortisone into active cortisol in target tissues (Figure 59–6). Consistent with this idea, overexpression of 11βHSD1 in adipocytes causes obesity in a transgenic mouse model. The potential role of this enzyme in adipocyte function has prompted speculation that 11βHSD1 inhibitors may have a role in the treatment of obesity.

**Electrolyte and Water Balance.** Aldosterone is by far the most potent endogenous corticosteroid with respect to fluid and electrolyte balance. Thus, electrolyte balance is relatively normal in patients with adrenal insufficiency due to pituitary disease, despite the loss of glucocorticoid production by the inner cortical zones. Mineralocorticoids act on the distal tubules and collecting ducts of the kidney to enhance reabsorption of Na+ from the tubular fluid; they also increase the urinary excretion of K+ and H+. Conceptually, it is useful to think of aldosterone as stimulating a renal exchange between Na+ and K+ or H+, although this does not involve a simple 1:1 exchange of cations in the renal tubule.

These actions on electrolyte transport, in the kidney and in other tissues (e.g., colon, salivary glands, and sweat glands), appear to account for the physiological and pharmacological activities that are characteristic of mineralocorticoids. Thus, the primary features of hyperaldosteronism are positive Na+ balance with consequent expansion of extracellular fluid volume, normal or slight increases in plasma Na+ concentration, hypokalemia, and alkalosis. Mineralocorticoid deficiency, in contrast, leads to Na+ wasting and contraction of the extracellular fluid volume, hyponatremia, hyperkalemia, and acidosis. Chronically, hyperaldosteronism can cause hypertension, whereas aldosterone deficiency can lead to hypotension and vascular collapse. Because of the effects of mineralocorticoids on electrolyte handling by sweat glands, patients who are adrenal insufficient are especially predisposed to Na+ loss and volume depletion through excessive sweating in hot environments.

Glucocorticoids also exert effects on fluid and electrolyte balance, largely due to permissive effects on tubular function and actions that maintain glomerular filtration rate. Glucocorticoids play a permissive role in the renal excretion of free water; the ability to excrete a water challenge was used at one time to diagnose adrenal insufficiency. In part, the inability of patients with glucocorticoid deficiency to excrete free water results from the increased secretion of AVP, which stimulates water reabsorption in the kidney.

In addition to their effects on monovalent cations and water, glucocorticoids also exert multiple effects on Ca2+ metabolism. Steroids interfere with Ca2+ uptake in the gut and increase Ca2+ excretion by the kidney. These effects collectively lead to decreased total body Ca2+ stores.

**Cardiovascular System.** The most striking effects of corticosteroids on the cardiovascular system result from mineralocorticoid-induced changes in renal Na+ excretion, as is evident in primary aldosteronism. The resultant hypertension can lead to a diverse group of adverse effects on the cardiovascular system, including increased atherosclerosis, cerebral hemorrhage, stroke, and hypertensive cardiomyopathy. Consistent with the known actions of mineralocorticoids in the kidney, restriction of dietary Na+ can lower the blood pressure considerably in mineralocorticoid excess.

Studies also have shown direct effects of aldosterone on the heart and vascular lining; aldosterone induces hypertension and interstitial cardiac fibrosis in animal models. The increased cardiac fibrosis is proposed to result from direct mineralocorticoid actions in the heart rather than from the effect of hypertension, because treatment with spironolactone, a MR antagonist, blocked the fibrosis without altering blood pressure. Similar effects of mineralocorticoids on cardiac fibrosis in human beings may explain, at least in part, the beneficial effects of
spironolactone in patients with congestive heart failure (see Chapter 33).

The second major action of corticosteroids on the cardiovascular system is to enhance vascular reactivity to other vasoactive substances. Hypoadrenalism is associated with reduced response to vasoconstrictors such as noradrenaline and angiotensin II, perhaps due to decreased expression of adrenergic receptors in the vascular wall. Conversely, hypertension is seen in patients with excessive glucocorticoid secretion, occurring in most patients with Cushing’s syndrome and in a subset of patients treated with synthetic glucocorticoids (even those lacking any significant mineralocorticoid action).

The underlying mechanisms in glucocorticoid-induced hypertension also are unknown; in hypertension related to the endogenous secretion of cortisol, as seen in patients with Cushing’s syndrome, it is not known if the effects are mediated by the GR or MR. Unlike hypertension caused by high aldosterone levels, the hypertension secondary to excess glucocorticoids is generally resistant to Na+ restriction.

**Skeletal Muscle.** Permissive concentrations of corticosteroids are required for the normal function of skeletal muscle, and diminished work capacity is a prominent sign of adrenocortical insufficiency. In patients with Addison’s disease, weakness and fatigue are frequent symptoms that may reflect an inadequacy of the circulatory system. Excessive amounts of either glucocorticoids or mineralocorticoids also impair muscle function. In primary aldosteronism, muscle weakness results primarily from hypokalemia rather than from direct effects of mineralocorticoids on skeletal muscle. In contrast, glucocorticoid excess over prolonged periods, either secondary to glucocorticoid therapy or endogenous hypercorticism, causes skeletal muscle wasting. This effect, termed **steroid myopathy**, accounts in part for weakness and fatigue in patients with glucocorticoid excess and is discussed in more detail below.

**Central Nervous System.** Corticosteroids exert a number of indirect effects on the CNS, through maintenance of blood pressure, plasma glucose concentrations, and electrolyte concentrations. Increasingly, direct effects of corticosteroids on the CNS have been recognized, including effects on mood, behavior, and brain excitability.

Patients with adrenal insufficiency exhibit a diverse array of psychiatric manifestations, including apathy, depression, and irritability; some patients are frankly psychotic. Appropriate replacement therapy corrects these abnormalities. Conversely, glucocorticoid administration can induce multiple CNS reactions. Most patients respond with mood elevation, which may impart a sense of well-being despite the persistence of underlying disease. Some patients exhibit more pronounced behavioral changes, such as euphoria, insomnia, restlessness, and increased motor activity. A smaller but significant percentage of patients treated with glucocorticoids becomes anxious, depressed, or overtly psychotic. A high incidence of neuroses and psychoses is seen in patients with Cushing’s syndrome. These abnormalities usually disappear after cessation of glucocorticoid therapy or treatment of the Cushing’s syndrome.

The mechanisms by which corticosteroids affect neuronal activity are unknown, but it has been proposed that steroids produced locally in the brain (termed **neurosteroids**) may regulate neuronal excitability. Studies in rodent models indicated that glucocorticoids deleteriously affect survival and function of hippocampal neurons, and that these changes are associated with diminished memory. In one study, basal cortisol levels in human beings correlated directly with hippocampal atrophy and memory deficits. To the extent that these results are confirmed, they have important prognostic implications for age-related memory decline, and they suggest therapeutic approaches directed at diminishing the negative effects of glucocorticoids on hippocampal neurons with aging.

**Formed Elements of Blood.** Glucocorticoids exert minor effects on hemoglobin and erythrocyte content of blood, as evidenced by the frequent occurrence of polycythemia in Cushing’s syndrome and of normochromic, normocytic anemia in adrenal insufficiency. More profound effects are seen in the setting of autoimmune hemolytic anemia, in which the immunosuppressive effects of glucocorticoids can diminish the self-destruction of erythrocytes.

Corticosteroids also affect circulating white blood cells. Addison’s disease is associated with an increased mass of lymphoid tissue and lymphocytes. In contrast, Cushing’s syndrome is characterized by lymphocytopenia and decreased mass of lymphoid tissue. The administration of glucocorticoids leads to a decreased number of circulating lymphocytes, eosinophils, monocytes, and basophils. A single dose of hydrocortisone leads to a decline of these circulating cells within 4 to 6 hours; this effect persists for 24 hours and results from the redistribution of cells away from the periphery rather than from increased destruction. In contrast, glucocorticoids increase circulating polymorphonuclear leukocytes as a result of increased release from the marrow, diminished rate of removal from the circulation, and increased demargination from vascular walls. Finally, certain lymphoid malignancies are destroyed by glucocorticoid treatment, an effect that may relate to the ability of glucocorticoids to activate programmed cell death.

**Antiinflammatory and Immunosuppressive Actions.** In addition to their effects on lymphocyte number, corticosteroids profoundly alter the immune responses of lymphocytes. These effects are an important facet of the antiinflammatory and immunosuppressive actions of the glucocorticoids. Glucocorticoids can prevent or suppress
inflammation in response to multiple inciting events, including radiant, mechanical, chemical, infectious, and immunological stimuli. Although the use of glucocorticoids as antiinflammatory agents does not address the underlying cause of the disease, the suppression of inflammation is of enormous clinical utility and has made these drugs among the most frequently prescribed agents. Similarly, glucocorticoids are of immense value in treating diseases that result from undesirable immune reactions. These diseases range from conditions that predominantly result from humoral immunity, such as urticaria (see Chapter 62), to those that are mediated by cellular immune mechanisms, such as transplantation rejection (see Chapter 52). The immunosuppressive and antiinflammatory actions of glucocorticoids are inextricably linked, perhaps because they both involve inhibition of leukocyte functions.

Multiple mechanisms are involved in the suppression of inflammation by glucocorticoids. It is now clear that glucocorticoids inhibit the production by multiple cells of factors that are critical in generating the inflammatory response. As a result, there is decreased release of vasoactive and chemoattractive factors, diminished secretion of lipolytic and proteolytic enzymes, decreased extravasation of leukocytes to areas of injury, and ultimately, decreased fibrosis. Glucocorticoids can also reduce expression of proinflammatory cytokines, such as COX-2 and NOS2. Of the cell types and mediators that are inhibited by glucocorticoids are summarized in Table 59–3. The net effect of these actions on various cell types is to diminish markedly the inflammatory response.

The influence of stressful conditions on immune defense mechanisms is well documented, as is the contribution of the HPA axis to the stress response (Sapolsky et al., 2000). This has led to a growing appreciation of the importance of glucocorticoids as physiological modulators of the immune system, where glucocorticoids appear to protect the organism against life-threatening consequences of a full-blown inflammatory response (Chrousos, 1995).

Stresses such as injury, infection, and disease result in the increased production of cytokines, a network of signaling molecules that integrate actions of macrophages/monocytes, T lymphocytes, and B lymphocytes in mounting immune responses. Among these cytokines, interleukin (IL)-1, IL-6, and tumor necrosis factor-α (TNF-α) stimulate the HPA axis, with IL-1 having the broadest range of actions. IL-1 stimulates the release of CRH by hypothalamic neurons, interacts directly with the pituitary to increase the release of ACTH, and may directly stimulate the adrenal gland to produce glucocorticoids. As detailed above, the increased production of glucocorticoids, in turn, profoundly inhibits the immune system at multiple sites. Factors that are inhibited include components of the cytokine network, including interferon-γ (IFN-γ), granulocyte-macrophage colony-stimulating factor (GM-CSF), interleukins (IL-1, IL-2, IL-3, IL-6, IL-8, and IL-12), and TNF-α. Thus, the HPA axis and the immune system are capable of bidirectional interactions in response to stress, and these interactions appear to be important for homeostasis (Chrousos, 1995).

Absorption, Transport, Metabolism, and Excretion

Absorption. Hydrocortisone and numerous congeners, including the synthetic analogs, are orally effective. Certain water-soluble esters of hydrocortisone and its synthetic congeners are administered intravenously to achieve high concentrations of drug rapidly in body fluids. More prolonged effects are obtained by intramuscular injection of suspensions of hydrocortisone, its esters, and congeners. Minor changes in chemical structure may markedly alter the rate of absorption, time of onset of effect, and duration of action.

Glucocorticoids also are absorbed systemically from sites of local administration, such as synovial spaces, the conjunctival sac, skin, and respiratory tract. When administration is prolonged, when the site of application is covered with an occlusive dressing, or when large areas of skin are involved, the absorption may be sufficient to cause systemic effects, including suppression of the HPA axis.

Transport, Metabolism, and Excretion. After absorption, 90% or more of cortisol in plasma is reversibly bound to protein under normal circumstances. Only the fraction of corticosteroid that is unbound can enter cells to mediate corticosteroid effects. Two plasma proteins account for almost all of the steroid-binding capacity: corticosteroid-binding globulin (CBG; also called transcortin), and albumin. CBG is an α-globulin secreted by the liver that has high affinity (estimated association constant of approximately 7.6 × 10^7 M⁻¹) for steroids but relatively low total binding capacity, whereas albumin, also produced by the liver, has low affinity (estimated association constant of 1 × 10^5 M⁻¹) but relatively large binding capacity. At normal or low concentrations of corticosteroids, most of the hormone is protein-bound. At higher steroid concentrations, the capacity of protein binding is exceeded, and a greater fraction of the steroid exists in the free state. Corticosteroids compete with each other for binding sites on CBG. CBG has relatively high affinity for cortisol and most of its synthetic congeners and low affinity for aldosterone and glucuronide-conjugated steroid metabolites; thus, greater percentages of these latter steroids are found in the free form.

A special state of physiological hypercorticism occurs during pregnancy. The elevated circulating estrogen levels induce CBG production, and CBG and total plasma cortisol increase severalfold. The physiological significance of these changes remains to be established.

All of the biologically active adrenocortical steroids and their synthetic congeners have a double bond in the 4,5 position and a ketone group at C 3 (Figure 59–7). As a general rule, the metabolism of steroid hormones involves sequential additions of oxygen or hydrogen atoms, followed by conjugation to form water-soluble derivatives. Reduction of the 4,5 double bond occurs at both hepatic and extrahepatic sites, yielding inactive compounds. Subsequent reduction of the 3-ketone substituent to the 3-hydroxyl derivative, forming tetrahydrocortisol, occurs only in the liver. Most of these A ring-reduced steroids are conjugated through the 3-hydroxyl group with sulfate or glucuronide by enzymatic reactions that take place in the liver, and to a lesser extent in the kidney. The resultant sulfate esters and glucuronides are water-soluble and are the predominant forms excreted in urine. Neither biliary nor fecal excretion is of quantitative importance in humans.

Synthetic steroids with an 11-keto substituent, such as cortisol and prednisolone, must be enzymatically reduced to the corresponding 11β-hydroxy derivative before they are biologically active. The type 1 isozyme of 11β-hydroxysteroid dehydrogenase catalyzes this reduction, predominantly in the liver, but also in specialized sites such as adipocytes, bone, eye, and skin. In settings in which this enzymatic activity is impaired, it is prudent to use steroids that do not require enzymatic activation (e.g., hydrocortisone and prednisolone rather than cortisone or prednisone). Such settings include severe hepatic failure and patients with the rare condition of cortisone reductase deficiency, who are unable to activate the 11-keto steroids because of a partial loss of 11βHSD1 activity and a relative deficiency in the enzyme hexose-6-phosphate dehydrogenase, which supplies reducing equivalents to the 11β-hydroxysteroid dehydrogenase.

Structure–Activity Relationships

Chemical modifications to the cortisol molecule have generated derivatives with greater separations of glucocorticoid and mineralocorticoid activity; for a number of synthetic glucocorticoids, the effects on electrolytes are minimal even at the highest doses used (Table 59–2). In addition, these modifications have led to derivatives with greater potencies and with longer durations of action. A vast array of steroid preparations is available for oral, parenteral, and topical use. Some of these agents are summarized in Table 59–4. None of these currently available derivatives effectively separates antiinflammatory effects from effects on carbohydrate, protein, and fat metabolism, or from suppressive effects on the HPA axis, as discussed above.

The structures of hydrocortisone (cortisol) and some of its major derivatives are shown in Figure 59–7. Changes in chemical structure may alter the specificity and/or potency due to changes in affinity and intrinsic activity at corticosteroid receptors, and alterations in absorption, protein binding, rate of metabolic transformation, rate of excretion, or membrane permeability. The effects of various substitutions on glucocorticoid and mineralocorticoid activity and on duration of action are summarized in Table 59–2. The 4,5 double bond and the 3-keto group on ring A are essential for glucocorticoid and mineralocorticoid activity; an 11β-hydroxyl group on ring C is required for glucocorticoid activity but not mineralocorticoid activity; a hydroxyl group at C 21 on ring D is present on all natural corti-

*Fludrocortisone acetate is intended for use as a mineralocorticoid. Note: Topical preparations include agents for application to skin or mucous membranes in creams, solutions, ointments, gels, pastes (for oral lesions), and aerosols; ophthalmic preparations include solutions, suspensions, and ointments; inhalation preparations include agents for nasal or oral inhalation.
corticosteroids and on most of the active synthetic analogs and seems to be an absolute requirement for mineralocorticoid activity, but not for glucocorticoid activity. The 17α-hydroxyl group on ring D is a substituent on cortisol and on all of the currently used synthetic glucocorticoids. While steroids without the 17α-hydroxyl group (e.g., corticosterone) have appreciable glucocorticoid activity, the 17α-hydroxyl group gives optimal potency.

Introduction of an additional double bond in the 1,2 position of ring A, as in prednisolone or prednisone, selectively increases glucocorticoid activity (approximately fourfold compared to hydrocortisone), resulting in an enhanced glucocorticoid/mineralocorticoid potency ratio. This modification also results in compounds that are metabolized more slowly than hydrocortisone.

Fluorination at the 9α position on ring B enhances both glucocorticoid and mineralocorticoid activity, possibly related to an electron-withdrawing effect on the nearby 11β-hydroxyl group. Fludrocortisone (9α-fluorocortisone) has enhanced activity at the GR (10 times relative to cortisol) but even greater activity at the MR (125 times relative to cortisol). It is used in mineralocorticoid replacement therapy (see below) and has no appreciable glucocorticoid effect at usual daily doses of 0.05 mg to 0.2 mg. When combined with the 1,2 double bond in ring A and other substitutions at C 16 on ring D (Figure 59–7), the 9α-fluoro derivatives formed (e.g., triamcinolone, dexamethasone, and betamethasone) have marked glucocorticoid activity. The substitutions at C 16 virtually eliminate mineralocorticoid activity.

**Other Substitutions.** 6α Substitution on ring B has somewhat unpredictable effects. 6α-Methylcortisol has increased glucocorticoid and mineralocorticoid activity, whereas 6α-methylprednisolone has somewhat greater glucocorticoid activity and somewhat less mineralocorticoid activity than prednisolone. A number of modifications convert the glucocorticoids to more lipophilic molecules with enhanced topical/systemic potency ratios. Examples include the introduction of an acetone between hydroxyl groups at C 16 and C 17, esterification of the hydroxyl group with valerate at C 17, esterification of hydroxyl groups with propionate at C 17 and C 21, and substitution of the hydroxyl group at C 21 with chlorine. Other approaches to achieve local glucocorticoid activity while minimizing systemic effects involve the formation of analogs that are rapidly inactivated after absorption; examples include C 21 carboxylate or carbothioate glucocorticoid esters, which are rapidly metabolized to inactive 21-carboxylic acids.

**Toxicity of Adrenocortical Steroids**

Two categories of toxic effects result from the therapeutic use of corticosteroids: those resulting from withdrawal of steroid therapy and those resulting from continued use at supraphysiological doses. The side effects from both categories are potentially life-threatening and mandate a careful assessment of the risks and benefits in each patient.

**Withdrawal of Therapy.** The most frequent problem in steroid withdrawal is flare-up of the underlying disease for which steroids were prescribed. There are several other complications associated with steroid withdrawal. The most severe complication of steroid cessation, acute adrenal insufficiency, results from overly rapid withdrawal of corticosteroids after prolonged therapy has suppressed the HPA axis. The therapeutic approach to acute adrenal insufficiency is detailed below. There is significant variation among patients with respect to the degree and duration of adrenal suppression after glucocorticoid therapy, making it difficult to establish the relative risk in any given patient. Many patients recover from glucocorticoid-induced HPA suppression within several weeks to months; however, in some individuals the time to recovery can be one year or longer.

In an effort to diminish the risk of iatrogenic acute adrenal insufficiency, protocols for discontinuing corticosteroid therapy in patients receiving long-term treatment with corticosteroids have been proposed, generally without rigorous documentation of their efficacy. Patients who have received supraphysiological doses of glucocorticoids for a period of 2 to 4 weeks within the preceding year should be considered to have some degree of HPA impairment in settings of acute stress and should be treated accordingly.

In addition to this most severe form of withdrawal, a characteristic glucocorticoid withdrawal syndrome consists of fever, myalgias, arthralgias, and malaise, which may be difficult to differentiate from some of the underlying diseases for which steroid therapy was instituted. Finally, pseudotumor cerebri, a clinical syndrome that includes increased intracranial pressure with papilledema, is a rare condition that sometimes is associated with reduction or withdrawal of corticosteroid therapy.

**Continued Use of Supraphysiological Glucocorticoid Doses.** Besides the consequences that result from the suppression of the HPA axis, there are a number of other complications that result from prolonged therapy with corticosteroids. These include fluid and electrolyte abnormalities, hypertension, hyperglycemia, increased susceptibility to infection, osteoporosis, myopathy, behavioral disturbances, cataracts, growth arrest, and the characteristic habitus of steroid overdose, including fat redistribution, striae, and ecchymoses.

**Fluid and Electrolyte Handling.** Alterations in fluid and electrolyte handling can cause hypokalemic alkalosis, edema, and hypertension, particularly in patients with primary hyperaldosteronism secondary to an adrenal adenoma or in patients treated with potent mineralocorticoids. Similarly, hypertension is a relatively common manifestation in patients with endogenous glucocorticoid excess and can even be seen in patients treated with glucocorticoids lacking appreciable mineralocorticoid activity.

**Metabolic Changes.** The effects of glucocorticoids on intermediary metabolism have been described above. Hyperglycemia with glycosuria usually can be managed with diet and/or insulin, and its occurrence should not be a major factor in the decision to continue corticosteroid therapy or to initiate therapy in diabetic patients.

**Immune Responses.** Because of their multiple effects to inhibit the immune system and the inflammatory response, glucocorticoid use is associated with an increased susceptibility to infection and a risk for reactivation of latent tuberculosis. In the presence of known infections of some consequence, glucocorticoids should be adminis-
Possible Risk of Peptic Ulcers. There is considerable debate about the association between peptic ulcers and glucocorticoid therapy. The possible onset of hemorrhage and perforation in these ulcers and their insidious onset make peptic ulcers serious therapeutic problems (see Chapter 36); estimating the degree of risk from corticosteroids has received much study. Most patients who develop gastrointestinal bleeding while receiving corticosteroids also received nonsteroidal antiinflammatory agents, which are known to promote ulceration, such that the pathogenic role of corticosteroids remains open to debate. Nonetheless, it is prudent to be especially vigilant for peptic ulcer formation in patients receiving therapy with corticosteroids, especially when administered concomitantly with nonsteroidal antiinflammatory drugs.

Myopathy. Myopathy, characterized by weakness of proximal limb muscles, can occur in patients taking large doses of corticosteroids and also is part of the clinical picture in patients with endogenous Cushing’s syndrome. It can be of sufficient severity to impair ambulation and is an indication for withdrawal of therapy. Attention also has focused on steroid myopathy of the respiratory muscles in patients with asthma or chronic obstructive pulmonary disease (see Chapter 27); this complication can diminish respiratory function. Recovery from the steroid myopathies may be slow and incomplete.

Behavioral Changes. Behavioral disturbances are common after administration of corticosteroids and in patients who have Cushing’s syndrome secondary to endogenous hypercorticism; these disturbances may take many forms, including nervousness, insomnia, changes in mood or psyche, and overt psychosis. Suicidal tendencies are not uncommon. A history of previous psychiatric illness does not preclude the use of steroids in patients for whom they are otherwise indicated. Conversely, the absence of a history of previous psychiatric illness does not guarantee that a given patient will not develop psychiatric disorders while on steroids.

Cataracts. Cataracts are a well-established complication of glucocorticoid therapy and are related to dosage and duration of therapy. Children appear to be particularly at risk. Cessation of therapy may not lead to complete resolution of opacities, and the cataracts may progress despite reduction or cessation of therapy. Patients on long-term glucocorticoid therapy at doses of prednisone of 10 to 15 mg/day or greater should receive periodic slit-lamp examinations to detect glucocorticoid-induced posterior subcapsular cataracts.

Osteoporosis. Osteoporosis, a frequent serious complication of glucocorticoid therapy, occurs in patients of all ages and is related to dosage and duration of therapy (Saag, 2003). A reasonable estimate is that 30% to 50% of all patients who receive chronic glucocorticoid therapy ultimately will develop osteoporotic fractures. Glucocorticoids preferentially affect trabecular bone and the cortical rim of the vertebral bodies; the ribs and vertebrae are the most frequent sites of fracture. Glucocorticoids decrease bone density by multiple mechanisms, including inhibition of gonadal steroid hormones, diminished gastrointestinal absorption of Ca^{2+}, and inhibition of bone formation due to suppressive effects on osteoblasts and stimulation of resorption due to effects on osteoclasts mediated by changes in the production of osteoprotegerin and RANK ligand. In addition, glucocorticoid inhibition of intestinal Ca^{2+} uptake may lead to secondary increases in parathyroid hormone, thereby increasing bone resorption.

The considerable morbidity of glucocorticoid-related osteoporosis has led to efforts to identify patients at risk for fractures and to prevent or reverse bone loss in patients requiring chronic glucocorticoid therapy. The initiation of glucocorticoid therapy is considered an indication for bone densitometry, preferably with techniques such as dual-energy x-ray absorptiometry of the lumbar spine and hip that most sensitively detect abnormalities in trabecular bone. Because bone loss associated with glucocorticoids predominantly occurs within the first 6 months of therapy, densitometric evaluation and prophylactic measures should be initiated with therapy or shortly thereafter. Most authorities advocate maintaining a Ca^{2+} intake of 1500 mg/day by diet plus Ca^{2+} supplementation and vitamin D intake of 400 IU/day, assuming that these measures do not increase urinary calcium excretion above the normal range. Although gonadal hormone replacement therapy has been widely used in specific groups of patients receiving chronic glucocorticoid therapy, this is the subject of considerable debate based on recently published results from randomized, placebo-controlled trials (see Chapter 57). Recombinant parathyroid hormone recently has received considerable attention as a potential therapy of glucocorticoid-induced osteoporosis.

The most important advance to date in the prevention of glucocorticoid-related osteoporosis is the successful use of bisphosphonates, which have been shown to decrease the decline in bone density and the incidence of fractures in patients receiving glucocorticoid therapy. Additional discussion of these issues is found in Chapters 57 and 61.

Osteonecrosis. Osteonecrosis (also known as avascular or aseptic necrosis) is a relatively common complication of glucocorticoid therapy. The femoral head is affected most frequently, but this process also may affect the humeral head and distal femur. Joint pain and stiffness usually are the earliest symptoms, and this diagnosis should be considered in patients receiving glucocorticoids who abruptly develop hip, shoulder, or knee pain. Although the risk increases with the duration and dose of glucocorticoid therapy, osteonecrosis also can occur when high doses of glucocorticoids are given for short periods of time. Osteonecrosis generally progresses, and most affected patients ultimately require joint replacement.

Regulation of Growth and Development. Growth retardation in children can result from administration of relatively small doses of glucocorticoids. Although the precise mechanism is unknown, there are reports that collagen synthesis and linear growth in these children can be restored by treatment with growth hormone; further studies are needed to define the role of concurrent treatment with growth hormone in this setting. Further studies also are needed to explore the possible effects of exposure to corticosteroids in utero. Studies in experimental animals have shown that antenatal exposure to glucocorticoids is clearly linked to cleft palate and altered neuronal development, ultimately resulting in complex behavioral abnormalities. Thus, although the actions of glucocorticoids to promote cellular differentiation play important physiological roles in human development in the neonatal period (e.g., induction of the hepatic gluconeogenic enzymes and surfactant production in the lung), the possibility remains that antenatal steroids can lead to subtle abnormalities in fetal development.

Therapeutic Uses

With the exception of replacement therapy in deficiency states, the use of glucocorticoids largely is empirical. Based on extensive clinical experience, a number of therapeutic principles can be proposed. Given the number and severity of potential side effects, the decision to institute therapy...
with glucocorticoids always requires a careful consideration of the relative risks and benefits in each patient. For any disease and in any patient, the appropriate dose to achieve a given therapeutic effect must be determined by trial and error and must be re-evaluated periodically as the activity of the underlying disease changes or as complications of therapy arise. A single dose of glucocorticoid, even a large one, is virtually without harmful effects, and a short course of therapy (up to one week), in the absence of specific contraindications, is unlikely to be harmful. As the duration of glucocorticoid therapy is increased beyond one week, there are time- and dose-related increases in the incidence of disabling and potentially lethal effects. Except in patients receiving replacement therapy, glucocorticoids are neither specific nor curative; rather, they are palliative by virtue of their antiinflammatory and immunosuppressive actions. Finally, abrupt cessation of glucocorticoids after prolonged therapy is associated with the risk of adrenal insufficiency, which may be fatal.

These principles have several implications for clinical practice. When glucocorticoids are to be given over long periods, the dose must be determined by trial and error and must be the smallest one that will achieve the desired effect. When the therapeutic goal is relief of painful or distressing symptoms not associated with an immediately life-threatening disease, complete relief is not sought, and the steroid dose is reduced gradually until worsening symptoms indicate that the minimal acceptable dose has been found. Where possible, the substitution of other medications, such as nonsteroidal antiinflammatory drugs, may facilitate the tapering process once the initial benefit of glucocorticoid therapy has been achieved. When therapy is directed at a life-threatening disease (e.g., pemphigus or lupus cerebritis), the initial dose should be a large one aimed at achieving rapid control of the crisis. If some benefit is not observed quickly, then the dose should be doubled or tripled. After initial control in a potentially lethal disease, dose reduction should be carried out under conditions that permit frequent, accurate observations of the patient. It is always essential to weigh carefully the relative dangers of therapy and of the disease being treated.

The lack of demonstrated deleterious effects of a single dose of glucocorticoids within the conventional therapeutic range justifies their administration to critically ill patients who may have adrenal insufficiency. If the underlying condition does result from deficiency of glucocorticoids, then a single intravenous injection of a soluble glucocorticoid may prevent immediate death and allow time for a definitive diagnosis to be made. If the underlying disease is not adrenal insufficiency, the single dose will not harm the patient.

In the absence of specific contraindications, short courses of high-dose, systemic glucocorticoids also may be given for diseases that are not life-threatening, but the general rule is that long courses of therapy at high doses should be reserved for life-threatening disease. In selected settings, as when a patient is threatened with permanent disability, this rule is justifiably violated.

In an attempt to dissociate therapeutic effects from undesirable side effects, various regimens of steroid administration have been utilized. To diminish HPA axis suppression, the intermediate-acting steroid preparations (e.g., prednisone or prednisolone) should be given in the morning as a single dose. Alternate-day therapy with the same glucocorticoids also has been employed, as certain patients obtain adequate therapeutic responses on this regimen. Alternatively, pulse therapy with higher glucocorticoid doses (e.g., doses as high as 1 to 1.5 g/day of methylprednisolone for 3 days) frequently is used to initiate therapy in patients with fulminant, immunologically related disorders such as acute transplantation rejection, necrotizing glomerulonephritis, and lupus nephritis. The benefit of such pulse therapy in long-term maintenance regimens remains to be defined.

Replacement Therapy. Adrenal insufficiency can result from structural or functional lesions of the adrenal cortex (primary adrenal insufficiency or Addison’s disease) or from structural or functional lesions of the anterior pituitary or hypothalamus (secondary adrenal insufficiency). In developed countries, primary adrenal insufficiency most frequently is secondary to autoimmune adrenal disease, whereas tuberculous adrenalitis is the most frequent etiology in underdeveloped countries. Other causes include adrenalectomy, bilateral adrenal hemorrhage, neoplastic infiltration of the adrenal glands, acquired immunodeficiency syndrome, inherited disorders of the steroidogenic enzymes, and X-linked adrenoleukodystrophy (Carey, 1997). Secondary adrenal insufficiency resulting from pituitary or hypothalamic dysfunction generally presents in a more insidious manner than does the primary disorder, probably because mineralocorticoid biosynthesis is preserved.

Acute Adrenal Insufficiency. This life-threatening disease is characterized by gastrointestinal symptoms (nausea, vomiting, and abdominal pain), dehydration, hyponatremia, hyperkalemia, weakness, lethargy, and hypotension. It usually is associated with disorders of the adrenal rather than the pituitary or hypothalamus, and sometimes follows abrupt withdrawal of glucocorticoids used at high doses or for prolonged periods.

The immediate management of patients with acute adrenal insufficiency includes intravenous therapy with isotonic sodium chloride solution supplemented with 5% glucose and corticosteroids and appropriate therapy for precipitating causes such as infection, trauma, or hemorrhage. Because cardiovascular function often is reduced in the setting of adrenocortical insufficiency, the patient should be monitored for evidence of volume overload such as rising central venous pressure or pulmonary edema. After an initial intravenous bolus of 100 mg, hydrocortisone (cortisol) should be given by continuous infu-
sion at a rate of 50 to 100 mg every 8 hours. At this dose, which approximates the maximum daily rate of cortisol secretion in response to stress, hydrocortisone alone has sufficient mineralocorticoid activity to meet all requirements. As the patient stabilizes, the hydrocortisone dose may be decreased to 25 mg every 6 to 8 hours. Thereafter, patients are treated in the same fashion as those with chronic adrenal insufficiency (see below).

For the treatment of suspected but unconfirmed acute adrenal insufficiency, 4 mg of dexamethasone sodium phosphate can be substituted for hydrocortisone, since dexamethasone does not cross-react in the cortisol assay and will not interfere with the measurement of cortisol (either basally or in response to the cosyntropin stimulation test). A failure to respond to cosyntropin in this setting is diagnostic of adrenal insufficiency. Often, a sample for the measurement of plasma ACTH also is obtained, as it will provide information about the underlying etiology if the diagnosis of adrenocortical insufficiency is established.

**Chronic Adrenal Insufficiency.** Patients with chronic adrenal insufficiency present with many of the same manifestations seen in adrenal crisis, but with lesser severity. These patients require daily treatment with corticosteroids (Coursin and Wood, 2002). Traditional replacement regimens have used hydrocortisone in doses of 20 to 30 mg/day. Cortisone acetate, which is inactive until converted to cortisol by 11βHSD, also has been used in doses ranging from 25 to 37.5 mg/day. In an effort to mimic the normal diurnal rhythm of cortisol secretion, these glucocorticoids generally have been given in divided doses, with two-thirds of the dose given in the morning and one-third given in the afternoon. Based on revised estimates of daily cortisol production and clinical studies showing that subtle degrees of glucocorticoid excess can decrease bone density in patients on conventional replacement regimens, many authorities advocate a lower daily hydrocortisone dose of 15 to 20 mg/day divided into either two doses (e.g., 10 to 15 mg on awakening and 5 mg in late afternoon) or three doses (e.g., 10 mg on awakening, 5 mg at lunch, and 5 mg in late afternoon). Others prefer to use intermediate- (e.g., prednisone) or long-acting (e.g., dexamethasone) glucocorticoids, since no regimen employing shorter-acting steroids can reproduce the peak serum glucocorticoid levels that normally occur before awakening in the morning. The superiority of any one of these regimens has not been rigorously demonstrated. Although some patients with primary adrenal insufficiency can be maintained on hydrocortisone and liberal salt intake, most of these patients also require mineralocorticoid replacement; fludrocortisone acetate generally is used in doses of 0.05 to 0.2 mg/day. For patients with secondary adrenal insufficiency, the administration of a glucocorticoid alone is generally adequate, as the zona glomerulosa, which makes mineralocorticoids, is intact. When initiating treatment in patients with panhypopituitarism, it is important to administer glucocorticoids before initiating treatment with thyroid hormone, because the administration of thyroid hormone may precipitate acute adrenal insufficiency by increasing the metabolism of cortisol.

The adequacy of corticosteroid replacement therapy is judged by clinical criteria and biochemical measurements. The subjective well-being of the patient is an important clinical parameter in primary and secondary disease. In primary adrenal insufficiency, the disappearance of hyperpigmentation and the resolution of electrolyte abnormalities are valuable indicators of adequate replacement. Overtreatment may cause manifestations of Cushing’s syndrome in adults and decreased linear growth in children. Plasma ACTH levels may be used to monitor therapy in patients with primary adrenal insufficiency: the early-morning ACTH level should not be suppressed, but should be less than 100 pg/ml (20 pmol/L). Although advocated by some endocrinologists, assessments of daily profiles of cortisol based on multiple blood samples or measurements of urinary free cortisol have been used more frequently as research tools than as a routine part of clinical practice.

Standard doses of glucocorticoids often must be adjusted upward in patients who also are taking drugs that increase their metabolic clearance (e.g., phenytoin, barbiturates, or rifampin). Dosage adjustments also are needed to compensate for the stress of intercurrent illness, and proper patient education is essential for the execution of these adjustments. All patients with adrenal insufficiency should wear a medical alert bracelet or tag that lists their diagnosis and carries information about their steroid regimen. During minor illness, the glucocorticoid dose should be doubled. Patients should be instructed to contact their physician if nausea and vomiting preclude the retention of oral medications. The patient and family members should also be trained to administer parenteral dexamethasone (4 mg subcutaneously or intramuscularly) in the event that severe nausea or vomiting precludes the oral administration of medications; they then should seek medical attention immediately. Based largely on empirical data, glucocorticoid doses also are adjusted when patients with adrenal insufficiency undergo either elective or emergency surgery (Axelrod, 2003). In this setting, the doses are designed to approximate or exceed the maximal cortisol secretory rate of 200 mg/day; a standard regimen is hydrocortisone, 100 mg parenterally every 8 hours. Fol-
Congenital Adrenal Hyperplasia. This term denotes a group of genetic disorders in which the activity of one of the several enzymes required for the biosynthesis of glucocorticoids is deficient. The impaired production of cortisol and the consequent lack of negative feedback inhibition lead to increased release of ACTH. As a result, other hormonally active steroids that are proximal to the enzymatic block in the steroidogenic pathway are produced in excess. Congenital adrenal hyperplasia (CAH) includes a spectrum of disorders whose precise clinical presentation, laboratory findings, and treatment depend on which of the steroidogenic enzymes is deficient.

In approximately 90% of patients, CAH results from mutations in CYP21, the enzyme that carries out the 21-hydroxylation reaction (Figure 59–3). Clinically, patients are divided into those with classic CAH, who have severe defects in enzymatic activity and first present during childhood, and those with nonclassic CAH, who present after puberty with signs and symptoms of mild androgen excess such as hirsutism, amenorrhea, infertility, and acne. Female patients with classic CAH, if not treated in utero with glucocorticoids, frequently are born with virilized external genitalia (female pseudohermaphroditism), which results from elevated production of adrenal androgen precursors at critical stages of sexual differentiation in utero. Males appear normal at birth and later may have precocious development of secondary sexual characteristics (isosexual precocious puberty). In both sexes, linear growth is accelerated in childhood, but the adult height is reduced by premature closure of the epiphyses.

In a subset of patients with classical CAH, the enzymatic deficiency is sufficiently severe to compromise aldosterone production. Such patients are unable to conserve Na⁺ normally and thus are called “salt wasters.” These patients can present with cardiovascular collapse secondary to volume depletion. In an effort to prevent such life-threatening events, especially in males who appear normal at birth, many centers routinely screen all newborn babies for elevated levels of 17-hydroxyprogesterone, the immediate steroid precursor to the enzymatic block.

All patients with classical CAH require replacement therapy with hydrocortisone or a suitable congener, and those with salt wasting also require mineralocorticoid replacement. The goals of therapy are to restore levels of physiological steroid hormones to the normal range and to suppress ACTH and thereby abrogate the effects of overproduction of adrenal androgens. The typical oral dose of hydrocortisone is approximately 0.6 mg/kg daily in two or three divided doses. The mineralocorticoid used is fludrocortisone acetate (0.05 to 0.2 mg/day). Many experts also administer table salt to infants (one-fifth of a teaspoon dissolved in formula daily) until the child is eating solid food. Therapy is guided by gain in weight and height, by plasma levels of 17-hydroxyprogesterone, and by blood pressure. Elevated plasma renin activity suggests that the patient is receiving an inadequate dose of mineralocorticoid. Sudden spurts in linear growth often indicate inadequate pituitary suppression and excessive androgen secretion, whereas growth failure suggests overtreatment with glucocorticoid.

The ability to detect classical CAH (21-hydroxylase deficiency) prenatally has made possible the treatment of affected females with glucocorticoids in utero, potentially eliminating the need for genital surgery to correct the virilization of the external genitalia. To effectively suppress fetal adrenal androgen production and consequent virilization, glucocorticoid therapy (e.g., dexamethasone, 20 μg/kg taken daily orally by mothers at risk) must be initiated before 10 weeks’ gestation, before a definitive diagnosis of CAH can be made. The genotype and sex of the fetus then are determined and steroid therapy is stopped if the sex is male or there is at least one wild-type allele for 21-hydroxylase. If genotyping reveals an affected female, steroid therapy is continued until delivery. Potential maternal side effects include hypertension, weight gain, edema, and mood changes. Although exposure to glucocorticoids in utero may have developmental consequences, adverse effects of this regimen have not yet been described.

Therapeutic Uses in Nonendocrine Diseases.Outlined below are important uses of glucocorticoids in diseases that do not directly involve the HPA axis. The disorders discussed are not inclusive; rather, they illustrate the principles governing glucocorticoid use in selected diseases for which glucocorticoids are more frequently employed. The dosage of glucocorticoids varies considerably depending on the nature and severity of the underlying disorder. For convenience, approximate doses of a representative glucocorticoid (generally prednisone) are provided. This choice is not an endorsement of one particular glucocorticoid preparation over other congeners but is made for illustrative purposes only.

Rheumatic Disorders. Glucocorticoids are used widely in the treatment of a variety of rheumatic disorders and are a mainstay in the treatment of the more serious inflammatory rheumatic diseases, such as systemic lupus erythematosus, and a variety of vasculitic disorders, such as polyarteritis nodosa, Wegener’s granulomatosis, Churg-Strauss syndrome, and giant cell arteritis. For these more serious disorders, the starting dose of glucocorticoids should be sufficient to suppress the disease rapidly and minimize resultant tissue damage. Initially, prednisone (1 mg/kg per day in divided doses) often is used, generally followed by consolidation to a single daily dose, with subsequent tapering to a minimal effective dose as determined by clinical variables.
While they are an important component of treatment of rheumatic diseases, glucocorticoids are often used in conjunction with other immunosuppressive agents such as cyclophosphamide and methotrexate, which offer better long-term control than steroids alone. The exception is giant cell arteritis, for which glucocorticoids remain superior to other agents. Caution should be exercised in the use of glucocorticoids in some forms of vasculitis (e.g., polyarteritis nodosa), for which underlying infections with hepatitis viruses may play a pathogenic role. Although glucocorticoids are indicated in these cases, there is at least a theoretical concern that glucocorticoids may complicate the course of the viral infection by suppressing the immune system. To facilitate drug tapering and/or conversion to alternate-day treatment regimens, the intermediate-acting glucocorticoids such as prednisone and methylprednisolone are generally preferred over longer-acting steroids such as dexamethasone.

In rheumatoid arthritis, because of the serious and debilitating side effects associated with chronic use, glucocorticoids are used as temporizing agents for progressive disease that fails to respond to first-line treatments such as physiotherapy and nonsteroidal anti-inflammatory agents. In this case, glucocorticoids provide relief until other, slower-acting anti-rheumatic drugs, such as methotrexate or newer agents targeted at tumor necrosis factor activity take effect. A typical starting dose is 5 to 10 mg of prednisone per day. In the setting of an acute exacerbation, higher doses of glucocorticoids may be employed (typically 20 to 40 mg/day of prednisone or equivalent), with rapid taper thereafter. Complete relief of symptoms is not sought, and the symptomatic effect of small reductions in dose (decreases of perhaps 1 mg/day of prednisone every 2 to 3 weeks) should be tested frequently, while concurrent therapy with other measures is continued, to maintain the lowest possible prednisone dose. Alternatively, patients with major symptomatology confined to one or a few joints may be treated with intra-articular steroid injections. Depending on joint size, typical doses are 5 to 20 mg of triamcinolone acetonide or its equivalent.

In noninflammatory degenerative joint diseases (e.g., osteoarthritis) or in a variety of regional pain syndromes (e.g., tendinitis or bursitis), glucocorticoids may be administered by local injection for the treatment of episodic disease flare-up. It is important to minimize the frequency of local steroid administration whenever possible. In the case of repeated intra-articular injection of steroids, there is a significant incidence of painless joint destruction, resembling Charcot’s arthropathy. It is recommended that intra-articular injections be performed with intervals of at least 3 months to minimize complications.

**Renal Diseases.** Patients with nephrotic syndrome secondary to minimal change disease generally respond well to steroid therapy, and glucocorticoids clearly are the first-line treatment in both adults and children. Initial daily doses of prednisone are 1 to 2 mg/kg for 6 weeks, followed by a gradual tapering of the dose over 6 to 8 weeks, although some nephrologists advocate alternate-day therapy. Objective evidence of response, such as diminished proteinuria, is seen within 2 to 3 weeks in 85% of patients, and more than 95% of patients will have remission within 3 months. Cessation of steroid therapy frequently is complicated by disease relapse, as manifested by recurrent proteinuria. Patients who relapse repeatedly are termed steroid-resistant and often are treated with other immunosuppressive drugs such as azathioprine or cyclophosphamide. Patients with renal disease secondary to systemic lupus erythematosus also are generally given a therapeutic trial of glucocorticoids.

Studies with other forms of renal disease, such as membranous and membranoproliferative glomerulonephritis and focal sclerosis, have provided conflicting data on the role of glucocorticoids. In clinical practice, patients with these disorders often are given a therapeutic trial of glucocorticoids with careful monitoring of laboratory indices of response. In the case of membranous glomerulonephritis, many nephrologists recommend a trial of alternate-day glucocorticoids for 8 to 10 weeks (e.g., prednisone, 120 mg every other day), followed by a 1- to 2-month period of tapering.

**Allergic Disease.** The onset of action of glucocorticoids in allergic diseases is delayed, and patients with severe allergic reactions such as anaphylaxis require immediate therapy with epinephrine: for adults, 0.3 to 0.5 ml of a 1:1000 solution intramuscularly or subcutaneously (repeated as often as every 15 minutes for up to three additional doses if necessary). The manifestations of allergic diseases of limited duration—such as hay fever, serum sickness, urticaria, contact dermatitis, drug reactions, bee stings, and angioneurotic edema—can be suppressed by adequate doses of glucocorticoids given as supplements to the primary therapy. In severe disease, intravenous glucocorticoids (methylprednisolone 125 mg intravenously every 6 hours, or equivalent) are appropriate. In less severe disease, antihistamines are the drugs of first choice. In allergic rhinitis, intranasal steroids are now viewed as the drug of choice by many experts.

**Bronchial Asthma and Other Pulmonary Conditions.** Corticosteroids frequently are used in bronchial asthma (see Chapter 27). They sometimes are employed in chronic obstructive pulmonary disease (COPD), particularly when there is some evidence of reversible obstructive disease. Data supporting the efficacy of corticosteroids are much more convincing for bronchial asthma than for COPD. The increased use of corticosteroids in asthma reflects an increased appreciation of the role of inflammation in the immunopathogenesis of this disorder. In severe asthma attacks requiring hospitalization, aggressive treatment with parenteral glucocorticoids is considered essential, even though their onset of action is delayed for 6 to 12 hours. Intravenous administration of 60 to 120 mg of methylprednisolone (or equivalent) every 6 hours is used initially, followed by daily oral doses of prednisone (30 to 60 mg) as the acute attack resolves. The dose then is tapered gradually, with withdrawal planned for 10 days to 2 weeks after initiation of steroid therapy. In general, patients subsequently can be managed on their prior medical regimen.

Less severe, acute exacerbations of asthma (as well as acute flares of COPD) often are treated with brief courses of oral glucocorticoids. In adult patients, 30 to 60 mg of prednisone is administered daily for 5 days; an additional week of therapy at lower doses also may be required. Upon resolution of the acute exacerbation, the glucocorticoids generally can be rapidly tapered without significant deleterious effects. Any suppression of adrenal function usually dissipates within 1 to 2 weeks. In the treatment of severe chronic bronchial asthma (or, less frequently, COPD) that is not controlled by other measures, the long-term administration of glucocorticoids may be necessary. As with other long-term uses of these agents, the lowest effective dose is used, and care must be exercised when withdrawal is attempted. Given the risks of long-term treatment with glucocorticoids, it is especially important to document objective evidence of a response (e.g., an improvement in pulmonary function tests). In addition, these risks dictate that long-term glucocorticoid therapy be reserved for those patients who have failed to respond to adequate regimens of other medications (see Chapter 27).

In many patients, inhaled steroids (e.g., beclomethasone dipropionate [VANCERIL], triamcinolone acetonide [AZMACORT], fluticasone [FOVENT], flunisolide [AEROBID], or budesonide [PULMICORT])
can either reduce the need for oral corticosteroids or replace them entirely. Many physicians prefer inhaled glucocorticoids over previously recommended oral theophylline in the treatment of children with moderately severe asthma, in part because of the behavioral toxicity associated with chronic theophylline administration (see Chapter 27). When used as recommended, inhaled glucocorticoids are effective in reducing bronchial hyperreactivity with less suppression of adrenal function than with oral glucocorticoids. Dysphonia or oropharyngeal candidiasis may develop, but the incidence of such side effects can be reduced substantially by maneuvers that reduce drug deposition in the oral cavity, such as spacers and mouth rinsing. The status of glucocorticoids in asthma therapy is discussed in detail in Chapter 27.

Antenatal glucocorticoids are used frequently in the setting of premature labor, decreasing the incidence of respiratory distress syndrome, intraventricular hemorrhage, and death in babies delivered prematurely. Betamethasone (12 mg intramuscularly every 24 hours for two doses) or dexamethasone (6 mg intramuscularly every 12 hours for four doses) are administered to women with premature labor between 27 and 34 weeks’ gestation. Due to evidence of decreased birth weight and adrenal suppression in babies whose mothers were given repeated courses of glucocorticoids, only a single course of glucocorticoids should be administered.

**Infectious Diseases.** Although the use of immunosuppressive glucocorticoids in infectious diseases may seem paradoxical, there are a limited number of settings in which they are indicated in the therapy of specific infectious pathogens. One dramatic example of such beneficial effects is seen in AIDS patients with *Pneumocystis carinii* pneumonia and moderate to severe hypoxia; addition of glucocorticoids to the antibiotic regimen increases oxygenation and lowers the incidence of respiratory failure and mortality. Similarly, glucocorticoids clearly decrease the incidence of long-term neurological impairment associated with *Haemophilus influenzae* type b meningitis in infants and children 2 months of age or older.

A long-standing controversy in medicine is the use of glucocorticoids in septic shock (Amann and Cavaillon, 2003). Although studies initially suggested a benefit from the routine administration of glucocorticoids to subjects with septic shock associated with gram-negative bacteremia, subsequent studies showed that glucocorticoid therapy in supraphysiologic doses was actually associated with increased mortality. Several recent trials have shown benefit in subjects treated early in their course with intermediate doses of glucocorticoids (e.g., 100 mg hydrocortisone every 8 hours). Of note, in one multicenter, randomized, placebo-controlled trial, beneficial effects were seen only in subjects who failed to increase their serum cortisol level by >9 μg/dl during the rapid cosyntropin stimulation test. To the extent that these results are confirmed, they suggest that glucocorticoid therapy may be beneficial in septic shock, presumably by damping the effects of cytokines that are induced by the disease.

**Ocular Diseases.** Ocular pharmacology, including some consideration of the use of glucocorticoids, is discussed in Chapter 63. Glucocorticoids frequently are used to suppress inflammation in the eye and can preserve sight when used properly. They are administered topically for diseases of the outer eye and anterior segment and attain therapeutic concentrations in the aqueous humor after instillation into the conjunctival cul-de-sac. For diseases of the posterior segment, systemic administration is required. Generally, ocular use of glucocorticoids should be supervised by an ophthalmologist.

A typical prescription is 0.1% dexamethasone sodium phosphate solution (ophthalmic), 2 drops in the conjunctival sac every 4 hours while awake, and 0.05% dexamethasone sodium phosphate ointment (ophthalmic) at bedtime. For inflammation of the posterior segment, typical doses are 30 mg of prednisone or equivalent per day, administered orally in divided doses.

Topical glucocorticoid therapy frequently increases intraocular pressure in normal eyes and exacerbates intraocular hypertension in patients with antecedent glaucoma. The glaucoma is not always reversible on cessation of glucocorticoid therapy. Intraocular pressure should be monitored when glucocorticoids are applied to the eye for more than 2 weeks.

Topical administration of glucocorticoids to patients with bacterial, viral, or fungal conjunctivitis can mask evidence of progression of the infection until sight is irreversibly lost. Glucocorticoids are contraindicated in herpes simplex keratitis, because progression of the disease may lead to irreversible clouding of the cornea. Topical steroids should not be used in treating mechanical lacerations and abrasions of the eye because they delay healing and promote the development and spread of infection.

**Skin Diseases.** Glucocorticoids are remarkably efficacious in the treatment of a wide variety of inflammatory dermatoses. As a result, a large number of different preparations and concentrations of topical glucocorticoids of varying potencies are available. A typical regimen for an eczematous eruption is 1% hydrocortisone ointment applied locally twice daily. Effectiveness is enhanced by application of the topical steroid under an occlusive film, such as plastic wrap; unfortunately, the risk of systemic absorption also is increased by occlusive dressings, and this can be a significant problem when the more potent glucocorticoids are applied to inflamed skin. Glucocorticoids are administered systemically for severe episodes of acute dermatologic disorders and for exacerbations of chronic disorders. The dose in these settings is usually 40 mg/day of prednisone. Systemic steroid administration can be lifesaving in pemphigus, which may require daily doses of up to 120 mg of prednisone. Further discussion of the treatment of skin diseases is given in Chapter 62.

**Gastrointestinal Diseases.** Glucocorticoid therapy is indicated in selected patients with inflammatory bowel disease (chronic ulcerative colitis and Crohn’s disease; see Chapter 38). Patients who fail to respond to more conservative management (i.e., rest, diet, and sulfasalazine) may benefit from glucocorticoids; steroids are most useful for acute exacerbations. In mild ulcerative colitis, hydrocortisone (100 mg) can be administered as a retention enema with beneficial effects. In more severe acute exacerbations, oral prednisone (10 to 30 mg/day) frequently is employed. For severely ill patients—with fever, anorexia, anemia, and impaired nutritional status—larger doses should be used (40 to 60 mg prednisone per day). Major complications of ulcerative colitis or Crohn’s disease may occur despite glucocorticoid therapy, and glucocorticoids may mask signs and symptoms of complications such as intestinal perforation and peritonitis.

Budesonide, a highly potent synthetic glucocorticoid that is inactivated by first-pass hepatic metabolism, reportedly has diminished systemic side effects commonly associated with glucocorticoids. Oral administration of budesonide in delayed-release capsules (ENTOCORT, 9 mg/day) facilitates drug delivery to the ileum and ascending colon; the drug also has been used as a retention enema in the treatment of ulcerative colitis.

**Hepatic Diseases.** The use of corticosteroids in hepatic disease has been highly controversial. Glucocorticoids clearly are of benefit in autoimmune hepatitis, where as many as 80% of patients show histological remission when treated with prednisone (40 to 60 mg daily initially, with tapering to a maintenance dose of 7.5 to
10 mg daily after serum transaminase levels fall). The role of corticosteroids in alcoholic liver disease is not fully defined; the most recent studies, including meta-analysis of previously published reports, suggest a beneficial role of prednisolone (40 mg/day for 4 weeks) in patients with severe disease indicators (e.g., hepatic encephalopathy) without active gastrointestinal bleeding. Further studies are needed to confirm or refute the role of steroids in this setting. In the setting of severe hepatic disease, prednisolone should be used instead of prednisone, which requires hepatic conversion to be active.

**Malignancies.** Glucocorticoids are used in the chemotherapy of acute lymphocytic leukemia and lymphomas because of their antilymphocytic effects. Most commonly, glucocorticoids are one component of combination chemotherapy administered under scheduled protocols. Further discussion of the chemotherapy of malignant disease is given in Chapter 51. Glucocorticoids once were frequently employed in the setting of hypercalcemia of malignancy, but more effective agents, such as the bisphosphonates, now are the preferred therapy.

**Cerebral Edema.** Corticosteroids are of value in the reduction or prevention of cerebral edema associated with parasites and neoplasms, especially those that are metastatic. Although corticosteroids are frequently used for the treatment of cerebral edema caused by trauma or cerebrovascular accidents, controlled clinical trials do not support their use in these settings.

**Miscellaneous Diseases and Conditions.** Sarcoidosis. Sarcoidosis is treated with corticosteroids (approximately 1 mg/kg per day of prednisone, or equivalent dose of alternative steroids) to induce remission. Maintenance doses, which often are required for long periods of time, may be as low as 10 mg/day of prednisone. These patients, like all patients who require chronic glucocorticoid therapy at doses exceeding the normal daily production rate, are at increased risk for secondary tuberculosis; therefore, patients with a positive tuberculin reaction or other evidence of tuberculosis should receive prophylactic antituberculosis therapy.

**Thrombocytopenia.** In thrombocytopenia, prednisone (0.5 mg/kg) is used to decrease the bleeding tendency. In more severe cases, and for initiation of treatment of idiopathic thrombocytopenia, daily doses of prednisone (1 to 1.5 mg/kg) are employed. Patients with refractory idiopathic thrombocytopenia may respond to pulsed, high-dose glucocorticoid therapy.

**Autoimmune Destruction of Erythrocytes.** Patients with autoimmune destruction of erythrocytes (i.e., hemolytic anemia with a positive Coombs test) are treated with prednisone (1 mg/kg per day). In the setting of severe hemolysis, higher doses may be used, with tapering as the anemia improves. Small maintenance doses may be required for several months in patients who respond.

**Organ Transplantation.** In organ transplantation, high doses of prednisone (50 to 100 mg) are given at the time of transplant surgery, in conjunction with other immunosuppressive agents, and most patients are kept on a maintenance regimen that includes lower doses of glucocorticoids (see Chapter 52). Of note, success rates for islet transplantation in type 1 diabetes mellitus have increased considerably following the use of immunosuppressive regimens that do not include glucocorticoids.

**Spinal Cord Injury.** Multicenter trials have shown significant decreases in neurological defects in patients with acute spinal cord injury treated within 8 hours of injury with large doses of methylprednisolone (30 mg/kg initially followed by an infusion of 5.4 mg/kg per hour for 23 hours). The ability of corticosteroids at these high doses to decrease neurological injury may reflect inhibition of free radical–mediated cellular injury, as occurs following ischemia and reperfusion.

**Diagnostic Applications of Adrenocortical Steroids**

In addition to their therapeutic uses, glucocorticoids also are used for diagnostic purposes. To determine if patients with clinical manifestations suggestive of hypercortisolism have biochemical evidence of increased cortisol biosynthesis, an overnight dexamethasone test has been devised. Patients are given 1 mg of dexamethasone orally at 11 P.M., and cortisol is measured at 8 A.M. the following morning. Suppression of plasma cortisol to less than 1.8 μg/dl suggests strongly that the patient does not have Cushing’s syndrome (Arnaldi et al., 2003).

The formal dexamethasone suppression test is used in the differential diagnosis of biochemically documented Cushing’s syndrome. Following determination of baseline cortisol levels for 48 hours, dexamethasone (0.5 mg every 6 hours) is administered orally for 48 hours. This dose markedly suppresses cortisol levels in normal subjects, including those who have nonspecific elevations of cortisol due to obesity or stress, but does not suppress levels in patients with Cushing’s syndrome. In the high-dose phase of the test, dexamethasone is administered orally at 2 mg every 6 hours for 48 hours. Patients with pituitary-dependent Cushing’s syndrome (i.e., Cushing’s disease) generally respond with decreased cortisol levels. In contrast, patients with ectopic production of ACTH or with adrenocortical tumors generally do not exhibit decreased cortisol levels. Despite these generalities, dexamethasone may suppress cortisol levels in some patients with ectopic ACTH production, particularly with tumors such as bronchial carcinoids, and many experts prefer to use inferior petrosal sinus sampling after CRH administration to make this distinction.

**INHIBITORS OF THE BIOSYNTHESIS AND ACTION OF ADRENOCORTICAL STEROIDS**

Five pharmacologic agents are useful inhibitors of adrenocortical secretion. Mitotane (o,p′-DDD), an adrenocorticolytic agent, is discussed in Chapter 51. The other inhibitors of steroid hormone biosynthesis—metyrapone, aminoglutethimide, ketoconazole, and trilostane—are discussed here. Metyrapone, aminoglutethimide, and ketoconazole inhibit cytochrome P450 enzymes involved in adrenocorticosteroid biosynthesis. Differential selectivity of these agents for the different steroid hydroxylases provides some degree of specificity to their actions. Trilostane is a competitive inhibitor of the conversion of pregnenolone to progesterone, a reaction catalyzed by 3β-hydroxysteroid dehydrogenase. In addition, agents that act as glucocorticoid receptor antagonists (anti-glucocorticoids) are discussed here (mineralocorticoid antagonists are discussed in Chapter 28). All of these agents pose the common risk of precipitating acute adrenal insufficiency; thus, they must be used in appropriate doses, and the status of the patient’s HPA axis must be carefully monitored.
Aminoglutethimide. Aminoglutethimide (α-ethyl-p-aminophenyl-glutarimide; CYTADREN) primarily inhibits CYP11A1, which catalyzes the initial and rate-limiting step in the biosynthesis of all physiological steroids. As a result, the production of all classes of steroid hormones is impaired. Aminoglutethimide also inhibits CYP11B1 and the enzyme aromatase, which converts androgens to estrogens. Aminoglutethimide has been used to decrease hypersecretion of cortisol in patients with Cushing’s syndrome secondary to autonomous adrenal tumors and hypersecretion associated with ectopic production of ACTH. Because of its actions to inhibit aromatase, aminoglutethimide also has been evaluated as a therapeutic agent for the treatment of hormonally responsive tumors such as prostate and breast cancer, although more effective agents such as tamoxifen and the aromatase inhibitors are preferred. Dose-dependent gastrointestinal and neurological side effects are relatively common, as is a transient, maculopapular rash. The usual dose is 250 mg every 6 hours, with gradual increases of 250 mg per day at 1- to 2-week intervals until the desired biochemical effect is achieved, side effects prohibit further increases, or a daily dose of 2 g is reached. Because aminoglutethimide can cause frank adrenal insufficiency, glucocorticoid replacement therapy is necessary, and mineralocorticoid supplements also may be indicated. Aminoglutethimide accelerates the metabolism of dexamethasone, and this steroid therefore should not be used for glucocorticoid replacement in this setting.

Ketoconazole. Ketoconazole (NIZORAL) is an antifungal agent, and this remains its most important clinical role (see Chapter 48). In doses higher than those employed in antifungal therapy, it is an effective inhibitor of adrenal and gonadal steroidogenesis, primarily because of its inhibition of the activity of CYP17 (17α-hydroxylase). At even higher doses, ketoconazole also inhibits CYP11A1, effectively blocking steroidogenesis in all primary steroidogenic tissues. Ketoconazole is the most effective inhibitor of steroid hormone biosynthesis in patients with Cushing’s disease. In most cases, a dosage regimen of 600 to 800 mg/day (in two divided doses) is required, and some patients may require up to 1200 mg/day given in two to three doses. Side effects include hepatic dysfunction, which ranges from asymptomatic elevations of transaminase levels to severe hepatic injury. The potential of ketoconazole to interact with CYP isoforms can lead to drug interactions of serious consequence (see Chapter 3). Further studies are needed to define the precise role of ketoconazole in the medical management of patients with excessive steroid hormonal production, and the FDA has not approved this indication for ketoconazole use.

Metyrapone. Metyrapone (METOPRONE) is a relatively selective inhibitor of CYP11B1 (11β-hydroxylase), which converts 11-deoxycorticisol to cortisol in the terminal reaction of the glucocorticoid biosynthetic pathway. Because of this inhibition, the biosynthesis of cortisol is markedly impaired, and the levels of steroid precursors (e.g., 11-deoxycorticisol) are markedly increased. Although the biosynthesis of aldosterone also is impaired, the elevated levels of 11-deoxycorticisol sustain mineralocorticoid-dependent functions. In a diagnostic test of the entire HPA axis, metyrapone (30 mg/kg, maximum dose of 3 g) is administered orally with a snack at midnight, and plasma cortisol and 11-deoxycorticisol are measured at 8 A.M. the next morning. A plasma cortisol of less than 8 μg/dl validates adequate inhibition of CYP11B1; in this setting, an 11-deoxycorticisol level of less than 7 μg/dl is highly suggestive of impaired hypothalamic-pituitary-adrenal function. An abnormal response does not identify the site of the defect—hypothalamic CRH release, ACTH production, or adrenal biosynthetic capacity could be impaired. Some authorities avoid overnight metyrapone testing in outpatients thought to have a reasonable probability of impaired HPA function, as there is some risk of precipitating acute adrenal insufficiency. Others believe that the ability to assess the entire HPA axis with a relatively easy test justifies the use of metyrapone testing in outpatients.

Metyrapone also is used to diagnose patients with Cushing’s syndrome who respond equivocally to the formal dexamethasone suppression test. Those with pituitary-dependent Cushing’s syndrome exhibit a normal response, whereas those patients with ectopic secretion of ACTH exhibit no changes in ACTH or 11-deoxycorticisol levels. Therapeutically, metyrapone has been used to treat the hypercorticism resulting from either adrenal neoplasms or tumors producing ACTH ectopically. Maximal suppression of steroidogenesis requires doses of 4 g/day. More frequently, metyrapone is used as adjunctive therapy in patients who have received pituitary irradiation or in combination with other agents that inhibit steroidogenesis. In this setting, a dose of 500 to 750 mg three or four times daily is employed. The use of metyrapone in the treatment of Cushing’s syndrome secondary to pituitary hypersecretion of ACTH is more controversial. Chronic administration of metyrapone can cause hirsutism, which results from increased synthesis of adrenal androgens upstream from the enzymatic block, and hypertension, which results from elevated levels of 11-deoxycorticisol. Other side effects include nausea, headache, sedation, and rash.

Metyrapone is not available from pharmacy sources in the United States, but can be obtained directly from Novartis for compassionate use.

ANTI-GLUCOCORTICOIDS

The progesterone receptor antagonist mifepristone [RU-486; (11β-4-dimethylaminophenyl)-17β-hydroxy-7α-(propyl-1-ynyl)estrane-4,9-dien-3-one] has received considerable attention because of its use as an antiprogestagen that can terminate early pregnancy (see Chapter 57). At higher doses, mifepristone also inhibits the GR, blocking feedback regulation of the HPA axis and secondarily increasing endogenous ACTH and cortisol levels. Because of its abili-
ty to inhibit glucocorticoid action, mifepristone also has been studied as a potential therapeutic agent in patients with hypercorticism, although it currently can be recommended only for patients with inoperable causes of cortisol excess that have not responded to other agents.

**CLINICAL SUMMARY**

Glucocorticoids are administered in multiple formulations (e.g., oral, parenteral, and topical) for disorders that share an inflammatory or immunological basis. Except in patients receiving replacement therapy for adrenal insufficiency, glucocorticoids are neither specific nor curative, but rather are palliative because of their antiinflammatory and immunosuppressive actions. Given the number and severity of potential side effects, the decision to institute therapy with glucocorticoids always requires a careful consideration of the relative risks and benefits in each patient. After therapy is initiated, the minimal dose needed to achieve a given therapeutic effect must be determined by trial and error and must be re-evaluated periodically as the activity of the underlying disease changes or as complications of therapy arise. A single dose of glucocorticoid, even a large one, is virtually without harmful effects, and a short course of therapy (up to 1 week) is unlikely to cause harm in the absence of specific contraindications. As the duration of glucocorticoid therapy increases beyond 1 week, adverse effects increase in a time- and dose-related manner. Finally, abrupt cessation of glucocorticoids after prolonged therapy is associated with the risk of adrenal insufficiency due to suppression of the HPA axis, which may be fatal.

**BIBLIOGRAPHY**

INSULIN

In recent years, developed nations have witnessed an explosive increase in the prevalence of diabetes mellitus (DM) predominantly related to lifestyle changes and the resulting surge in obesity. The metabolic consequences of prolonged hyperglycemia and dyslipidemia, including accelerated atherosclerosis, chronic kidney disease, and blindness, pose an enormous burden on patients with diabetes mellitus and on the public health system. Improvements in our understanding of the pathogenesis of diabetes and its complications and in the therapy and prevention of diabetes are critical to meeting this health care challenge.

History. Few events in the history of medicine are more dramatic than the discovery of insulin. Although the discovery is appropriately attributed to Banting and Best, others provided important observations and techniques that made it possible. In 1869, a German medical student, Paul Langerhans, noted that the pancreas contains two distinct groups of cells—the acinar cells, which secrete digestive enzymes, and cells that are clustered in islands, or islets, which he suggested served a second function. Direct evidence for this function came in 1889, when Minkowski and von Mering showed that pancreatectomized dogs exhibit a syndrome similar to diabetes mellitus in humans.

There were numerous attempts to extract the pancreatic substance responsible for regulating blood glucose. In the early 1900s, Gurg Zuelzer, an internist in Berlin, attempted to treat a dying diabetic patient with extracts of pancreas. Although the patient improved temporarily, he sank back into a coma and died when the supply of extract was exhausted. E.L. Scott, a student at the University of Chicago, made another early attempt to isolate an active principle in 1911. Using alcoholic extracts of the pancreas (not so different from those eventually used by Banting and Best), Scott treated several diabetic dogs with encouraging results; however, he lacked clear measures of control of blood glucose concentrations, and his professor considered the experiments inconclusive at best. Between 1916 and 1920, the Romanian physiologist Nicolas Paulesco found that injections of pancreatic extracts reduced urinary sugar and ketones in diabetic dogs. Although he published the results of his experiments, their significance was fully appreciated only years later.

Unaware of much of this work, Frederick Banting, a young Canadian surgeon, convinced J.J.R. Macleod, a professor of physiology in Toronto, to allow him access to a laboratory to search for the anti-diabetic principle of the pancreas. Banting assumed that the islets secreted insulin but that the hormone was destroyed by proteolytic digestion prior to or during extraction. Together with Charles Best, a fourth-year medical student, he attempted to overcome the problem by ligating the pancreatic ducts. The acinar tissue degenerated, leaving the islets undisturbed; the remaining tissue then was extracted with ethanol and acid. Banting and Best thus obtained a pancreatic extract that decreased the concentration of blood glucose in diabetic dogs.

The first patient to receive the active extracts prepared by Banting and Best was Leonard Thompson, aged 14. He presented at the Toronto General Hospital with a blood glucose level of 500 mg/dl (28 mM). Despite rigid control of his diet (450 kcal/day), he continued to excrete large quantities of glucose, and without insulin, the most likely outcome would be death after a few months. The administration of Banting and Best’s extracts reduced the plasma concentration and urinary excretion of glucose. Daily injections were given. Glucose excretion was reduced from over 100 to as little as 7.5 g/day, and the patient demonstrated marked clinical improvement. Thus replacement therapy with the newly discovered hormone, insulin, had interrupted what was clearly an otherwise fatal metabolic disorder. Banting and Best faced many trials and tribulations during the subsequent year. It was difficult to obtain active extracts reproducibly. This led to a greater involvement of Macleod; Banting also sought help from J.B. Collip, a chemist with expertise in extraction and purification of epinephrine. Stable extracts eventually were
obtained, and patients in many parts of North America soon were being treated with insulin from porcine and bovine sources. Now, as a result of recombinant DNA technology, human insulin is used for therapy.

The Nobel Prize in medicine and physiology was awarded to Banting and Macleod with remarkable rapidity in 1923, and a furor over credit followed immediately. Banting announced that he would share his prize with Best; Macleod did the same with Collip.

Chemistry. Insulin was purified and crystallized by Abel within a few years of its discovery. Sanger established the amino acid sequence of insulin in 1960, the protein was synthesized in 1963, and Hodgkin and coworkers elucidated insulin’s three-dimensional structure in 1972. Insulin was the hormone for which Yalow and Berson first developed the radioimmunoassay (Kahn and Roth, 2004).

The β (or B) cells of pancreatic islets synthesize insulin from a single-chain precursor of 110 amino acids termed preproinsulin. After translocation through the membrane of the rough endoplasmic reticulum, the 24-amino-acid N-terminal signal peptide of preproinsulin is cleaved rapidly to form proinsulin (Figure 60–1). Thereafter, proinsulin folds, and the disulfide bonds form. During conversion of human proinsulin to insulin, four basic amino acids and the remaining connector or C peptide are removed by proteolysis. This gives rise to the A and B peptide chains of the insulin molecule, which contains one intrasubunit and two intersubunit disulfide bonds. The A chain usually is composed of 21 amino acid residues, and the B chain has 30; the molecular mass is thus about 5734 daltons. Although the amino acid sequence of insulin has been highly conserved in evolution, there are significant variations that account for differences in both biological potency and immunogenicity (De Meyts, 1994). There is a single insulin gene and a single protein product in most species. However, rats and mice have two genes that encode insulin and synthesize two molecules that differ at two amino acid residues in the B chain.

The crystal structure reveals that the two chains of insulin form a highly ordered structure with α-helical regions in each of the chains. The isolated chains of insulin are inactive. In solution, insulin can exist as a monomer, dimer, or hexamer. Two molecules of Zn2+ are coordinated in the hexamer, and this form of insulin presumably is stored in the granules of the pancreatic β cell. It is believed that Zn2+ has a functional role in the hexamer formation and that this process facilitates the conversion of proinsulin to insulin and storage of the hormone. Traditional insulin is hexameric in most of the highly concentrated preparations used for therapy. When the hormone is absorbed and the concentration falls to physiological levels (nanomolar), the hormone dissociates into monomers, and the monomer is most likely the biologically active form of insulin. Monomeric insulin is now available for therapy.

Substantial information about the structure–activity relationship of insulin has been obtained by study of insulins purified from a wide variety of species and by modification of the molecule. A dozen invariant residues in the A and B chains form a surface that interacts with the insulin receptor (Figure 60–2). These residues—

Figure 60–1. Human proinsulin and its conversion to insulin. The amino acid sequence of human proinsulin is shown. By proteolytic cleavage, four basic amino acids (residues 31, 32, 64, and 65) and the connecting peptide are removed, converting proinsulin to insulin. The sites of action of the endopeptidases PC2 and PC3 are shown.
Insulin has only 2% of the metabolic potency of insulin and there may be discordance between the metabolic potency of an insulin appear to be mediated in part through the IGF-1 receptor, it is half as potent as insulin in stimulating mitogenesis. Insulin binds to surfaces located at the N- and C-terminal regions of the IGFs may form part of a second binding surface. Insulin binds to surfaces located at the N- and C-terminal regions of the α subunit of the receptor, including a cysteine-rich region in the receptor α chain. In most cases, the affinity of insulin for the insulin receptor correlates closely with its potency for eliciting effects on glucose metabolism. Human, bovine, and porcine insulins are equipotent; South American guinea pig insulin is much less potent, whereas certain avian insulins are significantly more so.

Insulin is a member of a family of related peptides termed insulin-like growth factors (IGFs). The two IGFs (IGF-1 and IGF-2) have molecular masses of about 7500 daltons and structures that are homologous to that of proinsulin. However, the short equivalents of the C peptide in proinsulin are not removed from the IGFs. In contrast with insulin, the IGFs are produced in many tissues, and they may serve a more important function in the regulation of growth than in the regulation of metabolism. These peptides, particularly IGF-1, are the presumed mediators of the action of growth hormone, and they originally were called somatomedins. The uterine hormone relaxin also may be a distant relative of this family of polypeptides, although the relaxin receptor clearly is distinct from those for insulin and IGF-1.

The receptors for insulin and IGF-1 are also closely related (Nakae et al., 2001). Thus, insulin can bind to the receptor for IGF-1 with low affinity and vice versa. The growth-promoting actions of insulin appear to be mediated in part through the IGF-1 receptor, and there may be discordance between the metabolic potency of an insulin analog and its ability to promote growth. For example, proinsulin has only 2% of the metabolic potency of insulin in vitro, but it is half as potent as insulin in stimulating mitogenesis.

Synthesis, Secretion, Distribution, and Degradation of Insulin

Insulin Production. The molecular and cellular events involved in the synthesis, storage, and secretion of insulin by the β cell and ultimate degradation of the hormone by its target tissues have been studied in great detail and have served as a model for study of other cell types in the pancreatic islet. The islet of Langerhans is composed of four types of cells, each of which synthesizes and secretes a distinct polypeptide hormone: insulin in the β (B) cell, glucagon in the α (A) cell, somatostatin in the δ (D) cell, and pancreatic polypeptide in the PP or F cell. The β cells make up 60% to 80% of the islet and form its central core. The α, δ, and F cells form a discontinuous mantle, one to three cells thick, around this core.

The cells in the islet are connected by tight junctions that allow small molecules to pass and facilitate coordinated control of groups of cells. Arterioles enter the islets and branch into a glomerulolike capillary mass in the β-cell core. Capillaries then pass to the rim of the islet and coalesce into collecting venules. Blood flows in the islet from the β cells to α and δ cells. Thus, the β cell is the primary glucose sensor for the islet, and the other cell types presumably are exposed to particularly high concentrations of insulin.

As noted earlier, insulin is synthesized as a single-chain precursor in which the A and B chains are connected by the C peptide. The initial translation product, proinsulin, contains a sequence of 24 primarily hydrophobic amino acid residues attached to the N terminus of the B chain. This signal sequence is required for the association and penetration of nascent proinsulin into the lumen of the rough endoplasmic reticulum. This sequence is cleaved rapidly, and proinsulin is then transported in small vesicles to the Golgi complex. Here, proinsulin is packaged into secretory granules along with the enzyme(s) responsible for its conversion to insulin.

The conversion of proinsulin to insulin begins in the Golgi complex, continues in the secretory granules, and is nearly complete at the time of secretion. Thus, equimolar amounts of C peptide and insulin are released into the circulation. The C peptide has no known biological function but serves as a useful index of insulin secretion in distinguishing between patients with factitious insulin injection and insulin-producing tumors. Small quantities of proinsulin and des-31,32 proinsulin also are released from β cells. This presumably reflects either exocytosis of granules in which the conversion of proinsulin to insulin is not complete or secretion by another pathway. Since the half-life of proinsulin in the circulation is much longer than that of insulin, up to 20% of immunoreactive insulin in plasma is, in reality, proinsulin and intermediates.

Two distinct Ca2+-dependent endopeptidases, which are found in the islet cell granules and in other neuroendocrine cells, are responsible for the conversion of proinsulin to insulin. These endopeptidases, PC2 and PC3, have catalytic domains related to that of subtilisin and cleave at Lys–Arg or Arg–Arg sequences (Steiner et al., 1996). PC2 selectively cleaves at the C peptide–A chain junction (Figure 60–1). PC3 preferentially cleaves at the C peptide–B chain junction but has some action at the A chain junction as well. Although there are at least two other members of the family of endopeptidases (PC1 and furin), PC2 and PC3 appear to be the enzymes responsible for processing proinsulin to insulin.

Regulation of Insulin Secretion. Insulin secretion is a tightly regulated process designed to provide stable concentrations of glucose in blood during both fasting and feeding. This regulation is achieved by the coordinated interplay of various nutrients, gastrointestinal hormones, pancreatic hormones, and autonomic neurotransmitters. Glu-
glucose, amino acids, fatty acids, and ketone bodies promote the secretion of insulin. The islets of Langerhans are richly innervated by both adrenergic and cholinergic nerves. Stimulation of \( \alpha_2 \) adrenergic receptors inhibits insulin secretion, whereas \( \beta_2 \) adrenergic receptor agonists and vagal nerve stimulation enhance release. In general, any condition that activates the sympathetic branch of the autonomic nervous system (such as hypoxia, hypoglycemia, exercise, hypothermia, surgery, or severe burns) suppresses the secretion of insulin by stimulation of \( \alpha_2 \) adrenergic receptors. Predictably, \( \alpha_2 \) adrenergic receptor antagonists increase basal concentrations of insulin in plasma, and \( \beta_2 \) adrenergic receptor antagonists decrease them.

Glucose is the principal stimulus to insulin secretion in human beings and is an essential permissive factor for the actions of many other secretagogues (Matschinsky, 1996). The sugar is more effective in provoking insulin secretion when taken orally than when administered intravenously because the ingestion of glucose (or food) induces the release of gastrointestinal hormones and stimulates vagal activity. Several gastrointestinal hormones promote the secretion of insulin. The most potent of these are gastrointestinal inhibitory peptide (GIP) and glucagonlike peptide 1 (GLP-1). Insulin release also is boosted by gastrin, secretin, cholecystokinin, vasoactive intestinal peptide, gastric-releasing peptide, and enteroglucagon.

When evoked by glucose, insulin secretion is biphasic: The first phase reaches a peak after 1 to 2 minutes and is short-lived; the second phase has a delayed onset but a longer duration.

Recent research has provided an outline of how glucose stimulates insulin secretion. Basically, the resting \( \beta \) cell is hyperpolarized, and its depolarization leads to the secretion of insulin. A rising plasma glucose concentration initiates a series of events that lead to depolarization. Glucose enters the \( \beta \) cell by facilitated transport, which is mediated by GLUT2, a specific subtype of glucose transporter, whereupon the sugar is phosphorylated to glucose-6-phosphate (G-6-P) by glucokinase. The increase in oxidizable substrate (glucose and G-6-P) enhances adenosine triphosphate (ATP) production, thereby raising the threshold for glucose-stimulated insulin release. This decrease in \( K_w \) conductance causes \( E_m \) to rise, opening a voltage-sensitive Ca\(^{2+}\) channel.

Intracellular Ca\(^{2+}\) acts as the insulin secretagogue, as it does for the secretion of many vesicular products. The influx of Ca\(^{2+}\) also activates several phospholipases, leading to the production of eicosanoids and IP\(_3\) and the mobilization of intracellular Ca\(^{2+}\) stores.

The ATP-sensitive \( K^+ \) channel in insulin-secreting cells is an octamer composed of four Kir 6.2 and four SUR1 subunits. Both types of subunits contain nucleotide-binding domains; Kir 6.2 appears to mediate the inhibitory response to ATP; SUR1 binds ADP, the channel activator diazoxide, and the channel inhibitors (and promoters of insulin secretion) sulfonylureas and meglitinide. Mutations in the channel proteins can lead to altered insulin secretion (see Proks et al., 2004).

Elevation of free Ca\(^{2+}\) concentrations also occurs in response to stimulation of phospholipase C by acetylcholine and cholecystokinin and by hormones that increase intracellular concentrations of cyclic AMP. In the \( \beta \) cell, G protein–coupled receptors (GPCRs) for glucagon, GIP, and GLP-1 couple to G\(_\alpha\) to stimulate adenylyl cyclase; somatostatin and \( \alpha_2 \) adrenergic receptor agonists couple to G\(_\beta\) to reduce cellular cyclic adenosine monophosphate (AMP) production.

The hexokinase involved in this process is a specific isoform, glucokinase, whose expression is limited primarily to cells and tissues involved in the regulation of glucose metabolism, such as the liver and pancreatic cells. Its relatively high \( K_m \) (10 to 20 mM) gives it an important regulatory role at physiological concentrations of glucose. The capacity of sugars to undergo phosphorylation and subsequent glycolysis correlates closely with their ability to stimulate insulin release. The role of glucokinase as a glucose sensor was inferred from the association of mutations of the glucokinase gene with a form of maturity-onset diabetes of the young (MODY2; see below), a rare genetic form of diabetes. These mutations, which compromise the ability of glucokinase to phosphorylate glucose, raise the threshold for glucose-stimulated insulin release.

Most of the nutrients and hormones that stimulate insulin secretion also enhance its biosynthesis. Although there is a close correlation between the two processes, some factors affect one pathway but not the other. For example, lowering extracellular concentrations of Ca\(^{2+}\) inhibits secretion of insulin without affecting biosynthesis.

There usually is a reciprocal relationship between the rates of secretion of insulin and glucagon from the pancreatic islet. This reciprocity reflects both the influence of insulin on the \( \alpha \) cell and the level of glucose and other substrates (see below). In addition, somatostatin, a third islet cell hormone, can modulate the secretion of both hormones (see below). Glucagon stimulates the release of somatostatin, which may suppress the secretion of insulin but is not a major physiological influence. Since the blood supply in the islet flows from the \( \beta \)-cell core to the \( \alpha \) and \( \delta \) cells, insulin can inhibit glucagon release in a paracrine manner, but somatostatin must pass through the circulation to reach the \( \alpha \) and \( \beta \) cells. Thus, while insulin affects the secretion of glucagon and pancreatic polypeptide, the paracrine of islet somatostatin is not clear.

Distribution and Degradation of Insulin. Insulin circulates in blood as the free monomer, and its volume of distribution approximates the volume of extracellular fluid. Under fasting conditions, the pancreas secretes about 40 \( \mu \)g (1 unit) of insulin per hour into the portal vein to achieve a concentration of insulin in portal blood of 2 to 4 ng/ml (50 to 100 \( \mu \)units/ml) and in the peripheral circulation of 0.5 ng/ml (12 \( \mu \)units/ml) or about 0.1 nM. After ingestion of a meal, there is a rapid rise in the concentration of insulin in portal blood, followed by a parallel but smaller rise in the peripheral circulation. A goal of insulin therapy is to mimic this pattern, but this is difficult to achieve with subcutaneous injections.

The half-life of insulin in plasma is about 5 to 6 minutes in normal subjects and patients with uncomplicated diabetes. This value may be increased in diabetics who develop anti-insulin antibodies. The half-life of proinsulin is longer than that of insulin (about 17 minutes), and this protein usually accounts for about 10% of the immunoreactive “insulin” in plasma. In patients with insulinoma, the percentage of proinsulin in the circulation usually is increased and may be as much as 80% of immunoreactivity. Since proinsulin is only about 2% as potent as insulin, the biologically effective concentration of insulin is somewhat lower than estimated by immunoassay. C peptide is secreted in equimolar amounts with insulin; however, its molar concentration in plasma is higher because of its lower hepatic clearance and considerably longer half-life.
Degradation of insulin occurs primarily in liver, kidney, and muscle (Duckworth, 1988). About 50% of the insulin that reaches the liver via the portal vein is destroyed and never reaches the general circulation. Insulin is filtered by the renal glomeruli and is reabsorbed by the tubules, which also degrade it. Severe impairment of renal function appears to affect the rate of disappearance of circulating insulin to a greater extent than does hepatic disease. Hepatic degradation of insulin operates near its maximal capacity and cannot compensate for diminished renal breakdown of the hormone. Peripheral tissues such as fat also inactivate insulin, but this is of less significance quantitatively.

Proteolytic degradation of insulin in the liver occurs primarily after internalization of the hormone and its receptor and, to a lesser extent, at the cell surface. The primary pathway for internalization is receptor-mediated endocytosis. The complex of insulin and its receptor is internalized into small vesicles termed endosomes, where degradation is initiated (Duckworth, 1988). Some insulin also is delivered to lysosomes for degradation.

The extent to which internalized insulin is degraded by the cell varies considerably with the cell type. In hepatocytes, over 50% of the internalized insulin is degraded, whereas most internalized insulin is released intact from endothelial cells. In the latter case, this finding appears to be related to the role of these cells in transcytosis of insulin molecules from the intravascular to the extracellular space. Transcytosis has an important role in the delivery of insulin to its target cells in tissues where endothelial cells form tight junctions, including skeletal muscle and adipose tissue.

Several enzymes have been implicated in insulin degradation. The primary insulin-degrading enzyme is a thiol metalloproteinase. It is localized primarily in hepatocytes, but immunologically related molecules also have been found in muscle, kidney, and brain (Duckworth, 1988). Most insulin-degrading enzyme activity appears to be cytosolic, raising the question of how the internalized vesicular insulin becomes associated with the degrading enzyme, although this activity also has been found in endosomes. A second insulin-degrading enzyme also has been described (Authier et al., 1994), but the relative roles of these enzymes have not been established. Insulin-degrading enzyme activity may also play a role in the degradation of other hormones, including glucagon.

**Cellular Actions of Insulin.** Insulin elicits a remarkable array of biological responses. The important target tissues for regulation of glucose homeostasis by insulin are liver, muscle, and fat, but insulin exerts potent regulatory effects on other cell types as well. Insulin is the primary hormone responsible for controlling the uptake, use, and storage of cellular nutrients. Insulin’s anabolic actions include the stimulation of intracellular use and storage of glucose, amino acids, and fatty acids, whereas it inhibits catabolic processes such as the breakdown of glycogen, fat, and protein. It accomplishes these general purposes by stimulating the transport of substrates and ions into cells, promoting the translocation of proteins between cellular compartments, activating and inactivating specific enzymes, and changing the amounts of proteins by altering the rates of gene transcription and specific mRNA translation (Figure 60–3).

Some effects of insulin occur within seconds or minutes, including the activation of glucose and ion transport systems, the covalent modification (i.e., phosphorylation or dephosphorylation) of enzymes, and some effects on gene transcription (i.e., inhibition of the phenolpyruvate carboxykinase gene) (O’Brien and Granner, 1996). Other effects, such as those on protein synthesis and gene transcription, may take a few hours. Effects of insulin on cell proliferation and differentiation may take days. It is not clear whether these kinetic differences result from the use of different mechanistic pathways or from the intrinsic kinetics of the various processes.

**Regulation of Glucose Transport.** Stimulation of glucose transport into muscle and adipose tissue is a crucial component of the physiological response to insulin. Glucose enters cells by facilitated diffusion through one of a family of glucose transporters. Five of these (GLUT1 through GLUT5) are thought to be involved in Na⁺-independent facilitated diffusion of glucose into cells (Shepherd and Kahn, 1999). The glucose transporters are integral membrane glycoproteins with molecular masses of about 50,000 daltons, and each has 12 membrane-spanning α-helical domains. Insulin stimulates glucose transport at least in part by promoting translocation of intracellular vesicles that contain the GLUT4 and GLUT1 glucose transporters to the plasma membrane (Figure 60–3). This effect is reversible; the transporters return to the intracellular pool on removal of insulin. Faulty regulation of this process may contribute to the pathophysiology of type 2 DM (Shepherd and Kahn, 1999).

**Regulation of Glucose Metabolism.** The facilitated diffusion of glucose into cells along a downhill gradient is ensured by glucose phosphorylation. This enzymatic reaction, the conversion of glucose to glucose-6-phosphate (G-6-P), is accomplished by one of a family of hexokinases. Like the glucose transporters described earlier, the four hexokinases (I through IV) are distributed differently in tissues, and two are regulated by insulin. Hexokinase IV, a 50,000-dalton enzyme more commonly known as glucokinase, is found in association with GLUT2 in liver and pancreatic β cells. There is one glucokinase gene, but different first exons and promoters are employed in the two tissues (Printz et al., 1993). The liver glucokinase gene is regulated by insulin. Hexokinase II, a 100,000-dalton enzyme, is found in associa-
tion with GLUT4 in skeletal and cardiac muscle and in adipose tissue. Like GLUT4, hexokinase II is regulated transcriptionally by insulin.

G-6-P is a branch-point substrate that can enter several pathways. Thus, following isomerization to G-1-P, G-6-P can be stored as glycogen (insulin enhances the activity of glycogen synthase); G-6-P can enter the glycolytic pathway (leading to ATP production); and G-6-P can also enter the pentose phosphate pathway (providing NADPH for reductive syntheses, for the xenobiotic metabolizing activities of CYPs, and for maintenance of reduced glutathione). Effects of insulin on cellular metabolic enzymes are myriad and generally are mediated via the activities of protein kinases and phosphoprotein phosphatases that are enhanced following insulin treatment. Figure 60–3 shows the initial signaling events following the binding of insulin to its membrane receptor.

**Regulation of Gene Transcription.** A major action of insulin is the regulation of transcription of specific genes. More than a hundred genes are known to be regulated by insulin (O’Brien and Granner, 1996), although the mechanisms of regulation are still being worked out. As an example, insulin inhibits the transcription of phosphoenolpyruvate carboxykinase, contributing to insulin’s inhibition of gluconeogenesis; this effect of insulin may explain why the liver overproduces glucose in the insulin-resistant state that is characteristic of type 2 DM.

**The Insulin Receptor.** Insulin initiates its actions by binding to a cell-surface receptor. Such receptors are present in virtually all mammalian cells, including not only the classic targets for insulin action (i.e., liver, muscle, and fat) but also such nonclassic targets as circulating...
blood cells, neurons, and gonadal cells. The number of receptors varies from as few as 40 per cell on erythrocytes to 300,000 per cell on adipocytes and hepatocytes.

The insulin receptor is a large transmembrane glycoprotein composed of two 135,000-dalton α subunits (719 or 731 amino acids, depending on whether a 12-amino-acid insertion has occurred through alternate RNA splicing) and two 95,000-dalton β subunits (620 amino acids); the subunits are linked by disulfide bonds to form a β-α-α-β heterotetramer (Figure 60–3) (Virkamäki et al., 1999). Both subunits are derived from a single-chain precursor molecule that contains the entire sequence of the α and β subunits separated by a processing site consisting of four basic amino acid residues. The α subunits are entirely extracellular and contain the insulin-binding domain (see above), whereas the β subunits are transmembrane proteins that possess tyrosine protein kinase activity. After insulin is bound, receptors aggregate and are internalized rapidly. Since bivalent (but not monovalent) anti-insulin receptor antibodies cross-link adjacent receptors and mimic the rapid actions of insulin, it has been suggested that receptor dimerization is essential for signal transduction. After internalization, the receptor may be degraded or recycled back to the cell surface.

Tyrosine Phosphorylation and the Insulin Action Cascade. Receptors for insulin and IGF-1 belong to the family of receptor tyrosine kinases, in common with many growth factor receptors.

The activated receptors undergo autophosphorylation, which seems to activate their tyrosine kinase activity toward other substrates, principally the four insulin receptor substrates IRS-1 through IRS-4 and Shc (White, 2002). The tyrosine phosphorylated IRS proteins direct the recruitment of signaling cascades via the interaction of SH2 domains with phosphoryrosines, recruiting such proteins as SHP2, Grb2, and SOS and resulting in the activation of MAP kinases and PI3-kinase, which transduce many of insulin’s cellular effects.

Insulin signaling is complicated by the fact that the IGF-1 receptor resembles the insulin receptor and uses similar signaling pathways; furthermore, the two receptors bind each other’s ligand, albeit with lower affinity. In addition, IGF-1 and insulin-receptor heterodimers can combine to form hybrid heterotetramers.

The tyrosine kinase activity of the insulin receptor is required for signal transduction. Mutation of the insulin receptor with modification of the ATP-binding site or replacement of the tyrosine residues at major sites of autophosphorylation decreases both insulin-stimulated kinase activity and the cellular response to insulin. An insulin receptor incapable of autophosphorylation is biologically inert. A polymorphism in the human IRS-1, G972R, is associated with insulin resistance and increased risk of type 2 DM; this polymorphic IRS-1 appears to act as an inhibitor of the insulin-receptor tyrosine kinase (McGettick et al., 2005). In intact cells, the insulin receptor also is phosphorylated on serine and threonine residues, presumably by protein kinase C (PKC) and protein kinase A (PKA). Such phosphorylation inhibits the tyrosine kinase activity of the insulin receptor.

Diabetes Mellitus and the Physiological Effects of Insulin

Diabetes mellitus (DM) consists of a group of syndromes characterized by hyperglycemia; altered metabolism of lipids, carbohydrates, and proteins; and an increased risk of complications from vascular disease. Most patients can be classified clinically as having either type 1 or type 2 DM (Expert Committee on the Diagnosis and Treatment of Diabetes Mellitus, 2003). DM or carbohydrate intolerance also is associated with certain other conditions or syndromes (Table 60–1). Criteria for the diagnosis of DM have been proposed by several medical organizations. The American Diabetes Association (ADA) criteria include symptoms of DM (e.g., polyuria, polydipsia, and unexplained weight loss) and a random plasma glucose concentration of greater than 200 mg/dl (11.1 mM), a fasting plasma glucose concentration of greater than 126 mg/dl (7 mM), or a plasma glucose concentration of greater than 200 mg/dl (11 mM) 2 hours after the ingestion of an oral glucose load (Expert Committee on the Diagnosis and Treatment of Diabetes Mellitus, 2003).

The incidence of each type of diabetes varies widely throughout the world. In the United States, about 5% to 10% of all diabetic patients have type 1 DM, with an incidence of 18 per 100,000 inhabitants per year. A similar incidence is found in the United Kingdom. The incidence of type 1 DM in Europe varies with latitude. The highest rates occur in northern Europe (Finland, 43 per 100,000) and the lowest in the south (France and Italy, 8 per 100,000). The one exception to this rule is the small island of Sardinia, close to Italy, which has an incidence of 30 per 100,000. However, even the relatively low incidence rates of type 1 DM in southern Europe are far higher than the rates in Japan (1 per 100,000 inhabitants).

The vast majority of diabetic patients have type 2 DM. In the United States, about 90% of all diabetic patients have type 2 DM. Incidence rates of type 2 DM increase with age, with a mean rate of about 440 per 100,000 per year by the sixth decade in males in the United States. Ethnicity within a country also can influence the incidence of type 2 DM; the mean rate in African-American males is 540 per 100,000, and that in Pima Indians is about 5000 per 100,000. Unlike those for type 1 DM, the incidence rates for type 2 DM are lower in northern Europe (100 to 250 per 100,000) than in the south (800 per 100,000). Although prevalence data exist for type 2 DM, these numbers almost certainly are underestimates because 33% of all cases are undiagnosed.

There are more than 125 million persons with diabetes in the world today, and by 2010, this number is expected to approach 220 million (Amos et al., 1997). Both type 1 and type 2 DM are increasing in frequency. The reason for the increase of type 1 DM is not known. The genetic basis for type 2 DM cannot change in such a short time; thus other contributing factors, including increasing age, obesity, sedentary lifestyle, and low birth weight, must account for this dramatic increase. In addition, type 2 DM is being diagnosed with remarkable frequency in preadolescents and adolescents. Up to 45% of newly diagnosed children and adolescents have type 2 DM.

In certain tropical countries, the most common cause of diabetes is chronic pancreatitis associated with nutritional or toxic factors (a form of secondary diabetes). Very rarely, diabetes results from point mutations in the insulin gene (Chan et al., 1987). Amino acid substi-
Different Forms of Diabetes Mellitus

### General—genetic and other factors not precisely defined

**Type 1 diabetes mellitus** (formerly called insulin-dependent diabetes mellitus)
- Autoimmune type 1 diabetes mellitus (type 1A)
- Non-autoimmune or idiopathic type 1 diabetes mellitus (type 1B)

**Type 2 diabetes mellitus** (formerly called non-insulin-dependent diabetes mellitus)

### Specific—defined gene mutations

- Maturity-onset diabetes of youth (MODY)
  - MODY 1 hepatic nuclear factor 4α (HNF4A) gene mutations
  - MODY 2 glucokinase (GCK) gene mutations
  - MODY 3 hepatic nuclear factor 1α (TCF1) gene mutations
  - MODY 4 insulin promoter factor 1 (IPF1) gene mutations
  - MODY 5 hepatic nuclear factor 1β (HNF1β) gene mutations
  - MODY 6 neurogenic differentiation 1 (NEUROD1) gene mutation
  - MODY X unidentified gene mutation(s)
- Maternally inherited diabetes and deafness (MIDD)
- Mitochondrial leucine tRNA gene mutations
- Insulin gene mutations
- Insulin receptor gene mutations

**Diabetes secondary to pancreatic disease**
- Chronic pancreatitis
- Surgery
- Tropical diabetes (chronic pancreatitis associated with nutritional and/or toxic factors)

**Diabetes secondary to other endocrinopathies**
- Cushing's disease
- Glucocorticoid administration
- Acromegaly

**Diabetes secondary to immune suppression**
- Diabetes associated with genetic syndromes; e.g., Prader-Willi syndrome
- Diabetes associated with drug therapy (see Table 60–5)

There are genetic and environmental components that affect the risk of developing either type 1 or type 2 DM. A positive family history of type 2 DM is predictive for the disease. Studies of identical twins show 70% to 80% concordance for developing type 2 DM. Furthermore, there is a high prevalence of type 2 DM in offspring of parents with the disease (up to 70%) as well as in siblings of affected individuals. Persons more than 20% over their ideal body weight also have a greater risk of developing type 2 DM. In fact, 80% to 90% of type 2 DM subjects in the United States are obese. Certain ethnic groups have a higher incidence of type 2 DM (e.g., American Indians, African-Americans, Hispanics, and Polynesian Islanders).

In addition, previously identified impaired glucose tolerance, gestational diabetes, hypertension, or significant hyperlipidemia is associated with an increased risk of type 2 DM. These data suggest a strong genetic basis for type 2 DM, but the genetic mechanism(s) involved are not known. A pancreatic β-cell defect and a reduction in tissue sensitivity to insulin both are required before overt type 2 DM is apparent. However, type 2 DM is an extremely heterogeneous disease, and it is likely that a number of different genes are involved. In addition, environmental factors may play a role. Type 2 DM thus is a multifactorial disease. Any combination of genetic and environmental factors that exceeds a threshold can result in type 2 DM. The genetic basis for type 2 DM in a small subset of patients has been established. MODY2 is a rare disorder that is inherited as an autosomal dominant trait and is caused by mutations of the glucokinase gene. Because of decreased glucokinase activity, these patients have an increased glycemic threshold for insulin release that results in persistent mild hyperglycemia. This and other rare genetic forms of MODY are quite distinct from the usual type 2 DM (Table 60–1).

With type 1 DM, the concordance rate for identical twins is only 25% to 50%; this suggests that environmental as well as genetic influences have an important role in the disease. However, the known genetic factors in type 1 DM relate to the genes that control the immune response. There is considerable evidence that type 1 DM involves an autoimmune attack on the pancreatic β cell. Antibodies to islet cell antigens are detected in up to 80% of patients with type 1 DM shortly after diagnosis or even prior to the onset of clinical disease. The antibodies are directed at both cytoplasmic and membrane-bound antigens and include islet cell antibodies and antibodies directed against insulin (IAAs), glutamic acid decarboxylase-65 and -67 (GAD-65 and -67), heat-shock protein 65 (HSP-65), and tyrosine phosphatase–like protein (IA-2 or IA-2B).

Although these autoantibodies are correlated with the clinical expression of type 1 DM, it is controversial whether they can predict the development of clinical diabetes. Most prospective studies designed to determine if type 1 DM can be predicted on the basis of antibodies have been performed in healthy first-degree relatives of diabetic patients. These studies have determined that the presence of IAAs confers only a small risk for the development of type 1 DM. On the other hand, the presence of high-titer islet-cell antibodies (ICAs) and GAD antibodies or ICAs combined with IAAs confers a very high risk for the development of type 1 DM in first-degree relatives (Verge et al., 1996).

Since most of the studies aimed at predicting the development of type 1 DM have been carried out in first-degree relatives of diabetic patients, it is not known whether the occurrence of ICAs in individuals from the general population confers a similar risk for development of clinical diabetes. Most available data indicate that the presence of ICAs in individuals from the general population is...
associated with a lower risk of developing type 1 DM. However, as in first-degree relatives of type 1 DM patients, it may be that the presence of more than one form of autoantibody in individuals from the general population is a more powerful predictor of the development of clinical diabetes. Individuals with type 1 DM also tend to have antibodies directed toward other endocrine tissues, including the adrenal, parathyroid, and thyroid glands, and have an increased incidence of other autoimmune diseases.

Type 1 DM is associated with specific human leukocyte antigen (HLA) alleles, especially at the B and DR loci (Florez et al., 2003). Approximately 90% of patients with type 1 DM are positive for HLA-DR3 or -DR4, as compared with only 40% of the general population. Compound heterozygotes appear to be at particular risk. In contrast, the haplotype HLA-DR2 appears to be negatively associated with the occurrence of the disease. A polymorphism of the HLA-DQβ chain at position 57 correlates even more closely with susceptibility to diabetes (Todd et al., 1987). Type 1 DM is associated with alleles coding for alanine, valine, or serine at position 57 in the HLA-DQβ chain, whereas aspartic acid in this position is negatively correlated with the disease in Caucasians. These findings implicate both humoral and cell-mediated immune mechanisms in the etiology of type 1 DM.

The trigger for the immune response remains unknown. The identification of triggering agents is difficult because autoimmune destruction of pancreatic β cells may occur over a period of many months or several years before the onset of overt disease. In about 10% of new cases of type 1 DM, there is no evidence of autoimmune insulitis (Imagawa et al., 2000). The ADA and the World Health Organization (WHO) therefore subdivide this disease into autoimmune (1A) and idiopathic (1B) subtypes. Whatever the causes, the final result in type 1 DM is an extensive and selective loss of pancreatic β cells and a state of absolute insulin deficiency.

The situation in type 2 DM is not so clear-cut. Most studies indicate that there is reduced β-cell mass in type 2 DM patients. Obesity, duration of diabetes, and prevailing hyperglycemia potentially can confound interpretation of data, but studies that have controlled for these variables have reported an approximately 50% reduction in β-cell volume in type 2 DM patients compared with nondiabetic control subjects. Owing to the heterogeneous nature of type 2 DM, mean 24-hour plasma concentrations of insulin in patients have been reported to vary from low to even normal relative to values in control subjects. Of note, standard insulin radioimmunoassays detect proinsulin and processing intermediates. Studies in which specific insulin and proinsulin assays have been used (Temple et al., 1989) have revealed that “true” insulin values in “hyperinsulinemic” type 2 DM patients are either no greater or distinctly less than values in control subjects. Therefore, increased amounts of proinsulin have confounded the appreciation of subnormal insulin levels in type 2 DM patients. Furthermore, even apparently “normal” values of plasma insulin in a hyperglycemic type 2 DM patient are considerably reduced relative to the insulin levels that would be observed in a similarly hyperglycemic nondiabetic individual.

In healthy persons, the contribution of proinsulin to basal immunoreactive insulin levels is low. Proinsulin intermediates make up about 10% of the total immunoreactive insulin in the portal vein. However, owing to its long half-life (about 44 minutes) and tenfold slower metabolic clearance, proinsulin and intermediates make up about 20% of circulating immunoreactive insulin. This amount is physiologically trivial because proinsulin has only about 5% of the metabolic effect of insulin (Davis et al., 1991). Nevertheless, plasma proinsulinlike molecules are increased in type 2 DM to about 20% or more of total immunoreactive insulin. Furthermore, proinsulin levels increase in response to any β-cell stimulation.

Type 2 DM also is associated with several distinct defects in insulin secretion. At diagnosis, virtually all persons with type 2 DM have a profound defect in first-phase insulin secretion in response to an intravenous glucose challenge. The responses to other secretagogues (e.g., isoproterenol or arginine) are preserved, although there is less potentiation by glucose. Some of these β-cell abnormalities in type 2 DM may be secondary to desensitization by chronic hyperglycemia. The relationship between fasting glycemia and insulinemia in type 2 DM subjects is complex. Patients who have fasting blood glucose levels of 6 to 10 mM (108 to 180 mg/dl) have fasting and stimulated insulin values equal to those of euglycemic control subjects. More severely hyperglycemic subjects are frankly hypoinsulinemic.

Virtually all forms of DM are caused by a decrease in the circulating concentration of insulin (insulin deficiency) and a decrease in the response of peripheral tissues to insulin (insulin resistance). These abnormalities lead to alterations in the metabolism of carbohydrates, lipids, ketones, and amino acids; the central feature of the syndrome is hyperglycemia (Figure 60–4).

Insulin lowers the concentration of glucose in blood by inhibiting hepatic glucose production and by stimu-

![Figure 60-4. Overview of insulin action.](image-url)
lating the uptake and metabolism of glucose by muscle and adipose tissue (Table 60–2). These two important effects occur at different concentrations of insulin. Production of glucose is inhibited half maximally by an insulin concentration of about 20 μunits/ml, whereas glucose utilization is stimulated half maximally at about 50 μunits/ml.

In both types of diabetes, glucagon (the levels of which are elevated in untreated patients) opposes the hepatic effects of insulin by stimulating glycogenolysis and gluconeogenesis, but it has relatively little effect on peripheral utilization of glucose. Thus, in the diabetic patient with insulin deficiency or insulin resistance and hyperglucagonemia, there is an increase in hepatic glucose production, a decrease in peripheral glucose uptake, and a decrease in the conversion of glucose to glycogen in the liver (DeFronzo et al., 1992).

Alterations in secretion of insulin and glucagon also profoundly affect lipid, ketone, and protein metabolism. At concentrations below those required to stimulate glucose uptake, insulin inhibits the hormone-sensitive lipase in adipose tissue and thus inhibits the hydrolysis of triglyceride stores. This counteracts the lipolytic action of catecholamines, cortisol, and growth hormone and reduces the concentrations of glycerol (a substrate for gluconeogenesis) and free fatty acids (a substrate for production of ketone bodies and a necessary fuel for gluconeogenesis). These actions of insulin are deficient in the diabetic patient, leading to increased gluconeogenesis and ketogenesis.

The liver produces ketone bodies by oxidation of free fatty acids to acetyl CoA, which then is converted to acetoacetate and β-hydroxybutyrate. The initial step in fatty acid oxidation is transport of the fatty acid into the mitochondria. This involves the interconversion of the coenzyme A (CoA) and carnitine esters of fatty acids by the enzyme acylcarnitine transferase. The activity of this enzyme is inhibited by intramitochondrial malonyl CoA, one of the products of fatty acid synthesis. Under normal conditions, insulin inhibits lipolysis, stimulates fatty acid synthesis (thereby increasing the concentration of malonyl CoA), and decreases the hepatic concentration of carnitine; these factors all decrease the production of ketone bodies. Conversely, glucagon stimulates ketone body production by increasing fatty acid oxidation and decreasing concentrations of malonyl CoA. In the diabetic patient, particularly the patient with type 1 DM, the consequences of insulin deficiency and glucagon excess provide a hormonal milieu that favors ketogenesis and, in the absence of appropriate treatment, may lead to ketonemia and acidosis.

Insulin also enhances the transcription of lipoprotein lipase in the capillary endothelium. This enzyme hydrolyzes triglycerides present in very low density lipoproteins (VLDL) and chylomicrons, resulting in release of intermediate-density lipoprotein (IDL) particles (see Chapter 35). The IDL particles are converted by the liver to the more cholesterol-rich low-density lipoproteins (LDL). Thus, in the untreated or undertreated diabetic patient, hypertriglyceridemia and hypercholesterolemia often occur. In addition, deficiency of insulin may be associated with increased production of VLDL.

The important role of insulin in protein metabolism usually is evident clinically only in diabetic patients with persistently poor control of their disease. Insulin stimulates amino acid uptake and protein synthesis and inhibits protein degradation in muscle and other tissues; it thus causes a decrease in the circulating concentrations of most amino acids. Glutamine and alanine are the major amino acids.

acid precursors for gluconeogenesis. Insulin lowers alanine concentrations during hyperinsulinemic euglycemic conditions. The rate of appearance of alanine is maintained in part by the enhanced rate of transamination of pyruvate to alanine. However, alanine utilization greatly exceeds production (owing to increased hepatic uptake and fractional extraction of the amino acid), and this results in a fall of peripheral alanine levels. In poorly controlled diabetics, there is increased conversion of alanine to glucose, contributing to the enhanced rate of gluconeogenesis. The increased conversion of amino acids to glucose also results in increased production and excretion of urea and ammonia. In addition, there are increased circulating concentrations of branched-chain amino acids as a result of increased proteolysis, decreased protein synthesis, and increased release of branched-chain amino acids from the liver.

A nearly pathognomonic feature of diabetes mellitus is thickening of the capillary basement membrane and other vascular changes that occur during the course of the disease. The cumulative effect is progressive narrowing of the vessel lumina, causing inadequate perfusion of critical regions of certain organs. The matrix is expanded in many vessel walls, in the basement membrane of the retina, and in the mesangial cells of the renal glomerulus (McMillan, 1997). Cellular proliferation in many large vessels further contributes to luminal narrowing. These pathological changes contribute to some of the major complications of diabetes, including premature atherosclerosis, intercapillary glomerulosclerosis, retinopathy, neuropathy, and ulceration and gangrene of the extremities.

It is hypothesized that the factor responsible for the development of most complications of diabetes is the prolonged exposure of tissues to elevated concentrations of glucose. Prolonged hyperglycemia results in the formation of advanced glycation end products (Beisswenger et al., 1995). These macromolecules are thought to induce many of the vascular abnormalities that result in the complications of diabetes (Brownlee, 1995). The results from the Diabetes Control and Complications Trial (DCCT) definitively answered this question: Most diabetic complications arise from prolonged exposure of tissue to elevated glucose concentrations.

The DCCT (DCCT Research Group, 1993) was a multicenter, randomized clinical trial designed to compare intensive and conventional diabetes therapies with regard to their effects on the development and progression of the early vascular and neurologic complications of type 1 DM. The intensive therapy regimen was designed to achieve blood glucose values as close to the normal range as possible with three or more daily insulin injections or with an external insulin pump. Conventional therapy consisted of one or two insulin injections daily. Two groups of patients were studied to answer separate but related questions. The first question was whether or not intensive therapy could prevent the development of diabetic complications such as retinopathy, nephropathy, and neuropathy (primary prevention). The second was whether or not intensive therapy could slow the progression of existing complications of diabetes (secondary intervention).

In the primary prevention group, intensive therapy reduced the mean risk for the development of retinopathy by 76% compared with conventional therapy. In the secondary intervention group, intensive therapy slowed the progression of retinopathy by 54%. Intensive therapy reduced the risk of nephropathy by 34% in the primary prevention group and by 43% in the secondary intervention group. Similarly, neuropathy was reduced by about 60% in both the primary prevention and secondary intervention groups. Intensive therapy reduced the development of hypercholesterolemia by 34% overall. Because of the relative youth of the patients, it was predicted that the detection of treatment-related differences in rates of macrovascular events would be unlikely. However, intensive therapy reduced the risk of macrovascular disease by 41% in the combined groups. These results established unequivocally that improving day-to-day glycemic control in type 1 DM patients can reduce and slow the development of diabetic complications dramatically. A follow-up study showed that the reduction in the risk of progressive retinopathy and nephropathy persists for at least 4 years, even if tight glycemic control was not maintained (DCCT Research Group, 2000).

A serious complication of intensive therapy was an increased incidence of severe hypoglycemia. Patients receiving intensive therapy had a threefold greater incidence of severe hypoglycemia (blood glucose concentration below 50 mg/dl or 2.8 mM and needing external resuscitative assistance) and hypoglycemic coma than did conventionally treated subjects. Therefore, the present guidelines for treatment given by the ADA include a contraindication for implementing tight metabolic control in infants younger than 2 years old and an extreme caution in children between 2 and 7 years of age because hypoglycemia may impair brain development. Older patients with significant arteriosclerosis also may be vulnerable to permanent injury from hypoglycemia.

The DCCT was performed in relatively young type 1 DM patients. The question was asked whether intensive therapy would provide similar benefits to typical middle-aged or elderly patients with type 2 DM. The results of the DCCT indeed also apply to patients with type 2 DM (U.K. Prospective Diabetes Study Group, 1998a, 1998b). The eye, kidney, and nerve abnormalities appear similar in type 1 and type 2 DM, and it is likely that the same or similar underlying mechanisms of disease apply. However, because of a higher prevalence of macrovascular disease, older patients with type 2 DM may be more vulnerable to serious consequences of hypoglycemia. Thus, as is the case for everyone with diabetes, treatment of type 2 DM patients must be tailored to the individual. Nevertheless, the results of the DCCT and U.K. Prospective Diabetes Study (UKPDS) suggest that many otherwise healthy patients with type 2 DM should attempt to achieve tight metabolic control.

The toxic effects of hyperglycemia may be the result of accumulation of non-enzymatically glycosylated products and osmotically active sugar alcohols such as sorbitol in tissues; the effects of glucose on cellular metabolism also may be responsible (Brownlee, 1995). The covalent reac-
tion of glucose with hemoglobin provides a convenient method to determine an integrated index of the glycemic state. Hemoglobin undergoes glycosylation on its amino-terminal valine residue to form the glucosyl valine adduct of hemoglobin, termed hemoglobin A1c (Brownlee, 1995). The half-life of the modified hemoglobin is equal to that of the erythrocyte (about 120 days). Since the amount of glycosylated protein formed is proportional to the glucose concentration and the time of exposure of the protein to glucose, the concentration of hemoglobin A1c in the circulation reflects the severity of the glycemic state over an extended period (4 to 12 weeks) prior to sampling. Thus a rise in hemoglobin A1c from 5% to 10% suggests a prolonged doubling of the mean blood glucose concentration. Although this assay is used widely, measurement of the glycosylation of proteins with somewhat shorter survival times (e.g., albumin) also has proven useful in the management of pregnant diabetic patients.

Glycosylated products accumulate in tissues and eventually may form cross-linked proteins termed advanced glycosylation end products (Beisswenger et al., 1995). Such nonenzymatic glycosylation may be directly responsible for expansion of the vascular matrix and the vascular complications of diabetes. This process also may explain the modified cellular proliferative activity in vascular lesions of diabetic patients because macrophages appear to have receptors for advanced glycosylation end products. Binding of such proteins to macrophages in these lesions may stimulate the production of cytokines such as tumor necrosis factor α and interleukin 1 (IL-1), which, in turn, induce degradative and proliferative cascades in mesenchymal and endothelial cells, respectively.

Other explanations for the toxic manifestations of hyperglycemia may exist. Intracellular glucose is reduced to its corresponding sugar alcohol, sorbitol, by the enzyme aldose reductase, and the rate of production of sorbitol is determined by the ambient glucose concentration. This is particularly true in tissues such as the lens, retina, arterial wall, and Schwann cells of peripheral nerves. In diabetic human beings and rodents, these tissues have increased intracellular concentrations of sorbitol, which may contribute to an increased osmotic effect and tissue damage. Inhibitors of aldose reductase currently are being evaluated for treatment of diabetic neuropathy and retinopathy. The results of studies with these agents thus far have been somewhat conflicting and inconclusive (reviewed by Frank, 1994).

In neural tissue and perhaps in other tissues, glucose competes with myoinositol for transport into cells. Reduction of cellular concentrations of myoinositol may contribute to altered nerve function and neuropathy. Hyperglycemia also may enhance the de novo synthesis of diacylglycerol, which could facilitate persistent activation of protein kinase C.

**Insulin Therapy**

Insulin is the mainstay for treatment of virtually all type 1 DM and many type 2 DM patients. When necessary, insulin may be administered intravenously or intramuscularly; however, long-term treatment relies predominantly on subcutaneous injection of the hormone. Subcutaneous administration of insulin differs from physiological secretion of insulin in at least two major ways: The kinetics do not reproduce the normal rapid rise and decline of insulin secretion in response to ingestion of nutrients, and the insulin diffuses into the peripheral circulation instead of being released into the portal circulation; the direct effect of secreted insulin on hepatic metabolic processes thus is eliminated. Nonetheless, when such treatment is performed carefully, considerable success is achieved.

Preparations of insulin can be classified according to their duration of action into short, intermediate, and long acting and by their species of origin—human or porcine. Human insulin (HUMULIN, NOVOLIN) is now widely available as a result of its recombinant production. Porcine insulin differs from human insulin by one amino acid (alanine instead of threonine at the carboxy terminal of the B chain, i.e., in position B30. Prior to the mid-1970s, commercially available insulin preparations contained proinsulin or glucagonlike substances, pancreatic polypeptide, somatostatin, and vasoactive intestinal peptides. These contaminants were avoided with the advent of monocomponent porcine insulins. During the late 1970s, intense work was carried out on the development of biosynthetic human insulin. During the last decade, human insulin rapidly has become the standard form of therapy, and beef insulin products have been discontinued in the United States.

The physicochemical properties of human and porcine insulins differ owing to their different amino acid sequences. Human insulin, produced using recombinant DNA technology, is more soluble than porcine insulin in aqueous solution owing to the presence of threonine (instead of alanine), with its extra hydroxyl group. The vast majority of preparations now are supplied at neutral pH, which improves stability and permits storage for several days at a time at room temperature.
For therapeutic purposes, doses and concentrations of insulin are expressed in units. This tradition dates to the time when preparations of the hormone were impure, and it was necessary to standardize them by bioassay. One unit of insulin is equal to the amount required to reduce the concentration of blood glucose in a fasting rabbit to 45 mg/dl (2.5 mM). The current international standard is a mixture of bovine and porcine insulins and contains 24 units/mg. Homogeneous preparations of human insulin contain between 25 and 30 units/mg. Almost all commercial preparations of insulin are supplied in solution or suspension at a concentration of 100 units/ml, which is about 3.6 mg insulin per milliliter (0.6 mM). Insulin also is available in a more concentrated solution (500 units/ml) for patients who are resistant to the hormone.

### Classification of Insulins

**Short- and rapid-acting insulins** are solutions of regular, crystalline zinc insulin (insulin injection) dissolved usually in a buffer at neutral pH. These preparations have the most rapid onset of action but the shortest duration (Table 60–3). Short-acting insulin (i.e., regular or soluble) usually should be injected 30 to 45 minutes before meals. Regular insulin also may be given intravenously or intramuscularly. After intravenous injection, there is a rapid fall in the blood glucose concentration, which usually reaches a nadir in 20 to 30 minutes. In the absence of a sustained infusion of insulin, the hormone is cleared rapidly, and counter-regulatory hormones (e.g., glucagon, epinephrine, norepinephrine, cortisol, and growth hormone) restore plasma glucose to baseline in 2 to 3 hours. In the absence of a normal counter-regulatory response (e.g., in diabetic patients with autonomic neuropathy), plasma glucose will remain suppressed for many hours following an insulin bolus of 0.15 units/kg because the cellular actions of insulin are prolonged far beyond its clearance from plasma. Intravenous infusions of insulin are useful in patients with ketoacidosis or when requirements for insulin may change rapidly, such as during the perioperative period, during labor and delivery, and in intensive care situations (see below).

When metabolic conditions are stable, regular insulin usually is given subcutaneously in combination with an intermediate- or long-acting preparation. Short-acting insulin is the only form of the hormone that can be used in subcutaneous infusion pumps. Special buffered formulations of regular insulin have been made for the latter purpose that are less likely to crystallize in the tubing during the slow infusion associated with this type of therapy.

The native insulin monomers are associated as hexamers in currently available insulin preparations. These hexamers slow the absorption and reduce postprandial peaks of subcutaneously injected insulin. These pharmacokinetics stimulated the development of short-acting insulin analogs that retain a monomeric or dimeric configuration. A number of compounds have been investigated, and two, insulin lispro (HUMALOG) and insulin aspart (NOVOLOG), are available for clinical use (Hirsch, 2005). These analogs are absorbed three times more rapidly from subcutaneous sites than is human insulin. Consequently, there is a more rapid increase in plasma insulin concentrations and an earlier hypoglycemic response. Injection of the analogs 15 minutes before a meal affords glycemic control similar to that from an injection of human insulin given 30 minutes before the meal. The first commercially available short-acting analog was human insulin lispro. This analog is identical to human insulin except at positions B28 and B29, where the sequence of the two residues has been

*Most insulin preparations are supplied at pH 7.2–7.4. Glargine is supplied at a pH of 4.0.  †These are approximate figures. There is considerable variation from patient to patient and from time to time in a given patient.
reversed to match the sequence in IGF-1, which does not self-associate. Like regular insulin, lispro exists as a hexamer in commercially available formulations. Unlike regular insulin, lispro dissociates into monomers almost instantaneously following injection. This property results in the characteristic rapid absorption and shorter duration of action compared with regular insulin. Two therapeutic advantages have emerged with lispro as compared with regular insulin. First, the prevalence of hypoglycemia is reduced by 20% to 30% with lispro; second, glucose control, as assessed by hemoglobin A1c, is modestly but significantly improved (0.3% to 0.5%) with lispro as compared with regular insulin.

Insulin aspart is formed by the replacement of proline at B28 with aspartic acid. This reduces self-association to that observed with lispro. Like lispro, insulin aspart dissociates rapidly into monomers following injection. Comparison of a single subcutaneous dose of aspart and lispro in a group of type 1 DM patients revealed similar plasma insulin profiles. In clinical trials, insulin aspart and insulin lispro have had similar effects on glucose control and hypoglycemia frequency, with lower rates of nocturnal hypoglycemia as compared with regular insulin (reviewed by Hirsh, 2005).

A third rapid-acting insulin analog called insulin glulisine has been approved for clinical use in the United States. In this compound, glutamic acid replaces lysine at B29, and lysine replaces asparagine at B23. Similar to the other two available rapid-acting analogs, this causes a reduction in self-association and rapid dissociation into active monomers. The time–action profile of insulin glulisine is similar to that of insulin aspart and lispro. Similar to insulin aspart, glulisine has been approved by the Food and Drug Administration (FDA) for continuous subcutaneous insulin infusion (CSII) pump use. Owing to their rapid onset, the fast-acting insulin analogs all may be injected immediately before or after a meal, which may confer considerable clinical advantages. Many individuals with diabetes consume smaller amounts of food than originally planned. This, in the presence of a previously injected dose of insulin that was based on a larger meal, could result in postprandial hypoglycemia. Thus, in patients who have gastroparis or loss of appetite, injection of a rapid-acting analog postprandially, based on the amount of food actually consumed, may provide smoother glycemic control.

Clinical trials of inhaled insulin are underway in a number of countries. Early results demonstrate that inhaled insulin and short-acting subcutaneously-injected insulin provide similar postprandial glycemic control in patients with type 1 and type 2 DM. Patient satisfaction is uniformly high with inhaled insulin, and the prevalence of hypoglycemia is no higher (and may even be reduced) compared with regular (soluble) insulin. Smoking increases and duration of action in the presence of a previously injected dose of insulin that was based on a larger meal, could result in postprandial hypoglycemia. Thus, in patients who have gastroparis or loss of appetite, injection of a rapid-acting analog postprandially, based on the amount of food actually consumed, may provide smoother glycemic control.

Intermediate-acting insulins are formulated to dissolve more gradually when administered subcutaneously; thus their durations of action are longer. The two preparations used most frequently are neutral protamine Hagedorn (NPH) insulin (isophane insulin suspension) and lente insulin (insulin zinc suspension). NPH insulin is a suspension of insulin in a complex with zinc and protamine in a phosphate buffer. Lente insulin is a mixture of crystallized (ultralente) and amorphous (semilente) insulins in an acetate buffer, which minimizes the solubility of insulin. The pharmacokinetic properties of human intermediate-acting insulins are slightly different from those of porcine preparations. Human insulins have a more rapid onset and shorter duration of action than do porcine insulins. This difference may be related to the more hydrophobic nature of human insulin, or human and porcine insulins may interact differently with protamine and zinc crystals. This difference may create a problem with optimal timing for evening therapy; human insulin preparations taken before dinner may not have a duration of action sufficient to prevent hyperglycemia by morning. It should be noted that there is no evidence that lente or NPH insulin has different pharmacodynamic effects when used in combination with regular (soluble) insulin in a twice-a-day dosage regimen. Intermediate-acting insulins usually are given either once a day before breakfast or twice a day. In patients with type 2 DM, intermediate-acting insulin given at bedtime may help normalize fasting blood glucose. When lente insulin is mixed with regular insulin, some of the regular insulin may form a complex with the protamine or Zn2+ after several hours, and this may slow the absorption of the fast-acting insulin. NPH insulin does not retard the action of regular insulin when the two are mixed vigorously by the patient or when they are available commercially as a mixture (Davis et al., 1991) (see below).

Ultralente insulin (extended insulin zinc suspension) and protamine zinc insulin suspension are long-acting insulins; they have a slower onset and a prolonged peak of action. These insulins have been advocated to provide a low basal concentration of insulin throughout the day. The long half-life of ultralente insulin makes it difficult to determine the optimal dosage because several days of treatment are required before a steady-state concentration of circulating insulin is achieved. Doses given once or twice daily are adjusted according to the fasting blood glucose concentration. Protamine zinc insulin is used rarely today because of its very unpredictable and prolonged course of action, and it is no longer available in the United States. Preparations of insulin that are available for clinical use in the United States are shown in Table 60–4.

In the vast majority of patients, insulin-replacement therapy includes intermediate- or long-acting insulin. A search for the ideal intermediate-acting insulin identified human proinsulin (HPI) as a promising candidate. Animal studies using porcine proinsulin indicated that the compound was a soluble intermediate-acting insulin agonist that had a greater suppressive effect on hepatic glucose production than on stimulation of peripheral glucose disposal. This profile of action appeared favorable for clinical use in diabetic subjects because unrestrained hepatic glucose production is a hallmark of the disease, and a liver-specific insulin would tend to reduce peripheral hyperinsulinemia and the attendant risk of hypoglycemia. Early studies with HPI in human beings confirmed its relatively specific action on hepatocytes and demonstrated that its duration of action was similar to that of NPH insulin. Preliminary results from clinical trials, however, indicated that HPI conferred no additional benefit over currently available human insulins, and all clinical studies soon were suspended because of a high incidence of myocardial infarction in HPI-treated subjects.

The pharmacokinetic limitations of ultralente insulin have prompted efforts to develop an insulin analog that does not have a significant peak in its action. Considerable research has been directed to the development of such a product. Insulin glargine (LANTUS) is the first long-acting analog of human insulin to be approved for clinical use in the United States and Europe. Insulin glargine is produced following two alterations of human insulin (Hirsch, 2005). Two arginine residues are added to the C terminus of the B chain, and an asparagine molecule in position A21 on the A chain is
replaced with glycine. Glargine is a clear solution with a pH of 4.0. This pH stabilizes the insulin hexamer and results in a prolonged and predictable absorption from subcutaneous tissues. Owing to insulin glargine’s acidic pH, it cannot be mixed with currently available short-acting insulin preparations (i.e., regular insulin, aspart, or lispro) that are formulated at a neutral pH. In clinical studies, insulin glargine results in less hypoglycemia, has a sustained “peakless” absorption profile, and provides a better once-daily 24-hour insulin coverage than ultralente or NPH insulin. Glargine may be administered at any time during the day with equivalent efficacy and no difference in the frequency of hypoglycemic episodes. Glargine does not accumulate after several injections. A recent study has demonstrated that duration of action remains at approximately 24 hours and intersubject variability actually improves after seven as compared to one injection.

Insulin glargine can be combined with various oral antihyperglycemic agents (see below) to effectively lower plasma glucose levels. Combination of glargine with sulfonylureas and/or metformin can reduce both fasting (basal) and postprandial glucose levels. It should be noted that the use of a long-acting basal insulin alone will not control postprandial glucose elevations in insulin-deficient type 1 or type 2 DM. Glargine has been shown in clinical studies to normalize fasting (postabsorptive) glucose levels following once-daily administration in patients with type 2 DM. Rarely, splitting the dose of glargine may be needed in very lean, insulin-sensitive type 1 DM patients in order to achieve good fasting (basal) glucose levels. Unlike traditional insulin preparations that are absorbed more rapidly from the abdomen than from the arm or leg, the site of administration does not influence the time–action profile of glargine. Similarly, exercise does not influence glargine’s unique absorption kinetics, even when the insulin is injected into a working limb. Glargine binds with a slightly greater affinity to IGF-1 receptors as compared with human insulin. However, this slightly increased binding is still approximately two log scales lower than that of IGF-1. The deterioration of retinopathy is a concern that it might be involved in the development of retinopathy. However, none of the patients had optic disc swelling, which is pathognomonic of IGF-1 effects, suggesting that the finding was probably due to the well-recognized “glucose reentry phenomenon” that occurs with improvement of glycemic control rather than the insulin per se.

Other approaches to prolong the action of soluble insulin analogs are under investigation. One approach is the addition of a saturated fatty acid to the ε amino group of LysB29, yielding a myristoylated insulin called insulin detemir (Hirsch, 2005). When insulin detemir is injected subcutaneously, it binds to albumin via its fatty acid chain. Clinical studies in patients with type 1 DM have demonstrated that when insulin detemir is administered twice a day, it has a smoother time–action profile and a reduced prevalence of hypoglycemia as compared with NPH insulin. Additional clinical studies are currently in progress with the aim of submitting insulin detemir for registration in the United States.

The wide variability in the kinetics of insulin action between and even within individuals must be emphasized. The time to peak hypoglycemic effect and insulin levels can vary by 50%. This variability is caused, at least in part, by large variations in the rate of subcutaneous absorption and often has been said to be more noticeable with the intermediate- and long-acting insulins. However, the administration of regular insulin can result in similar variability. When this variability is coupled with normal variations in diet and exercise, it is sometimes surprising how many patients do achieve good control of blood glucose concentrations.

**Indications and Goals for Therapy.** Subcutaneous administration of insulin is the primary treatment for all patients with type 1 DM, for patients with type 2 DM that is not controlled adequately by diet and/or oral hypoglycemic agents, and for patients with postpancreatectomy diabetes or gestational diabetes (American Diabetes Association, 1999). In addition, insulin is critical for the management of diabetic ketoacidosis, and it has an important role in the treatment of hyperglycemic, nonketotic coma and in the perioperative management of both type 1 and type 2 DM. In all cases, the goal is to normalize not only blood glucose but also all aspects of metabolism; the latter is difficult to achieve. Optimal treatment requires a coordinated approach to diet, exercise, and the administration of insulin. A brief overview of the principles of therapy is given below. (For a more detailed description, see LeRoith et al., 2000.)

**ABBREVIATIONS:** S, standard insulins; P, purified insulins; C, concentrated insulin; R, recombinant or semisynthetic human insulins.
Near-normoglycemia can be attained in patients with multiple daily doses of insulin or with infusion pump therapy. The goal is to achieve a fasting blood glucose concentration of between 90 and 120 mg/dl (5 to 6.7 mM) and a 2-hour postprandial value below 150 mg/dl (8.3 mM). Goal hemoglobin A1C values should be below 7% and are advocated by some authorities to be below 6.5%.

In less disciplined patients, or in those with defective responses of counter-regulatory hormones, it may be necessary to accept higher fasting [e.g., 140 mg/dl (7.8 mM)] and 2-hour postprandial [e.g., 200 to 250 mg/dl (11.1 to 13.9 mM)] blood glucose concentrations.

Daily Requirements. Insulin production by a normal, thin, healthy person is between 18 and 40 units/day or about 0.2 to 0.5 units/kg of body weight per day. About half this amount is secreted in the basal state and about half in response to meals. Thus, basal secretion is about 0.5 to 1 units/h; after an oral glucose load, insulin secretion may increase to 6 units/h. In nondiabetic, obese, and insulin-resistant individuals, insulin secretion may be increased fourfold or more. Insulin is secreted into the portal circulation, and about 50% is destroyed by the liver before reaching the systemic circulation.

In a mixed population of type 1 DM patients, the average dose of insulin is usually 0.6 to 0.7 units/kg body weight per day, with a range of 0.2 to 1 units/kg per day. Obese patients generally require more (about 2 units/kg per day) because of resistance of peripheral tissues to insulin. Patients who require less insulin than 0.5 units/kg per day may have some endogenous production of insulin or may be more sensitive to the hormone because of good physical conditioning. As in nondiabetics, the daily requirement for insulin can be divided into basal and postprandial needs. The basal dose suppresses lipolysis, proteolysis, and hepatic glucose production; it is usually 40% to 60% of the total daily dose. The dose necessary for disposition of nutrients after meals usually is given before meals. Insulin often has been administered as a single daily dose of intermediate-acting insulin, alone or in combination with regular insulin. This is rarely sufficient to achieve true euglycemia; since hyperglycemia is the major determinant of long-term complications of diabetes, more complex regimens that include combinations of intermediate- or long-acting insulins with regular insulin are used to reach this goal.

A number of commonly used dosage regimens that include mixtures of insulin given in two or three daily injections are depicted in Figure 60–5 (LeRoith et al., 2000). The most frequently used is the so-called split-mixed regimen involving the prebreakfast and presupper injection of a mixture of regular and intermediate-acting insulins (Figure 60–5A). When the presupper NPH or lente insulin is not sufficient to control hyperglycemia throughout the night, the evening dose may be divided into a presupper dose of regular insulin followed by NPH or lente insulin at bedtime (Figure 60–5B). Both normal and diabetic individuals have an increased requirement for insulin in the early morning; this is termed the dawn phenomenon and makes the kinetics and timing of the evening dose of insulin extremely important.

An alternative regimen that is gaining widespread use involves multiple daily injections consisting of basal administration of long-acting insulin (e.g., insulin glargine) either before breakfast or at bedtime and preprandial injections of a short-acting insulin (Figure 60–5C). This method is called basal/bolus and is very similar to the pattern of insulin administration achieved with a subcutaneous infusion pump (Figure 60–5E). Following the successful demonstration that intensive glycemic control can reduce the risk of micro- and macrovascular complications in patients with type 2 DM, there has been increased interest in using insulin earlier in the treatment of these patients. Data from the UKPDS indicate that 50% of relative β-cell insulin secretory capacity is lost for every 6 years of type 2 DM. This progressive insulin deficiency as type 2 DM progresses makes it increasingly difficult to achieve tight glycemic control (hemoglobin A1C < 7.0%) with oral antihyperglycemic agents. One way to improve control in this setting is to introduce basal-acting insulin in combination with oral hypoglycemic agents. The exact combination of therapies should be guided by the β-cell secretory reserve in each patient. Thus, in an individual with some exogenous insulin secretory capacity (i.e., a measurable circulating C peptide level), combining an oral insulin secretagogue (see below) with basal insulin may provide smooth and efficient glycemic control. The addition of a second oral agent, such as an insulin sensitizer (see below), either alone or in combination with an oral insulin secretagogue, also may provide good therapeutic results. This combination allows the oral agents to provide postprandial glycemic control while the basal insulin provides the foundation for normalizing fasting or “basal” glucose levels.

In all patients, careful monitoring of therapeutic end points directs the insulin dose used. This approach is facilitated by the use of home glucose monitors and measurements of hemoglobin A1c. Special care must be taken when the patient has other underlying diseases, deficiencies in other endocrine systems (e.g., adrenocortical or pituitary failure), or substantial resistance to insulin.

Factors That Affect Insulin Absorption. The degree of control of plasma glucose may be modified by changes in insulin absorption, factors that alter insulin action, diet, exercise, and other factors. Factors that determine the rate of absorption of insulin after subcutaneous administration include the site of injection, the type of insulin, subcutaneous blood flow, smoking, regional muscular activity at the site of the injection, the volume and concentration of the injected insulin, and depth of injection (insulin has a more rapid onset of action if delivered intramuscularly rather than subcutaneously).

When insulin is injected subcutaneously, there can be an initial “lag phase” followed by a slow but steadily increasing rate of absorption. The initial lag phase almost disappears when a reduced concentration or volume of insulin is injected.

Insulin usually is injected into the subcutaneous tissues of the abdomen, buttock, anterior thigh, or dorsal arm. Absorption is usually most rapid from the abdominal wall, followed by the arm, buttock, and thigh. Rotation of insulin injection sites traditionally has been advocated to avoid lipohypertrophy or lipoatrophy, although these conditions are less likely to occur with highly purified preparations of insulin. If a patient is willing to inject into the abdomen, injections can be rotated
throughout the entire area, thereby eliminating the injection site as a cause of variability in the rate of absorption. The abdomen currently is the preferred site of injection in the morning because insulin is absorbed about 20% to 30% faster from that site than from the arm. If the patient refuses to inject into the abdominal area, it is preferable to select a consistent injection site for each component of insulin treatment (e.g., prebreakfast dose into the thigh, evening dose into the arm).

Several other factors may affect the absorption of insulin. In a small group of patients, subcutaneous degradation of insulin has been observed, and this has necessitated the injection of large amounts of insulin for adequate metabolic control. Increased subcutaneous blood flow (brought about by massage, hot baths, or exercise) increases the rate of absorption. In the upright posture, subcutaneous blood flow diminishes considerably in the legs and to a lesser extent in the abdominal

Figure 60–5. Common multidose insulin regimens. A. Typical split-mixed regimen consisting of twice-daily injections of a mixture of regular (regular/lispro/aspart) and intermediate-acting (NPH or lente) insulin. B. A variation in which the evening dose of intermediate-acting insulin is delayed until bedtime to increase the amount of insulin available the next morning. C. A regimen that incorporates ultralente or glargine insulin. D. A variation that includes premeal short-acting insulin with intermediate-acting insulin at breakfast and bedtime. E. Patterns of insulin administration with a regimen of continuous subcutaneous insulin infusion.
many diabetic patients. Aspart combinations have proven to be popular with ultralente-NPH, lispro protamine-lispro, or aspart protamine-prefilled regular, lispro, NPH, glargine, or premixed regularly in the United States (Table 60–4). “Pen devices” containing NPH and regular insulin in proportions of 50:50, 60:40, 70:30, and 80:20, respectively, are available commercially; in the United States, only the 70:30 and 50:50 combinations are available. Combinations of lispro protamine-lispro (75/25, HUMALOG MIX) and aspart protamine-aspart (70/30, NOVOLOG MIX) are also available in the United States (Table 60–4). “Pen devices” containing prefilled regular, lispro, NPH, glargine, or premixed regular-NPH, lispro protamine-lispro, or aspart protamine-aspart combinations have proven to be popular with many diabetic patients.

Jet injector systems that enable patients to receive subcutaneous insulin “injections” without a needle are available. These devices are rather expensive and cumbersome but are preferred by some patients. Dispersal of insulin throughout an area of subcutaneous tissue theoretically should increase the rate of absorption of both regular and intermediate-acting insulins; however, this result has not always been observed.

Subcutaneous insulin administration results in anti-insulin IgG antibody formation. Older, impure preparations of animal insulins were far more antigenic than the more recent purified porcine and recombinant human preparations. It is disputed whether chronic therapy with human insulin reduces antibody production compared with monocomponent porcine insulin. Regardless, it is clear that human insulin is immunogenic. In the vast majority of patients receiving insulin treatment, circulating anti-insulin antibodies do not alter the pharmacokinetics of the injected hormone.

In rare patients who have a high titer of anti-insulin antibodies, the kinetics of action of regular insulin may resemble those of an intermediate-acting insulin, which itself may become longer acting. Such effects could lead to increased postprandial hyperglycemia (owing to decreased action of regular insulin) but nighttime hypoglycemia (owing to the prolonged action of intermediate insulin).

IgG antibodies can cross the placenta, raising the possibility that anti-insulin antibodies could cause fetal hyperglycemia by neutralizing fetal insulin. On the other hand, fetal or neonatal hyperglycemia could result from the undesirable and unpredictable release of insulin from insulin–antibody complexes. Switching from bovine/porcine to monoclonal component insulin preparations has been shown to reduce anti-insulin antibodies, leading to the recommendation that only human insulin be used during pregnancy.

**Continuous Subcutaneous Insulin Infusion.** A number of pumps are available for continuous subcutaneous insulin infusion (CSIIT) therapy. CSIIT, or “pump,” therapy is not suitable for all patients because it demands considerable attention, especially during the initial phases of treatment. However, for patients interested in intensive insulin therapy, a pump may be an attractive alternative to several daily injections. Most modern pumps provide a constant basal infusion of insulin and have the option of different infusion rates during the day and night to help avoid the dawn phenomenon and bolus injections that are programmed according to the size and nature of a meal.

Pump therapy presents some unique problems. Since all the insulin used is short acting and there is a minimal amount of insulin in the subcutaneous pool at any given time, insulin deficiency and ketoacidosis may develop rapidly if therapy is interrupted accidentally. Although modern pumps have warning devices that detect changes in line pressure, mechanical problems such as pump failure, dislodgement of the needle, aggregation of insulin in the infusion line, or accidental kinking of the infusion catheter may occur. There also is a possibility of subcutaneous abscesses and cellulitis. Selection of the most appropriate patients is extremely important for success with pump therapy. Offsetting these potential problems, pump therapy is capable of producing a more physiologic profile of insulin replacement during exercise (where insulin production is decreased) and therefore less hypoglycemia than do traditional subcutaneous insulin injections.

**Adverse Reactions. Hypoglycemia.** The most common adverse reaction to insulin is hypoglycemia. This may result from an inappropriately large dose, from a mismatch between the time of peak delivery of insulin and food intake, or from superimposition of additional factors that increase sensitivity to insulin (e.g., adrenal or pituitary insufficiency) or that increase insulin-independent glucose uptake (e.g., exercise). The more vigorous the attempt to achieve euglycemia, the more frequent are the episodes of hypoglycemia. In the DCCT, the incidence of severe hypoglycemic reactions was three times higher in the intensive insulin therapy group than in the conventional therapy group (DCCT Research Group, 1993). Milder but significant hypoglycemic episodes were much more common than were severe reactions, and their frequency also increased with intensive therapy. Hypoglycemia is the major risk that always must be weighed against benefits of intensive therapy.

There is a hierarchy of physiological responses to hypoglycemia. The first response is a reduction of endogenous insulin secretion, which occurs at a plasma
glucose level of about 70 mg/dl (3.9 mM); thereafter, the counter-regulatory hormones—epinephrine, glucagon, growth hormone, cortisol, and norepinephrine—are released. Symptoms of hypoglycemia are first discerned at a plasma glucose level of 60 to 80 mg/dl (3.3 to 4.4 mM). Sweating, hunger, paresthesias, palpitations, tremor, and anxiety, principally of autonomic origin, usually are seen first. Difficulty in concentrating, confusion, weakness, drowsiness, a feeling of warmth, dizziness, blurred vision, and loss of consciousness (i.e., the neuroglycopenic symptoms) usually occur at lower plasma glucose levels than do autonomic symptoms. In a normal individual, plasma glucose levels are tightly regulated, and it is only under rare conditions that hypoglycemia occurs.

Glucagon and epinephrine are the predominant counter-regulatory hormones in acute hypoglycemia in newly diagnosed type 1 DM patients and normal subjects. In patients with type 1 DM of longer duration, the glucagon secretory response to hypoglycemia becomes deficient, but effective glucose counter-regulation still occurs because epinephrine plays a compensatory role. Patients with type 1 DM thus become dependent on epinephrine for counter-regulation, and if this mechanism becomes deficient, the incidence of severe hypoglycemia increases. This occurs in patients with diabetes of long duration who have autonomic neuropathy. The absence of both glucagon and epinephrine can lead to prolonged hypoglycemia, particularly during the night, when some individuals can have extremely low plasma glucose levels for several hours. Severe hypoglycemia can lead to convulsions and coma.

In addition to autonomic neuropathy, several related syndromes of defective counter-regulation contribute to the increased incidence of severe hypoglycemia in intensively treated type 1 DM patients. These include hypoglycemic unawareness, altered thresholds for release of counter-regulatory hormones, and deficient secretion of counter-regulatory hormones (reviewed by Cryer 1993).

With the ready availability of home glucose monitoring, hypoglycemia can be documented in most patients who experience suggestive symptoms. Hypoglycemia that occurs during sleep may be difficult to detect but should be suspected from a history of morning headaches, night sweats, or symptoms of hypothermia. Nocturnal hypoglycemia has been proposed as a cause of morning hyperglycemia in type 1 DM patients. This syndrome, known as the Somogyi phenomenon, was reputedly due to an elevation of counter-regulatory hormones in response to nocturnal hypoglycemia, but several groups of investigators have been unable to reproduce it. Moreover, neuroendocrine counter-regulatory responses are severely diminished with disease duration and intensive control. Therefore, it is unlikely that in patients with reduced neuroendocrine responses to hypoglycemia, nocturnal counter-regulatory responses to hypoglycemia could be responsible for morning hyperglycemia. The practice of reducing nighttime insulin doses in type 1 DM subjects with morning hyperglycemia thus cannot now be recommended. Rather, the current recommended therapeutic approach to treating morning hyperglycemia is to administer more long- or intermediate-acting insulin the night before, perhaps at bedtime, or to increase the basal rate of a CSII pump between the hours of 3 and 7 A.M.

All diabetic patients who receive insulin should be aware of the symptoms of hypoglycemia, carry some form of easily ingested glucose, and carry an identification card or bracelet containing pertinent medical information. When possible, patients who suspect that they are experiencing hypoglycemia should document the glucose concentration with a measurement. Mild-to-moderate hypoglycemia may be treated simply by ingestion of glucose. When hypoglycemia is severe, it should be treated with intravenous glucose or an injection of glucagon (see below).

**Insulin Allergy and Resistance.** Although there has been a dramatic decrease in the incidence of resistance and allergic reactions to insulin with the use of recombinant human insulin or highly purified preparations of the hormone, these reactions still occur as a result of reactions to the small amounts of aggregated or denatured insulin in all preparations, to minor contaminants, or because of sensitivity to one of the components added to insulin in its formulation (protamine, Zn²⁺, phenol, etc.). The most frequent allergic manifestations are IgE-mediated local cutaneous reactions, although on rare occasions patients may develop life-threatening systemic responses or insulin resistance owing to IgG antibodies. Attempts should be made to identify the underlying cause of the hypersensitivity response by measuring insulin-specific IgG and IgE antibodies. Skin testing also is useful; however, many patients exhibit positive reactions to intradermal insulin without experiencing any adverse effects from subcutaneous insulin. If patients have allergic reactions to porcine insulin, human insulin should be used. If allergy persists, desensitization may be attempted; it is successful in about 50% of cases. Antihistamines may provide relief in patients with cutaneous reactions, whereas glucocorticoids have been used in patients with resistance to insulin or more severe systemic reactions.

**Lipoatrophy and Lipohypertrophy.** Atrophy of subcutaneous fat at the site of insulin injection (lipoatrophy) is probably a variant of an immune response to insulin, whereas lipohypertrophy (enlargement of subcutaneous fat deposits) has been ascribed to the lipogenic action of high local concentrations of insulin (LeRoith et al., 2000). Both problems may be related to some contaminant in insulin and are rare with more purified preparations. However, hypertrophy occurs frequently with human insulins if patients inject themselves repeatedly in the same site. When these problems occur, they may cause irregular absorption of insulin, as well as a cosmetic problem. The recommended treatment is to avoid the hypertrophic areas by using other injection sites and to inject insulin into the periphery of the atrophic sites in an attempt to restore the subcutaneous adipose tissue.

**Insulin Edema.** Some degree of edema, abdominal bloating, and blurred vision develops in many diabetic patients with severe hyperglycemia or ketoacidosis that is brought under control with insulin. This is associated with a weight gain of 0.5 to 2.5 kg. The edema usually disappears spontaneously within several days to a week unless there is underlying cardiac or renal disease. Edema is attributed primarily to retention of Na⁺, although increased capil-
lary permeability associated with inadequate metabolic control also may contribute.

**Insulin Treatment of Ketoacidosis and Other Special Situations.** Acutely ill diabetic patients may have metabolic disturbances that are sufficiently severe or labile to justify intravenous administration of insulin. Such treatment is most appropriate in patients with ketoacidosis. Although there has been some controversy over appropriate dosage, infusion of a relatively low dose of insulin (0.1 units/kg per hour) will produce plasma concentrations of insulin of about 100 μunits/ml—a level sufficient to inhibit lipolysis and gluconeogenesis completely and to produce near-maximal stimulation of glucose uptake in normal individuals. In most patients with diabetic ketoacidosis, blood glucose concentrations will fall by about 10% per hour; the acidosis is corrected more slowly. As treatment proceeds, it often is necessary to administer glucose along with the insulin to prevent hypoglycemia but to allow clearance of all ketones. Some physicians prefer to initiate therapy with a loading dose of insulin, but this tactic appears unnecessary because steady-state concentrations of the hormone are achieved within 30 minutes with a constant infusion. Patients with nonketotic hyperglycemic coma typically are more sensitive to insulin than are those with ketoacidosis. Appropriate replacement of fluid and electrolytes is an integral part of the therapy in both situations because there is always a major deficit. Regardless of the exact insulin regimen, the key to effective therapy is careful and frequent monitoring of the patient’s clinical status, glucose, and electrolytes. A frequent error in the management of such patients is the failure to administer insulin subcutaneously at least 30 minutes before intravenous therapy is discontinued. This is necessary because of the very short half-life of insulin.

Intravenous administration of insulin also is well suited to the treatment of diabetic patients during the perioperative period and during childbirth (Jacober and Sower, 1999). There is debate, however, about the optimal route of insulin administration during surgery. Although some clinicians advocate subcutaneous insulin administration, most recommend intravenous insulin infusion. The two most widely used protocols for intravenous insulin administration are the variable-rate regimen and the glucose–insulin–potassium (GIK) infusion method (see LeRoith et al., 2000). Both protocols provide stable plasma glucose, fluid, and electrolyte levels during the operative and postoperative period. Despite this, many physicians give patients half their normal daily dose of insulin as intermediate-acting insulin subcutaneously on the morning of an operation and then administer 5% dextrose infusions during surgery to maintain glucose concentrations. This approach provides less minute-to-minute control than is possible with intravenous regimens and also may increase the likelihood of hypoglycemia. Newer subcutaneously administered basal and rapid-acting analogs may provide smoother glycemic control without the drawback of hypoglycemia. Recent multicenter trials have demonstrated dramatic improvement in patient outcome, including significant reductions in mortality, when intensive insulin regimens (predominantly intravenous) have been used to reduce glycemia after myocardial infarction or surgery (Malmberg et al., 1995; Davies and Lawrence, 2002; van den Berghe et al., 2001; van den Berghe 2004).

**Drug Interactions and Glucose Metabolism.** A large number of drugs can cause hypoglycemia or hyperglycemia or may alter the response of diabetic patients to their existing therapeutic regimens. Some drugs with hypoglycemic or hyperglycemic effects and their presumed sites of action are listed in Table 60–5.

Aside from insulin and oral hypoglycemic drugs, the most common drug-induced hypoglycemic states are those caused by ethanol, β adrenergic receptor antagonists, and salicylates. The primary action of ethanol is to inhibit gluconeogenesis. This is not an idiosyncratic reaction but is observed in all individuals. In diabetic patients, β adrenergic receptor antagonists pose a risk of hypoglycemia because of their capacity to inhibit the effects of catecholamines on gluconeogenesis and glycogenolysis. These agents also may mask the sympathetically mediated symptoms associated with the fall in blood glucose (e.g., tremor and pallitations). Salicylates, on the other hand, exert their hypoglycemic effect by enhancing pancreatic β-cell sensitivity to glucose and potentiating insulin secretion. These agents also have a weak insulinlike action in the periphery. Pentamidine, an antiprotozoal agent used for the treatment of infections caused by Pneumocystis carinii, apparently can cause both hypoglycemia and hyperglycemia. The hypoglycemic effect results from destruction of β cells and release of insulin; continued use may cause secondary hypoinsulinemia and hyperglycemia. A number of drugs have no direct hypoglycemic action but may potentiate the actions of sulfonylureas (see below).

An equally large number of drugs may cause hyperglycemia in normal individuals or impair metabolic control in diabetic patients. Many of these agents have direct effects on peripheral tissues that counter the actions of insulin; examples include epinephrine, glucocorticoids, atypical antipsychotic drugs such as clozapine and olanzapine, and drugs used in highly active antiretroviral therapy (HAART) of HIV-1 infection (especially the protease inhibitors). Other drugs cause hyperglycemia by inhibiting insulin secretion directly (e.g., phenytoin, clonidine, and Ca^2+^-channel blockers) or indirectly via depletion of K^+ (diuretics). It is important to be aware of such interactions and to modify treatment regimens for diabetic patients accordingly.

**New Forms of Insulin Therapy.** There are a number of experimental approaches to insulin delivery, including the use of new insulins, new routes of administration, intraperitoneal delivery devices, implantable pellets, the closed-loop artificial pancreas, islet cell and pancreatic transplantation, and gene therapy.

**New Routes of Delivery.** Attempts have been made to administer insulin orally, nasally, rectally, by inhalation, and by subcutaneous implantation of pellets. The most promising of these alternatives is by inhalation, which can be achieved by addition of various adjuvants such as mannitol, glycine, and sodium citrate to insulin to increase its absorption through the pulmonary mucosa (Skyler et al., 2001; Cefalu et al., 2001). Absorption is rapid and approaches the

*Although these drugs are reported to have an effect on control of diabetes, there are no conclusive data about their effects on carbohydrate metabolism. †Short-term effect is insulin release and hypoglycemia. ‡Atypical antipsychotics: clozapine, olanzapine, risperidone. §HIV-1 protease inhibitors: ritonavir, lopinavir, aprenavir, nelfinavir, indinavir, saquinavir. SOURCE: Adapted from Koffler et al., 1989, with permission.
rate achieved with subcutaneous administration of regular insulin. Further work was under way with the aim of reducing the size and increasing the convenience of the inhaled delivery systems. Implantable pellets have been designed to release insulin slowly over days or weeks. Although oral delivery of insulin would be preferred by patients and would provide higher relative concentrations of insulin in the portal circulation, attempts to increase intestinal absorption of the hormone have met with only limited success. Efforts have focused on protection of insulin by encapsulation or incorporation into liposomes. Intraperitoneal infusion of insulin into the portal circulation has been used experimentally in human subjects for periods of several months.

**Transplantation and Gene Therapy.** Transplantation and gene therapy are provocative approaches to insulin replacement. Segmental pancreatic transplantation has been employed successfully in hundreds of patients (Sutherland et al., 2004). However, the surgery is technically complex and usually is considered only in patients with advanced disease and complications. The best-documented benefits have been in patients who also require a kidney transplant for diabetic nephropathy. Islet cell transplants theoretically are less complicated. Successful protocols for islet cell transplants were based on advances in islet preparation and a novel glucocorticoid-free immunosuppressive regimen (Robertson, 2004). The precise role of islet cell transplantation is debated, and the surgery is technically complex and usually is considered only in patients with advanced disease and complications. The best-documented benefits have been in patients who also require a kidney transplant for diabetic nephropathy. Islet cell transplants theoretically are less complicated. Successful protocols for islet cell transplants were based on advances in islet preparation and a novel glucocorticoid-free immunosuppressive regimen (Robertson, 2004). The precise role of islet cell transplantation is debated, and the supply of available islet preparations remains very limited. In rodents, gene therapy using transcription factors that regulate β-cell function has been used to transdifferentiate hepatocytes into a functional endocrine pancreas, eliminating the need for insulin therapy for months in experimental models of diabetes mellitus (Meivar-Levy and Ferber, 2004).

**ORAL HYPOGLYCEMIC AGENTS**

**History.** In contrast to the systematic studies that led to the isolation of insulin, the sulfonylureas were discovered accidentally. In 1942, Janbon and colleagues noted that some sulfonamides caused hypoglycemia in experimental animals. Soon thereafter, 1-butyl-3-sulfonylurea (carbutamide) became the first clinically useful sulfonylurea for the treatment of diabetes. Although later withdrawn because of adverse effects on the bone marrow, this compound led to the development of the entire class of sulfonylureas. Clinical trials of tolbutamide, the first widely used member of this group, were instituted in patients with type 2 DM in the early 1950s. Since that time, approximately 20 different agents of this class have been in use worldwide.

In 1997, repaglinide, the first member of a new class of oral insulin secretagogues called meglitinides (benzoic acid derivatives), was approved for clinical use; this agent has gained acceptance as a fast-acting premeal therapy to limit postprandial hyperglycemia.

The goat’s rue plant (Galega officinalis), used to treat diabetes in Europe in medieval times, was found in the early twentieth century to contain guanadine. Guanadine has hypoglycemic properties but was too toxic for clinical use. During the 1920s, biguanides were investigated for use in diabetes, but they were overshadowed by the discovery of insulin. Later, the antimalarial agent chloroguanide was found to have weak hypoglycemic action. Shortly after the introduction of the sulfonylureas, the first biguanides became available for clinical use. However, phenformin, the primary drug in this group, was withdrawn from the market in the United States and Europe because of an increased frequency of lactic acidosis associated with its use. Another biguanide, metformin, has been used extensively in Europe without significant adverse effects and was approved for use in the United States in 1995.

Thiazolidinediones were introduced in 1997 as the second major class of “insulin sensitizers.” These agents bind to peroxisome proliferator–activated receptors (principally PPARγ), resulting in increased glucose uptake in muscle and reduced endogenous glucose production. The first of these agents, troglitazone, was withdrawn from use in the United States in 2000 because of an association with hepatic toxicity. Two other agents of this class, rosiglitazone and pioglitazone, have not been associated with widespread liver toxicity and are used worldwide.

**Sulfonylureas**

**Chemistry.** The sulfonylureas are divided into two groups or generations of agents. Their structural relationships are shown in Table 60–6. All members of this class of drugs are substituted arylsulfonylureas. They differ by substitutions at the para position on the benzene ring and at one nitrogen residue of the urea moiety. The first group of sulfonylureas includes tolbutamide, acetohexamide, tolazamide, and chlorpropamide. A second, more potent generation of hypoglycemic sulfonylureas has emerged, including glyburide (glibenclamide), glipizide, gliclazide, and glimepiride.

**Mechanism of Action.** Sulfonylureas cause hypoglycemia by stimulating insulin release from pancreatic β cells. Their effects in the treatment of diabetes, however, are more complex. The acute administration of sulfonylureas to type 2 DM patients increases insulin release from the pancreas. Sulfonylureas also may further increase insulin levels by reducing hepatic clearance of the hormone. In the initial months of sulfonylurea treatment, fasting plasma insulin levels and insulin responses to oral glucose challenges are increased. With chronic administration, circulating insulin levels decline to those that existed before treatment, but despite this reduction in insulin levels, reduced plasma glucose levels are maintained. The explanation for this is not clear, but it may relate to reduced plasma glucose allowing circulating insulin to have more pronounced effects on its target tissues and to the fact that chronic hyperglycemia per se impairs insulin secretion (glucose toxicity).

The absence of acute stimulatory effects of sulfonylureas on insulin secretion during chronic treatment is attributed to down-regulation of cell surface receptors for sulfonylureas on the pancreatic β cell. If chronic sulfonylurea therapy is discontinued, pancreatic β-cell response to acute administration of the drug is restored. Sulfonylureas also stimulate release of somatostatin, and they may suppress the secretion of glucagon slightly.
Sulfonylureas bind to the SUR1 subunits and block the ATP-sensitive K⁺ channel (Aguilar-Bryan et al., 1995; Philipson and Steiner, 1995). The drugs thus resemble physiological secretagogues (e.g., glucose, leucine), which also lower the conductance of this channel. Reduced K⁺ conductance causes membrane depolarization and influx of Ca²⁺ through voltage-sensitive Ca²⁺ channels.

There has been controversy about whether or not sulfonylureas have clinically significant extrapancreatic effects. In general, attempts to ascribe the long-term blood glucose-lowering effects of sulfonylureas to specific changes in insulin action on target tissues are confounded by the effects of a lower prevailing blood glucose level. Although extrapancreatic effects of sulfonylureas can be demonstrated, they are of minor clinical significance in the treatment of type 2 DM patients.

**Absorption, Fate, and Excretion.** The sulfonylureas have similar spectra of activities; thus their pharmacokinetic properties are their most distinctive characteristics (see Appendix II). Although the rates of absorption of the different sulfonylureas vary, all are effectively absorbed from the gastrointestinal tract. However, food and hyperglycemia can reduce the absorption of sulfonylureas. Hyperglycemia per se inhibits gastric and intestinal motility and thus can retard the absorption of many drugs. In view of the time required to reach an optimal concentration in plasma, sulfonylureas with short half-lives may be more effective when given 30 minutes before eating. Sulfonylureas in plasma are largely (90% to 99%) bound to protein, especially albumin; plasma protein binding is least for chlorpropamide and greatest for glyburide. The volumes of distribution of most of the sulfonylureas are about 0.2 L/kg.

The first-generation sulfonylureas vary considerably in their half-lives and extents of metabolism. The half-life of acetohexamide is short, but the drug is reduced to an active compound whose half-life is similar to those of tolbutamide and tolagamide (4 to 7 hours). It may be necessary to take these drugs in divided daily doses. Chlorpropamide has a long half-life (24 to 48 hours). The second-generation agents are approximately 100 times more potent than those in the first group. Although their half-lives are short (3 to 5 hours), their hypoglycemic effects are evident for 12 to 24 hours, and they often can be administered once daily. The reason for the discrepancies between their half-lives and duration of action is not clear.

All the sulfonylureas are metabolized by the liver, and the metabolites are excreted in the urine. Metabolism of chlorpropamide is incomplete, and about 20% of the drug is excreted unchanged. Thus sulfonylureas should be administered with caution to patients with either renal or hepatic insufficiency.

**Adverse Reactions.** Adverse effects of the sulfonylureas are infrequent, occurring in about 4% of patients taking first-generation drugs and perhaps slightly less often in patients receiving second-generation agents. Not unexpectedly, sulfonylureas may cause hypoglycemic reactions, including coma. This is a particular problem in elderly patients with impaired hepatic or renal function who are taking longer-acting sulfonylureas. Sulfonylureas can be ranked in order of decreasing risk of causing hypoglycemia. It used to be thought that longer-acting sulfonylureas resulted in a greater prevalence of hypoglycemia. That is certainly the case when comparing the older preparations such as chlorpropamide (long acting) against tolbutamide (short acting). However, more recent second-generation sulfonylureas have very differing incidences of causing hypoglycemia despite similar half-lives. Thus glyburide (glibenclamide) has been reported to result in hypoglycemia in up to 20% to 30% of users, whereas another long-acting sulfonylurea, glimepiride, results in hypoglycemia in only 2% to 4% of users. A modified long-acting version of glipizide also results in a lower hypoglycemia frequency relative to gliburide.

Recent studies have provided an insight into the physiological basis for the differing rates of hypoglycemia occurring with these long-acting sulfonylureas. As described earlier for insulin, the ability of the body to inhibit endogenous insulin secretion is central to the homeostatic defense against hypoglycemia. This glucose-dependent inhibition of insulin secretion during hypoglycemia occurs with glimepiride but not with glyburide. Additionally, the major anti-insulin counter-regulatory hormone glucagon appears to be reduced by glyburide during hypoglycemia but is preserved during glimepiride therapy.

Severe hypoglycemia in the elderly can present as an acute neurological emergency that may mimic a cerebrovascular accident. Thus, it is important to check the plasma glucose level of any elderly patient presenting with acute neurological symptoms. Because of the long half-life of some sulfonylureas, it may be necessary to treat elderly hypoglycemic patients for 24 to 48 hours with an intravenous glucose infusion.

Many other drugs may potentiate the effects of the sulfonylureas, particularly the first-generation agents, by inhibiting their metabolism or excretion. Some drugs also displace the sulfonylureas from binding proteins, thereby transiently increasing the free concentration. These include other sulfonamides, clofibrate, and salicylates. Other drugs, especially ethanol, may enhance the action of sulfonylureas by causing hypoglycemia.

Other side effects of sulfonylureas include nausea and vomiting, cholestatic jaundice, agranulocytosis, aplastic and hemolytic anemias, generalized hypersensitivity reactions, and dermatological reactions. About 10% to 15% of patients who receive these drugs, particularly chlorpropa-
mide, develop an alcohol-induced flush similar to that caused by disulfiram (see Chapter 23). Sulfonylureas, especially chlorpropamide, also may induce hypotension by potentiating the effects of antidiuretic hormone on the renal collecting duct (see Chapter 29). This undesirable side effect occurs in up to 5% of all patients; it is less frequent with glyburide, glipizide, and glimepiride. This effect on water retention has been used to therapeutic advantage in patients with mild forms of central diabetes insipidus.

A long-running debate centered on whether treatment with sulfonylureas is associated with increased cardiovascular mortality; this possibility was suggested by a large multicenter trial [the University Group Diabetes Program (UGDP)]. The UGDP was designed to compare the effect of diet, oral agents (tolbutamide or phenformin), and fixed-dose insulin therapy on the development of vascular complications in type 2 DM. During an 8-year period of observation, patients who received tolbutamide had a twofold higher rate of cardiovascular death than patients treated with placebo or insulin (Meinert et al., 1970). A 10-year debate followed on the validity of this conclusion because the observation was unexpected, the study had not been designed to test this question, and all the excess mortality occurred in only three centers. The recent UKPDS (U.K. Prospective Diabetes Study Group, 1998a) clearly demonstrated no excess cardiovascular mortality over a 14-year period in patients receiving first- or second-generation sulfonylureas. It is worth noting that some of the newer sulfonylurea agents may confer even greater cardiovascular benefits compared with earlier second-generation compounds. Glimepiride, the most recent sulfonylurea, exerts beneficial effects with regard to ischemic preconditioning as compared with glyburide. The physiological response to an ischemic event in the coronary vasculature is a reflex vasodilation to a subsequent ischemic episode. This reflex appears to be preserved with glimepiride but reduced with glyburide.

**Therapeutic Uses.** Sulfonylureas are used to control hyperglycemia in type 2 DM patients who cannot achieve appropriate control with changes in diet alone. In all patients, continued dietary restrictions are essential to maximize the efficacy of the sulfonylureas. Contraindications to the use of these drugs include type 1 DM, pregnancy, lactation, and for the older preparations, significant hepatic or renal insufficiency.

Between 50% and 80% of properly selected patients will respond initially to an oral hypoglycemic agent. All the drugs appear to be equally efficacious. Concentrations of glucose often are lowered sufficiently to relieve symptoms of hyperglycemia but may not reach normal levels. To the extent that complications of diabetes are related to hyperglycemia, the goal of treatment should be normalization of both fasting and postprandial glucose concentrations. About 5% to 10% of patients per year who respond initially to a sulfonylurea become secondary failures, as defined by unacceptable levels of hyperglycemia. This may occur as a result of a change in drug metabolism, progression of β-cell failure, change in dietary compliance, or misdiagnosis of a patient with slow-onset type 1 DM. Additional oral agent(s) can produce a satisfactory response, but most of these patients eventually will require insulin.

The usual initial daily dose of tolbutamide is 500 mg, and 3000 mg is the maximally effective total dose. Tolazamide and chlorpropamide usually are initiated in a daily dose of 100 to 250 mg, with maximal doses of 1000 (tolazamide) or 750 mg (chlorpropamide). Tolbutamide and tolazamide often are taken twice daily 30 minutes before breakfast and dinner. The initial daily dose of glyburide is 2.5 to 5 mg, and daily doses of more than 20 mg are not recommended. Therapy with glipizide usually is initiated with 5 mg given once daily. The maximal recommended daily dose is 40 mg; daily doses of more than 15 mg should be divided. The starting dose of gliclazide is 40 to 80 mg/day, and the maximal daily dose is 320 mg. Glimepiride therapy can begin with doses as low as 0.5 mg once per day. The maximal effective daily dose of the agent is 8 mg. Treatment with the sulfonylureas must be guided by the patient’s response, which must be monitored frequently.

Combinations of insulin and sulfonylureas have been used in some patients with type 1 and type 2 DM. Studies in type 1 DM patients have provided no evidence that glucose control is improved by combination therapy. The results in type 2 DM patients have shown significant improvements in metabolic control. A prerequisite for a beneficial effect of combination therapy is residual β-cell activity; a short duration of diabetes also may predict a good response.

**Repaglinide**

Repaglinide (Prandin) is an oral insulin secretagogue of the meglitinide class. This agent is a derivative of benzoic acid, and its structure (shown below) is unrelated to that of the sulfonylureas.

Like sulfonylureas, repaglinide stimulates insulin release by closing ATP-dependent potassium channels in pancreatic β-cells. The drug is absorbed rapidly from the gastrointestinal tract, and peak blood levels are obtained within 1 hour. The half-life of the drug is about 1 hour. These features of the drug allow for multiple preprandial use as compared with the classical once- or twice-daily
dosing of sulfonylureas. Repaglinide is metabolized primarily by the liver to inactive derivatives. Repaglinide should be used cautiously in patients with hepatic insufficiency. Because a small proportion (about 10%) of repaglinide is metabolized by the kidney, increased dosing of the drug in patients with renal insufficiency also should be performed cautiously. As with sulfonylureas, the major side effect of repaglinide is hypoglycemia.

**Nateglinide**

Nateglinide (STARLIX) is an orally effective insulin secretagogue derived from D-phenylalanine. Like sulfonylureas and repaglinide, nateglinide stimulates insulin secretion by blocking ATP-sensitive potassium channels in pancreatic β cells. Nateglinide promotes a more rapid but less sustained secretion of insulin than do other available oral antidiabetic agents (Kalbag et al., 2001). The drug’s major therapeutic effect is reducing postprandial glycemic elevations in type 2 DM patients. Nateglinide is approved by the FDA for use in type 2 DM and is most effective if administered in a dose of 120 mg 1 to 10 minutes before a meal. Nateglinide is metabolized primarily by the liver and thus should be used cautiously in patients with hepatic insufficiency. About 16% of an administered dose is excreted by the kidney as unchanged drug. Dosage adjustment is unnecessary in renal failure. Nateglinide therapy may produce fewer episodes of hypoglycemia than most other currently available oral insulin secretagogues including repaglinide (Horton et al., 2001).

**Biguanides**

Metformin (GLUCOPHAGE, others) and phenformin were introduced in 1957, and buformin was introduced in 1958. The latter was of limited use, but metformin and phenformin were used widely. Phenformin was withdrawn in many countries during the 1970s because of an association with lactic acidosis. Metformin has been associated only rarely with that complication and has been used widely in Europe and Canada; it became available in the United States in 1995. Metformin given alone or in combination with a sulfonylurea improves glycemic control and lipid concentrations in patients who respond poorly to diet or to a sulfonylurea alone (DeFronzo et al., 1995).

**Mechanism of Action.** Metformin is antihyperglycemic, not hypoglycemic (see Bailey, 1992). It does not cause insulin release from the pancreas and generally does not cause hypoglycemia, even in large doses. Metformin has no significant effects on the secretion of glucagon, cortisol, growth hormone, or somatostatin. Metformin reduces glucose levels primarily by decreasing hepatic glucose production and by increasing insulin action in muscle and fat. At a molecular level, these actions are mediated at least in part by activation of the cellular kinase AMP-activated protein kinase (AMP kinase) (see below and Zhou et al., 2001). The mechanism by which metformin reduces hepatic glucose production is controversial, but most data indicate an effect on reducing gluconeogenesis (Stumvoll et al., 1995). Metformin also may decrease plasma glucose by reducing the absorption of glucose from the intestine, but this action has not been shown to have clinical relevance.

**Absorption, Excretion, and Dosing.** Metformin is absorbed mainly from the small intestine. The drug is stable, does not bind to plasma proteins, and is excreted unchanged in the urine. It has a half-life of about 2 hours. The maximum recommended daily dose of metformin in the United States is 2.5 g given in three doses with meals.

**Precautions and Adverse Effects.** Patients with renal impairment should not receive metformin. Other contraindications include hepatic disease, a past history of lactic acidosis (of any cause), cardiac failure requiring pharmacological therapy, or chronic hypoxic lung disease. The drug also should be discontinued temporarily prior to the administration of intravenous contrast media and prior to any surgical procedure. The drug should not be readministered any sooner than 48 hours after such procedures and should be withheld until renal function is determined to be normal. These conditions all predispose to increased lactate production and hence to the potentially fatal complication of lactic acidosis. The reported incidence of lactic acidosis during metformin treatment is less than 0.1 cases per 1000 patient-years, and the mortality risk is even lower.

Acute side effects of metformin, which occur in up to 20% of patients, include diarrhea, abdominal discomfort, nausea, metallic taste, and anorexia. These usually can be minimized by increasing the dosage of the drug slowly and taking it with meals. Intestinal absorption of vitamin B12 and folate often is decreased during chronic metformin therapy, and calcium supplements reverse the effect of metformin on vitamin B12 absorption.

Consideration should be given to stopping treatment with metformin if the plasma lactate level exceeds 3 mM or in the setting of decreased renal or hepatic function. It also is prudent to stop metformin if a patient is undergoing a prolonged fast or is treated with a very low calorie diet. Myocardial infarction or septicemia mandates immediate drug discontinuation. Metformin usually is administered in divided doses two or three times daily. The maximum effective dose is 2.5 g/day. Metformin lowers hemoglobin A1c values by about 2%, an effect comparable with that of the sulfonylureas. Metformin does not promote weight gain and can reduce plasma triglycerides by 15% to 20%. There is a strong consensus that reduction in hemoglobin A1c by any therapy (insulin or
oral agents) diminishes microvascular complications. Metformin, however, is the only therapeutic agent that has been demonstrated to reduce macrovascular events in type 2 DM (U.K. Prospective Diabetes Study Group, 1998b). Metformin can be administered in combination with sulfonylureas, thiazolidinediones, and/or insulin. Fixed-dose combinations containing metformin and glyburide (GLUCOVANCE, others), glipizide (METAGLIP), and rosiglitazone (AVANDAMET) are available.

**Thiazolidinediones**

Three thiazolidinediones have been used in clinical practice (troglitazone, rosiglitazone, and pioglitazone); however, troglitazone was withdrawn from use because it was associated with severe hepatic toxicity. Rosiglitazone and pioglitazone can lower hemoglobin A1c levels by 1% to 1.5% in patients with type 2 DM. These drugs can be combined with insulin or other classes of oral glucose-lowering agents. The thiazolidinediones tend to increase high-density lipoprotein (HDL) cholesterol but have variable effects on triglycerides and low-density lipoprotein (LDL) cholesterol. The structures of rosiglitazone and pioglitazone are:

![Structure of Rosiglitazone](image1.png)

**Mechanism of Action.** Thiazolidinediones are selective agonists for nuclear peroxisome proliferator–activated receptor-γ (PPARγ). These drugs bind to PPARγ which activates insulin-responsive genes that regulate carbohydrate and lipid metabolism. Thiazolidinediones require insulin to be present for their action. Thiazolidinediones exert their principal effects by increasing insulin sensitivity in peripheral tissue but also may lower glucose production by the liver. Thiazolidinediones increase glucose transport into muscle and adipose tissue by enhancing the synthesis and translocation of specific forms of the glucose transporters. The thiazolidinediones also can activate genes that regulate fatty acid metabolism in peripheral tissue. Although muscle is a major insulin-sensitive tissue, PPARγ is virtually absent in skeletal muscle. This has provoked questions as to how thiazolidinediones can reduce peripheral insulin resistance. One suggestion is that activation of PPARγ in adipose tissue reduces the flux of fatty acids into muscle, thereby lowering insulin resistance. Other suggestions include the activation of adipocyte hormones and/or adipokines, the most promising of which is adiponectin. Adiponectin is associated with increased insulin sensitivity and reportedly increases insulin sensitivity by elevating AMP kinase, which stimulates glucose transport into muscle and increases fatty acid oxidation (Havel, 2003).

Because the actions of both metformin and the thiazolidinediones apparently converge on AMP kinase, it has emerged as an attractive target for drug development (Ruderman and Prentki, 2004).

**Absorption, Excretion, and Dosing.** Rosiglitazone (AVANDIA) and pioglitazone (ACTOS) are taken once a day. Both agents are absorbed within about 2 hours, but the maximum clinical effect is not observed for 6 to 12 weeks. The thiazolidinediones are metabolized by the liver and may be administered to patients with renal insufficiency but should not be used if there is active hepatic disease or significant elevations of serum liver transaminases.

Rosiglitazone is metabolized by hepatic cytochrome P450 (CYP) 2C8, whereas pioglitazone is metabolized by CYP3A4 and CYP2C8. As discussed in Chapter 3, other drugs that induce or inhibit these enzymes can cause drug interactions. Clinically significant interactions between the available thiazolidinediones and other drug classes have not yet been described, but further studies are in progress.

**Precautions and Adverse Effects.** Liver function should be monitored in patients receiving thiazolidinediones, even though pioglitazone and rosiglitazone rarely have been associated with hepatotoxicity (12 cases up to July 2004). This lower hepatotoxicity has been attributed to the lack of the tocopherol side chain that was included in the troglitazone molecule. Additionally, the rare cases of hepatotoxicity occurring with second-generation thiazolidinediones appear to be less severe than those occurring with troglitazone. Hepatotoxicity can occur several months after initiation of the drugs. Any patient who has suffered any hepatotoxicity (even abnormal liver function tests) while on a thiazolidinediones should not receive any drugs in this class. Thiazolidinediones also have been reported to cause anemia, weight gain, edema, and plasma volume expansion. Edema is more likely to occur when these agents are combined with insulin; these drugs should not be used in patients with New
York Heart Association class 3 or 4 heart failure. Fluid retention and even overt heart failure usually occur within 6 months of thiazolidinedione therapy. In most cases, the subjects had no past history of heart failure, but all had underlying abnormal cardiac function. Obese hypertensive individuals and those with cardiac diastolic dysfunction are at greatest risk for fluid retention with thiazolidinediones. Thiazolidinediones also can induce peripheral edema independent of heart failure; proposed mechanisms include an increase in weight, an expansion of plasma volume following a reduction in renal sodium excretion, or a direct effect to increase vascular permeability. Exacerbations of fluid retention and/or heart failure should be treated, and the thiazolidinedione should be discontinued.

The availability of thiazolidinediones as powerful PPARγ ligands has sparked a number of novel avenues of clinical research. Studies have investigated whether thiazolidinediones can improve insulin sensitivity in HIV-associated lipodystrophy (see Chapter 50). Studies also are underway to explore the effects of thiazolidinediones on nonalcoholic hepatic steatosis. Finally, small single-site studies have investigated whether rosiglitazone can slow the progression of atheromatous lesions in carotid and coronary arteries in both nondiabetic and type 2 DM patients. Results to date have been mixed, and further multicenter studies are ongoing.

**α-Glucosidase Inhibitors**

α-Glucosidase inhibitors reduce intestinal absorption of starch, dextrin, and disaccharides by inhibiting the action of α-glucosidase in the intestinal brush border. Inhibition of this enzyme slows the absorption of carbohydrates; the postprandial rise in plasma glucose is blunted in both normal and diabetic subjects.

α-Glucosidase inhibitors do not stimulate insulin release and therefore do not result in hypoglycemia. These agents may be considered as monotherapy in elderly patients or in patients with predominantly postprandial hyperglycemia. α-Glucosidase inhibitors typically are used in combination with other oral antidiabetic agents and/or insulin. The drugs should be administered at the start of a meal. They are poorly absorbed.

Acarbose (PRECOSE), an oligosaccharide of microbial origin, and miglitol (GLYSET), a desoxyojirimycin derivative, also competitively inhibit glucoamylase and sucrase but have weak effects on pancreatic α-amylase. They reduce postprandial plasma glucose levels in type 1 and type 2 DM subjects. α-Glucosidase inhibitors can significantly improve hemoglobin A1c levels in severely hyperglycemic type 2 DM patients. However, in patients with mild-to-moderate hyperglycemia, the glucose-lowering potential of α-glucosidase inhibitors (assessed by hemoglobin A1c levels) is about 30% to 50% of that of other oral antidiabetic agents.

α-Glucosidase inhibitors cause dose-related malabsorption, flatulence, diarrhea, and abdominal bloating. Titrating the dose of drug slowly (25 mg at the start of a meal for 4 to 8 weeks, followed by increases at 4- to 8-week intervals to a maximum of 75 mg before each meal) reduces gastrointestinal side effects. Smaller doses are given with snacks. Acarbose is most effective when given with a starchy, high-fiber diet with restricted amounts of glucose and sucrose. If hypoglycemia occurs when α-glucosidase inhibitors are used with insulin or an insulin secretagogue, glucose rather than sucrose, starch, or maltose should be administered.

**Reduction in the Incidence of Type 2 DM**

Type 2 DM is a rapidly expanding worldwide health problem. In addition, the number of individuals who have impaired glucose tolerance (often termed prediabetes) may be equal to or even higher than the number of people with diabetes. In the United States, nearly 20 million individuals are diagnosed with diabetes, but perhaps twice that number have impaired glucose tolerance (IGT), which is defined as a fasting plasma glucose concentration of between 100 and 126 mg/dl (5.6 to 7 mM) or 2-hour values in the oral glucose tolerance test of between 140 and 199 mg/dl (7.8 to 11 mM) (Expert Committee on the Diagnosis and Classification of Diabetes, 2003). The rate of progression of IGT to overt diabetes ranges from 9% to 15% worldwide. A major factor in this increased incidence of diabetes is obesity. In the United States, approximately 60% of the population is overweight or obese. Particularly troubling is the rapid increase of obesity in children. Owing to the deleterious effects of obesity and decreased physical activity on insulin sensitivity, the incidence of type 2 DM in U.S. children has increased by tenfold over the last generation. Several large multicenter studies have investigated the effects of lifestyle and/or differing pharmacologic agents on reducing the incidence of type 2 DM. In the Diabetes Prevention Program study (Diabetes Prevention Program Research Group, 2002), a lifestyle intervention consisting of 150 minutes of exercise per week and a 7% weight loss over 2.8 years reduced the incidence of type 2 DM by 58% compared with placebo. Metformin (1700 mg/day) reduced the progression by 31%. Interestingly, when metformin was stopped, its protective effect in preventing diabetes dissi-
Glucagon-like Peptide 1

Over four decades ago, McIntyre and colleagues reported that oral as compared with intravenous delivery of glucose produced a greater release of insulin. Subsequent work identified two hormones—glucose-dependent insulinotropic polypeptide (GIP) and glucagon-like peptide (GLP-1)—that are released from the upper and lower bowel that augment glucose-dependent insulin secretion. These hormones are termed incretins. The two incretins differentially stimulate insulin secretion. GIP has little effect on augmenting insulin secretion in type 2 DM, whereas GLP-1 significantly augments glucose-dependent insulin secretion. Consequently, GLP-1 has become an attractive target for therapeutic development in type 2 DM. GLP-1 also reduces glucagon secretion, slows gastric emptying, and decreases appetite. Thus, the compound may have unique properties to reduce postprandial glucose excursions (i.e., increase in insulin, reduction of glucagon, slowing of gastric emptying) and also to induce weight loss. Offsetting these advantages, circulating GLP-1 is rapidly (1 to 2 minutes) inactivated by the dipeptidyl peptidase IV enzyme (DPP-IV). Thus, GLP-1 must be infused continuously to have therapeutic benefits. Consequently, considerable work has been performed to produce GLP-1 receptor agonists that maintain the physiologic effects of the native incretin but are resistant to the actions of DPP-IV. To date, two synthetic GLP-1 analogs have entered clinical trials. Exendin-4 is derived from the salivary gland of the Gila monster and has 53% homology with human GLP-1. Exendin-4 is resistant to DPP-IV and has full agonist activity at GLP-1 receptors. Several clinical studies have demonstrated that exendin-4 (exenatide, BYETTA) is effective in lowering hemoglobin A1c (approximately 1% to 1.3%) and also promotes weight loss in type 2 DM. The compound is administered as twice-daily injections, although studies are planned to test a weekly or perhaps even a longer-acting formulation. Based on results of clinical trials, the FDA recently approved exenatide for twice-daily injection in combination therapy with other agents in subjects with type 2 DM. Reported exendin-4 side effects include a self-limiting nausea in 15% to 30% of patients; hypoglycemia can occur when GLP-1 agonists are used in conjunction with oral insulin secretagogues.

A second long-acting analog of GLP-1, known as NN2211, is also in clinical trials. NN2211 contains a fatty acid moiety (hexaeeconyl residue) covalently linked to GLP-1. NN2211 is resistant to the action of DPP-IV but also must be injected. Early clinical studies show that NN2211 is effective in lowering hemoglobin A1c but may not induce as much weight loss as exendin-4. Nausea and hypoglycemia also occur with NN2211 when used with oral hypoglycemic agents.

An alternative approach to GLP-1 therapy is to inactivate the DPP-IV protease, thereby increasing endogenous circulating GLP-1 levels. A number of orally effective DPP-IV inhibitors have entered clinical trials. One study in type 2 DM reported similar reductions in hemoglobin A1c as compared with the GLP-1 receptor analogs. These agents are well tolerated and appear to result in less nausea than the GLP-1 analogs. However, since DPP-IV can metabolize a wide range of peptides, there is a theoretical concern about the long-term safety of these compounds. Furthermore, the potency of the DPP-IV inhibitors may be limited by the amount of endogenous production of GLP-1. In contrast, pharmacological amounts of the injectable GLP-1 analogs can be administered with possibly increased therapeutic effect. Ongoing studies are currently being performed to further delineate the therapeutic effects of these agents, which offer promise for a novel pharmacotherapy in type 2 DM.
Glucagon is synthesized from preproglucagon, a 180-amino-acid precursor with five separately processed domains. An amino-terminal signal peptide is followed by glicentin-related pancreatic polypeptide, glucagon, GLP-1, and glucagon-like peptide-2. Processing of the protein is sequential and occurs in a tissue-specific fashion; this highly controlled nature of the processing suggests that the peptides may have distinct biological functions. In the pancreatic \( \alpha \) cell, the granule consists of a central core of glucagon surrounded by a halo of glicentin. Intestinal L cells contain only glicentin and presumably lack the enzyme required to process this precursor to glucagon. Enterogluca
gon binds to hepatic glucagon receptors and stimulates adenyl cyclase with 10% to 20% of the potency of glucagon. GLP-1 is an extremely potent potentiator of insulin secretion (see above), although it apparently lacks significant hepatic actions. Glicentin, enterogluca
gon, and the glucagon-like peptides are found predominantly in the intestine, and their secretion continues after total pancreatectomy.

Regulation of Secretion. Glucagon secretion is regulated by dietary glucose, insulin, amino acids, and fatty acids. As in insulin secretion, glucose is a more effective inhibitor of glucagon secretion when taken orally than when administered intravenously, suggesting a possible role for gastrointestinal hormones in the response. The effect of glucose is lost in untreated or undertreated type 1 DM patients and in isolated pancreatic \( \alpha \) cells, indicating that at least part of the effect is secondary to stimulation of insulin secretion. Somatostatin also inhibits glucagon secretion, as do free fatty acids and ketones.

Most amino acids stimulate the release of both glucagon and insulin. This coordinated response to amino acids may prevent insulin-induced hypoglycemia in individuals who ingest a meal of pure protein. Like glucose, amino acids are more potent when taken orally and thus may exert some of their effects via gastrointestinal hormones. Secretion of glucagon also is regulated by the autonomic innervation of the pancreatic islet. Stimulation of sympathetic nerves or administration of sympathomimetic amines increases glucagon secretion. Acetylcholine has a similar effect.

Glucagon in Diabetes Mellitus. Plasma concentrations of glucagon are elevated in poorly controlled diabetic patients. Because it enhances gluconeogenesis and glycogenolysis, glucagon exacerbates the hyperglycemia of diabetes. However, this abnormality of glucagon secretion appears to be secondary to the diabetic state and is corrected with improved control of the disease. The importance of the hyperglucagonemia in diabetes has been evaluated by administration of somatostatin. Although somatostatin does not restore glucose metabolism to normal, it significantly slows the rate of development of hyperglycemia and ketonemia in insulin-deficient subjects with type 1 DM. In normal individuals, glucagon secretion increases in response to hypoglycemia, but this important defense mechanism against insulin-induced hypoglycemia is lost in type 1 DM.

Degradation. Glucagon is degraded extensively in liver, kidney, plasma, and other sites of action. Its half-life in plasma is approximately 3 to 6 minutes. Proteolytic removal of the amino-terminal histidine residue leads to loss of biological activity.

Cellular and Physiological Actions. Glucagon interacts with a glycoprotein GPCR on the plasma membrane of target cells that signals through G\( _s \) (Mayo et al., 2003) (see Chapter 1). The primary effects of glucagon on the liver are mediated by cyclic AMP. In general, modifications of the amino-terminal region of glucagon (e.g., [Phe\(^1\)]glucagon and des-His\(_1\)-[Glu\(^9\)]glucagon amide) result in molecules that behave as partial agonists that retain some affinity for the glucagon receptor but have a markedly reduced capacity to stimulate adenyl cyclase.

Glucagon activates phosphorylase, the rate-limiting enzyme in glycogenolysis, via cyclic AMP–stimulated phosphorylation, whereas concurrent phosphorylation of glycogen synthase inactivates the enzyme; glycogenolysis is enhanced, and glycogen synthesis is inhibited. Cyclic AMP also stimulates transcription of the gene for phosphoenolpyruvate carboxykinase, a rate-limiting enzyme in gluconeogenesis. These effects normally are opposed by insulin, and insulin is dominant when maximal concentrations of both hormones are present.

Cyclic AMP also stimulates phosphorylation of the bifunctional enzyme 6-phosphofructo-2-kinase/fructose-2,6-bisphosphatase. This enzyme determines the cellular concentration of fructose-2,6-bisphosphate, which acts as a potent regulator of gluconeogenesis and glycogenolysis. When the concentration of glucagon is high relative to that of insulin, this enzyme is phosphorylated and acts as a phosphatase, reducing the concentration of fructose-2,6-bisphosphate in the liver. When the concentration of insulin is high relative to that of glucagon, the dephosphorylated enzyme acts as a kinase, raising fructose-2,6-bisphosphate concentrations. Fructose-2,6-bisphosphate interacts allosterically with phosphofructokinase-1, the rate-limiting

**Figure 60–6.** The amino acid sequence of glucagon.
enzymatic activity in glycolysis, increasing its activity. Thus, when glucagon concentrations are high, glycolysis is inhibited, and gluconeogenesis is stimulated. This also leads to a decrease in the concentration of malonyl CoA, stimulation of fatty acid oxidation, and production of ketone bodies. Conversely, when insulin concentrations are high, glycolysis is stimulated, and gluconeogenesis and ketogenesis are inhibited (see Foster, 1984).

Glucagon exerts effects on tissues other than liver, especially at higher concentrations. In adipose tissue, it stimulates adenyl cyclase and increases lipolysis. In the heart, glucagon increases the force of contraction. Glucagon has relaxant effects on the gastrointestinal tract; this has been observed with analogs that apparently do not stimulate adenyl cyclase. Some tissues (including liver) possess a second type of glucagon receptor that is linked to generation of IP_3, diacylglycerol, and Ca^{2+}. The role of this receptor in metabolic regulation remains uncertain.

**Therapeutic Use.** Glucagon is used to treat severe hypoglycemia, particularly in diabetic patients when intravenous glucose is not available; it also is used by radiologists for its inhibitory effects on the gastrointestinal tract.

All glucagon used clinically is extracted from bovine and porcine pancreas; its sequence is identical to that of the human hormone. For hypoglycemic reactions, 1 mg is administered intravenously, intramuscularly, or subcutaneously. The first two routes are preferred in an emergency. Clinical improvement is sought within 10 minutes to minimize the risk of neurological damage from hypoglycemia. The hyperglycemic action of glucagon is transient and may be inadequate if hepatic stores of glycogen are depleted. After the initial response to glucagon, patients should be given glucose or urged to eat to prevent recurrent hypoglycemia. Nausea and vomiting are the most frequent adverse effects.

Glucagon also is used to relax the intestinal tract to facilitate radiographic examination of the upper and lower gastrointestinal tract with barium and retrograde ileography and in magnetic resonance imaging of the gastrointestinal tract. Glucagon has been used to treat the spasm associated with acute diverticulitis and disorders of the biliary tract and sphincter of Oddi, as an adjunct in basket retrieval of biliary calculi, and for impaction of the esophagus and intussusception. Finally, it has been used diagnostically to distinguish obstructive from hepatocellular jaundice.

Glucagon releases catecholamines from pheochromocytomas and has been used experimentally as a diagnostic test for this disorder. Based on this effect, glucagon therapy is contraindicated in known pheochromocytoma. The hormone also has been used as a cardiac inotropic agent for the treatment of shock, particularly when prior administration of a β adrenergic receptor antagonist has rendered β adrenergic receptor agonists ineffective.

**SOMATOSTATIN**

Somatostatin was first isolated in 1973, following a search for hypothalamic factors that might regulate secretion of growth hormone from the pituitary gland (see Chapter 5). A potential physiological role for somatostatin in the islet was suggested by the observation that somatostatin inhibits secretion of insulin and glucagon. The peptide subsequently was identified in the δ cells of the pancreatic islet, in similar cells of the gastrointestinal tract, and in the central nervous system.

Somatostatin, the name originally given to a cyclic peptide containing 14 amino acids, is now known to be one of a group of related peptides. These include the original somatostatin (S-14), an extended 28-amino-acid peptide molecule (S-28), and a fragment containing the initial 12 amino acids of somatostatin-28 [S-28(1–12)]. S-14 is the predominant form in the brain, whereas S-28 is the main form in the gut. Acting via a family of GPCRs (see Chapter 55), somatostatin inhibits the release of thyroid-stimulating hormone and growth hormone from the pituitary gland; of gastrin, motilin, VIP, glicentin, and gastrointestinal polypeptide from the gut; and of insulin, glucagon, and pancreatic polypeptide from the pancreas.

Somatostatin secreted from the pancreas can regulate pituitary function, thereby acting as a true endocrine hormone. In the gut, however, somatostatin acts as a paracrine agent that influences the functions of adjacent cells. It also can act as an autocrine agent by inhibiting its own release in the pancreas. As the last cell to receive blood flow in the islets, the δ cell is downstream of the β and α cells. Thus, somatostatin may regulate the secretion of insulin and glucagon only via the systemic circulation.

Somatostatin is released in response to many of the nutrients and hormones that stimulate insulin secretion, including glucose, arginine, leucine, glucagon, VIP, and cholecystokinin. The physiological role of somatostatin has not been defined precisely. When administered in pharmacologic doses, somatostatin inhibits virtually all endocrine and exocrine secretions of the pancreas, gut, and gallbladder. Somatostatin also can inhibit secretion of the salivary glands and, under some conditions, can block parathyroid, calcitonin, prolactin, and adrenocorticotropic hormone (ACTH) secretion. The α cell is about 50 times more sensitive to somatostatin than is the β cell, but inhibition of glucagon secretion is more transient. Somatostatin also inhibits nutrient absorption from the intestine, decreases intestinal motility, and reduces splanchnic blood flow.

Therapeutic uses of somatostatin are confined mainly to blocking hormone release in endocrine-secreting tumors, including insulinomas, glucagonomas, VIPomas, carcinoid tumors, and growth hormone–secreting adenomas (causing acromegaly). Because of its short half-life (3 to 6 minutes), substantial effort has been directed toward the production of longer-acting analogs. One such agent, octreotide (SANDOSTATIN), is available in the United States for treatment of carcinoid tumors, glucagonomas, VIPomas, and acromegaly. Another agent, lanreotide, is available in Europe. A depot form of octreotide administered intramuscularly every 4 weeks (SANDOSTATIN LAR) may be particularly suitable for chronic administration (see Chapter 55). Octreotide or lanreotide successfully controls excess secretion of growth hormone in most patients, and both have been reported to reduce the size of pituitary tumors in about one-third of cases. Octreotide also has been used to reduce the disabling form of diarrhea that occasionally occurs in diabetic autonomic neuropathy. Since octreotide also can decrease blood flow to the gastrointestinal tract, it has been used to treat bleeding esophageal varices, peptic ulcers, and postprandial orthostatic hypotension.

Gallbladder abnormalities (stones and biliary sludge) occur frequently with chronic use of the somatostatin analogs, as do gastrointestinal symptoms. Hypoglycemia, hyperglycemia, hypothyroidism, and goiter have been reported in patients being treated with octreotide for acromegaly.

**DIAZOXIDE**

Diazoxide is an antihypertensive, antidiuretic benzothiadiazine derivative with potent hyperglycemic actions when given orally (see
Chapter 32). Hyperglycemia results primarily from inhibition of insulin secretion. Diazoxide interacts with the ATP-sensitive K⁺ channel on the β-cell membrane and either prevents its closing or prolongs the open time; this effect is opposite to that of the sulfonylureas. The drug does not inhibit insulin synthesis, and thus there is an accumulation of insulin within the β cell. Diazoxide also has a modest capacity to inhibit peripheral glucose utilization by muscle and to stimulate hepatic gluconeogenesis.

Diazoxide (PROGLYCEM) has been used to treat patients with various forms of hypoglycemia. The usual oral dose is 3 to 8 mg/kg per day in adults and 8 to 15 mg/kg per day in infants and neonates. The drug can cause nausea and vomiting and thus usually is given in divided doses with meals. Diazoxide circulates largely bound to plasma proteins and has a half-life of about 48 hours. Thus, the patient should be maintained at any dosage for several days before evaluating the therapeutic result.

Diazoxide has a number of adverse effects, including retention of Na⁺ and fluid, hyperuricemia, hypertrichosis (especially in children), thrombocytopenia, and leucopenia, which sometimes limit its use. Despite these side effects, the drug may be quite useful in patients with inoperable insulinomas and in children with hyperinsulinism owing to nesidioblastosis.

**MONOGRAPHs and reviews**

Calcium

Ca\(^{2+}\), the ionized form of elemental calcium, is essential for the Ca\(^{2+}\) component of current flow across excitable membranes, fusion and release of storage vesicles, and muscle contraction. Intracellular Ca\(^{2+}\) also acts in the sub-micromolar range as a critical second messenger (see Chapter 1). In extracellular fluid, millimolar concentrations of calcium promote blood coagulation (Figure 61–3) (see below) and support the formation and continuous remodeling of the skeleton.

Ca\(^{2+}\) has an adaptable coordination sphere that facilitates binding to the irregular geometry of proteins. The capacity of an ion to cross-link two proteins requires a high coordination number, which dictates the number of electron pairs that can be formed and generally is six to eight for Ca\(^{2+}\). Unlike disulfide or sugar–peptide cross-links, Ca\(^{2+}\) linking is readily reversible. Cross-linking of structural proteins in bone matrix is enhanced by the relatively high extracellular concentration of calcium.

In the face of millimolar extracellular Ca\(^{2+}\), intracellular free Ca\(^{2+}\) is maintained at a low level, approximately 100 nM in cells in their basal state, by active extrusion by Ca\(^{2+}\)–ATPases and by Na\(^{+}/Ca^{2+}\) exchange. As a consequence, changes in cytosolic Ca\(^{2+}\) (whether released from intracellular stores or entering via membrane Ca\(^{2+}\) channels) can modulate effector targets, often by interacting with the Ca\(^{2+}\)-binding protein calmodulin. The rapid association–dissociation kinetics of Ca\(^{2+}\) and the relatively high affinity and selectivity of Ca\(^{2+}\)-binding domains permit effective regulation of Ca\(^{2+}\) over the 100 nM to 1 \(\mu\)M range.

Healthy adult men and women possess about 1300 and 1000 g of calcium, respectively, of which more than 99% is in bone and teeth. Ca\(^{2+}\) is the major extracellular divalent cation. Although the absolute amount of calcium in extracellular fluids is small, this fraction is stringently regulated within narrow limits. In adult humans, the normal serum calcium concentration ranges from 8.5 to 10.4 mg/dl (4.25 to 5.2 mEq/L, 2.1 to 2.6 mM) and includes three distinct chemical forms of Ca\(^{2+}\): ionized (50%), protein-bound (40%), and complexed (10%). Thus, whereas total plasma calcium concentration is approximately 2.54 mM, the concentration of ionized Ca\(^{2+}\) in human plasma is approximately 1.2 mM.

The various pools of calcium are illustrated schematically in Figure 61–1. Only diffusible calcium, \textit{i.e.}, ionized plus complexed, can cross cell membranes. Of the serum calcium bound to plasma proteins, albumin accounts for some 90%. Smaller percentages are bound, albeit with greater affinity, to \(\beta\)-globulin, \(\alpha_2\)-globulin, \(\alpha_1\)-globulin, and \(\gamma\)-globulin. The remaining 10% of the serum calcium is complexed in ion pairs with small polyvalent anions, primarily phosphate and citrate. The degree of complex formation depends on the ambient pH and the concentrations of ionized calcium and complexing anions. As the physiologically relevant component, it is ionized Ca\(^{2+}\) that exerts biological effects and, when perturbed, produces the characteristic signs and symptoms of hypo- or hypercalcemia.

The total plasma calcium concentration can be interpreted only by correcting for the concentration of plasma proteins. A change in plasma albumin concentration of 1.0 g/dl from the normal value of 4.0 g/dl can be expected to alter total calcium concentration by approximately 0.8 mg/dl.
The extracellular Ca\(^{2+}\) concentration is tightly controlled by hormones that affect its entry at the intestine and its exit at the kidney; when needed, these same hormones regulate withdrawal from the large skeletal reservoir.

**Calcium Stores.** The skeleton contains 99% of total body calcium in a crystalline form resembling the mineral hydroxyapatite \([\text{Ca}_{10}(\text{PO}_4)_{6}(\text{OH})_2]\); other ions, including Na\(^+\), K\(^+\), Mg\(^{2+}\), and F\(^-\), also are present in the crystal lattice. The steady-state content of calcium in bone reflects the net effect of bone resorption and bone formation, coupled with aspects of bone remodeling (see below). In addition, a labile pool of bone Ca\(^{2+}\) exchanges readily with interstitial fluid. This exchange is modulated by hormones, vitamins, drugs, and other factors that directly alter bone turnover or that influence the Ca\(^{2+}\) level in interstitial fluid.

**Calcium Absorption and Excretion.** In the United States, about 75% of dietary calcium is obtained from milk and dairy products. The adequate intake value for calcium is 1300 mg/day in adolescents and 1000 mg/day in adults. After age 50, the adequate intake is 1200 mg/day. This contrasts with median intakes of calcium for boys and girls aged 9 years and older of 865 and 625 mg, respectively, and a median daily calcium intake of 517 mg for women after age 50.

Figure 61–2 illustrates the components of whole-body daily calcium turnover. Ca\(^{2+}\) enters the body only through the intestine. Active vitamin D–dependent transport (see below) occurs in the proximal duodenum, whereas facilitated diffusion throughout the small intestine accounts for the majority of total Ca\(^{2+}\) uptake. This uptake is counterbalanced by an obligatory daily intestinal calcium loss of about 150 mg/day that reflects the mineral contained in mucosal and biliary secretions and in sloughed intestinal cells.

The efficiency of intestinal Ca\(^{2+}\) absorption is inversely related to calcium intake. Thus, a diet low in calcium leads to a compensatory increase in fractional absorption owing partly to activation of vitamin D. In older persons, this response is considerably less robust. Disease states associated with steatorrhea, diarrhea, or chronic malabsorption promote fecal loss of calcium, whereas drugs such as glucocorticoids and phenytoin depress intestinal Ca\(^{2+}\) transport.

Urinary Ca\(^{2+}\) excretion is the net difference between the quantity filtered at the glomerulus and the amount reabsorbed. About 9 g of Ca\(^{2+}\) is filtered each day. Tubular reabsorption is very efficient, with more than 98% of filtered Ca\(^{2+}\) returned to the circulation. The efficiency of reabsorption is highly regulated by parathyroid hormone (PTH) but also is influenced by filtered Na\(^+\), the presence of nonreabsorbed anions, and diuretic agents (see Chapter 28). Sodium intake, and therefore sodium excretion, is directly related to urinary calcium excretion. Diuretics that act on the
ascending limb of the loop of Henle (e.g., furosemide) increase calcium excretion. By contrast, thiazide diuretics uncouple the relationship between Na\(^+\) and Ca\(^{2+}\) excretion, increasing sodium excretion but diminishing calcium excretion (Friedman and Bushinsky, 1999). Dietary protein is directly related to urine Ca\(^{2+}\) excretion, presumably owing to the effect of sulfur-containing amino acids on renal tubular function.

### Phosphate

In addition to its roles as a dynamic constituent of intermediary and energy metabolism and as a key regulator of enzyme activity when transferred by protein kinases from ATP to phosphorylatable serine, threonine, and tyrosine residues, phosphate is an essential component of all body tissues, being present in plasma, extracellular fluid, cell membrane phospholipids, intracellular fluid, collagen, and bone tissue. More than 80% of total body phosphorus is found in bone, and about 15% is in soft tissue.

Biologically, phosphorus (P) exists in both organic and inorganic forms. Organic forms include phospholipids and various organic esters. In extracellular fluid, the bulk of phosphorus exists as inorganic phosphate in the form of NaH\(_2\)PO\(_4\) and Na\(_2\)HPO\(_4\); the ratio of disodium to monosodium phosphate at pH 7.40 is 4:1, so plasma phosphate has an intermediate valence of 1.8. Owing to its relatively low concentration in extracellular fluid, phosphate contributes little to buffering capacity. The aggregate level of inorganic phosphate (P\(_i\)) modifies tissue concentrations of Ca\(^{2+}\) and plays a major role in renal H\(^+\) excretion. Within bone, phosphate is complexed with calcium as hydroxyapatites having the general formula Ca\(_{10}\)(PO\(_4\))\(_6\)(OH)\(_2\) and as calcium phosphate.

**Absorption, Distribution, and Excretion.** Phosphate is absorbed from and to a limited extent secreted into the gastrointestinal tract. Phosphate is a ubiquitous component of ordinary foods; thus, an inadequate diet rarely causes phosphate depletion. Transport of phosphate from the intestinal lumen is an active, energy-dependent process that is regulated by several factors, including vitamin D, which stimulates absorption. In adults, about two-thirds of ingested phosphate is absorbed and is excreted almost entirely into the urine. In growing children, phosphate balance is positive, and plasma concentrations of phosphate are higher than in adults.

Phosphate excretion in the urine represents the difference between the amount filtered and that reabsorbed. More than 90% of plasma phosphate is freely filtered at the glomerulus, and 80% is actively reabsorbed, predominantly in the initial segment of the proximal convoluted tubule but also in the proximal straight tubule (pars recta). Renal phosphate absorption is regulated by a variety of hormones and other factors; the most important are PTH and dietary phosphate, with extracellular volume and acid–base status playing lesser roles. Dietary phosphate deficiency up-regulates renal phosphate transporters and decreases excretion, whereas a high-phosphate diet increases phosphate excretion; these changes are independent of any effect on plasma P\(_i\), Ca\(^{2+}\), or PTH. PTH increases urinary phosphate excretion by blocking phosphate absorption. Expansion of plasma volume increases urinary phosphate excretion. Effects of vitamin D and its metabolites on proximal tubular phosphate are modest at best.

**Role of Phosphate in Urine Acidification.** Despite the fact that the concentration and buffering capacity of phosphate in extracellular fluid are low, phosphate is concentrated progressively in the renal tubule and becomes the most abundant buffer system in the distal tubule and terminal nephron. The exchange of H\(^+\) and Na\(^+\) in the tubular urine converts disodium hydrogen phosphate (Na\(_2\)HPO\(_4\)) to sodium dihydrogen phosphate (NaH\(_2\)PO\(_4\)), permitting the excretion of large amounts of acid without lowering the urine pH to a degree that would block H\(^+\) transport.

**Actions of Phosphate Ion.** If large amounts of phosphate are introduced into the gastrointestinal tract by oral administration or enema, a cathartic action will result. Thus phosphate salts are employed as mild laxatives (see Chapter 37). If excessive phosphate salts are introduced either intravenously or orally, they may reduce the concentration of Ca\(^{2+}\) in the circulation and induce precipitation of calcium phosphate in soft tissues.

### PHYSIOLOGY OF CALCIUM AND PHOSPHATE REGULATION

A number of hormones interact to regulate the calcium and phosphate ions. The most important are parathyroid hormone (PTH) and 1,25-dihydroxyvitamin D (calcitriol), which regulate mineral homeostasis by effects on the kidney, intestine, and bone (Figure 61–3).

**Parathyroid Hormone (PTH)**

PTH is a polypeptide hormone that helps to regulate plasma Ca\(^{2+}\) by affecting bone resorption/formation, renal Ca\(^{2+}\) excretion/reabsorption, and calcitriol synthesis (thus gastrointestinal Ca\(^{2+}\) absorption).

**History.** Sir Richard Owen, the curator of the British Museum of Natural History, discovered the parathyroid glands in 1852 while dissecting a rhinoceros that had died in the London Zoo. Credit for discovery of the human parathyroid glands usually is given to Sandstrom, a Swedish medical student who published an anatomical report in 1890. In 1891, von Recklinghausen reported a new bone disease, which he termed “osteitis fibrosa cystica,” which Askanazy subsequently described in a patient with a parathyroid tumor in...
Calcium homeostasis and its regulation by parathyroid hormone (PTH) and 1,25-dihydroxyvitamin D. PTH has stimulatory effects on bone and kidney, including the stimulation of 1α-hydroxylase activity in kidney mitochondria leading to the increased production of 1,25-dihydroxyvitamin D (calcitriol) from 25-hydroxycholecalciferol, the monohydroxylated vitamin D metabolite (see Figure 61–6). Calcitriol is the biologically active metabolite of vitamin D. Solid lines indicate a positive effect; dashed lines refer to negative feedback.

Figure 61–3. Calcium homeostasis and its regulation by parathyroid hormone (PTH) and 1,25-dihydroxyvitamin D. PTH has stimulatory effects on bone and kidney, including the stimulation of 1α-hydroxylase activity in kidney mitochondria leading to the increased production of 1,25-dihydroxyvitamin D (calcitriol) from 25-hydroxycholecalciferol, the monohydroxylated vitamin D metabolite (see Figure 61–6). Calcitriol is the biologically active metabolite of vitamin D. Solid lines indicate a positive effect; dashed lines refer to negative feedback.

1904. The glands were rediscovered a decade later by Gley, who determined the effects of their extirpation with the thyroid. Vassale and Generali then successfully removed only the parathyroids and noted that tetany, convulsions, and death quickly followed unless calcium was given postoperatively.

MacCallum and Voegtlin first noted the effect of parathyroidectomy on plasma Ca\(^{2+}\). The relation of low plasma Ca\(^{2+}\) concentration to symptoms was quickly appreciated, and a comprehensive picture of parathyroid function began to form. Active glandular extracts alleviated hypocalcemic tetany in parathyroidectomized animals and raised the level of plasma Ca\(^{2+}\) in normal animals. For the first time, the relation of clinical abnormalities to parathyroid hyperfunction was appreciated.

While American and British investigators used physiological approaches to explore the function of the parathyroid glands, German and Austrian pathologists related the skeletal changes of osteitis fibrosa cystica to the presence of parathyroid tumors; these two diverse types of investigations finally arrived at the same conclusions. Much of the history of the parathyroid has been recounted by Carney (1996).

Chemistry. Human, bovine, and porcine PTH molecules are all single polypeptide chains of 84 amino acids with molecular masses of approximately 9500 daltons. Biological activity is associated with the N-terminal portion of the peptide; residues 1 to 27 are required for optimal binding to the PTH receptor and hormone activity. Derivatives lacking the first or second residue bind to PTH receptors but do not activate the cyclic AMP or IP\(_3\)-Ca\(^{2+}\) signaling pathways. The PTH fragment lacking the first six amino acids inhibits PTH action.

Synthesis, Secretion, and Immunoassay. PTH is synthesized as a 115-amino-acid translation product called preproparathyroid hormone. This single-chain peptide is converted to preproparathyroid hormone by cleavage of 25-amino-terminal residues as the peptide is transferred to the intracisternal space of the endoplasmic reticulum. Preparathyroid hormone then moves to the Golgi complex, where it is converted to PTH by cleavage of six amino acids. PTH(1–84) resides within secretory granules until it is discharged into the circulation. Neither preproparathyroid hormone nor proparathyroid hormone appears in plasma. The synthesis and processing of PTH have been reviewed (Jüppner et al., 2001).

A major proteolytic product of PTH is PTH(7–84). PTH(7–84) and other amino-truncated PTH fragments accumulate significantly during renal failure in part because they are cleared from the circulation predominantly by the kidneys, whereas intact PTH is also removed by extrarenal mechanisms. Rather than competitively displacing PTH(1–84), PTH(7–84) may inhibit the PTH receptor by causing it to internalize from the plasma membrane in a cell-specific manner (Sneddon et al., 2003).

During periods of hypocalemia, more PTH is secreted and less is hydrolyzed. In this setting, PTH(7–84) release is augmented. In prolonged hypocalemia, PTH synthesis also increases, and the gland hypertrophies.

PTH(1–84) has a half-life in plasma of 2 to 5 minutes; removal by the liver and kidney accounts for about 90% of its clearance. As noted earlier, metabolism of PTH generates smaller fragments [e.g., PTH(7–84)] that also circulate in blood and are measured by standard immunoradiometric assays (IRMAs) using two monoclonal antibodies, one directed toward but not at the amino terminus and the other directed toward the carboxyl-terminal portion of the hormone. Large amino-terminal PTH fragments such as PTH(7–84) also react with antibodies prepared against the intact hormone and are measured by standard IRMAs. Therefore, second-generation PTH assays have been developed that differentiate between PTH(1–84), or whole PTH, and “intact” PTH [PTH(1–84) and PTH(7–84)]. The ability to measure whole PTH separately from large amino-terminally truncated PTH fragments has increased the accuracy of laboratory testing of parathyroid and bone status in patients with renal failure (Monier-Faugere et al., 2001).

Physiological Functions. The primary function of PTH is to maintain a constant concentration of Ca\(^{2+}\) in the extracellular fluid. The principal processes regulated are renal Ca\(^{2+}\) absorption and mobilization of bone Ca\(^{2+}\) (Figure 61–3). PTH also affects a variety of nonclassical
target tissues that include cartilage, vascular smooth muscle, placenta, liver, pancreatic islets, brain, dermal fibroblasts, and lymphocytes (Tian et al., 1993; Urena et al., 1993). The actions of PTH on its target tissues are mediated by at least two receptors. The PTH-1 receptor (PTH1R or PTH/PTHrP receptor) also binds PTH-related protein (PTHrP), and the PTH-2 receptor, found in vascular tissues, brain, pancreas, and placenta, binds only PTH. Both of these are G protein–coupled receptors that can couple with Gs and Gq in cell-type specific manners; thus, cells may show one, the other, or both types of responses. There is also evidence that PTH can activate phospholipase D through a G_{12/13}–RhoA pathway (Singh et al., 2005). A third receptor, designated the CPTH receptor, interacts with forms of PTH that are truncated in the amino-terminal region but that contain most of the carboxy terminus.

**Regulation of Secretion.** Plasma Ca^{2+} is the major factor regulating PTH secretion. As the concentration of Ca^{2+} diminishes, PTH secretion increases. Sustained hypocalcemia induces parathyroid hypertrophy and hyperplasia. Conversely, if the concentration of Ca^{2+} is high, PTH secretion decreases. Studies of parathyroid cells in culture show that amino acid transport, nucleic acid and protein synthesis, cytoplasmic growth, and PTH secretion are all stimulated by low concentrations of Ca^{2+} and suppressed by high concentrations. Thus, Ca^{2+} itself appears to regulate parathyroid gland growth as well as hormone synthesis and secretion.

Changes in plasma Ca^{2+} regulate PTH secretion by the plasma membrane–associated calcium-sensing receptor (CaSR) on parathyroid cells (Brown and MacLeod, 2001). The CaSR is a GPCR that couples with G_{q}–PLC and G_{i}. Occupancy of the CaSR by Ca^{2+} inhibits PTH secretion, whereas reduced CaSR occupancy promotes hormone secretion. Thus, the extracellular concentration of Ca^{2+} is controlled by a classical negative-feedback system, the afferent limb of which is sensitive to the ambient activity of Ca^{2+} and the efferent limb of which releases PTH. Acting via the CaSR, hypercalcemia reduces intracellular cyclic AMP content and protein kinase C (PKC) activity, whereas hypocalcemia leads to activation of PKC. However, the precise links between these changes and alterations in PTH secretion remain to be defined. Other agents that increase parathyroid cell cyclic AMP levels, such as β adrenergic receptor agonists and dopamine, also increase PTH secretion, but the magnitude of response is far less than that seen with hypocalcemia. The active vitamin D metabolite, 1,25-dihydroxyvitamin D (calcitriol), directly suppresses PTH gene expression. There appears to be no relation between physiological concentrations of extracellular phosphate and PTH secretion, except insofar as changes in phosphate concentration alter circulating Ca^{2+}. Severe hypermagnesemia or hypomagnesemia can inhibit PTH secretion.

**Effects on Bone.** PTH increases bone resorption and thereby increases Ca^{2+} delivery to the extracellular fluid. This process involves the release of organic and mineral matrix components (see below). The apparent skeletal target cell for PTH is the osteoblast, although evidence for the presence of PTH receptors on mammalian osteoblasts is limited (Manen et al., 1998). PTH also recruits osteoclast precursor cells to form new bone remodeling units (see below). Sustained increases in circulating PTH cause characteristic histological changes in bone that include an increase in the prevalence of osteoclastic resorption sites and in the proportion of bone surface that is covered with unmineralized matrix (Martin and Ng, 1994).

Direct effects of PTH on osteoblasts in vitro generally are inhibitory and include reduced formation of type I collagen, alkaline phosphatase, and osteocalcin. However, the response to PTH in vivo reflects not only hormone action on individual cells but also the increased total number of active osteoblasts owing to initiation of new remodeling units. Thus plasma levels of osteocalcin and alkaline phosphatase activity actually may be increased. No simple model can fully explain the molecular basis of PTH effects on bone. PTH stimulates cyclic AMP production in osteoblasts, but there also is evidence that intracellular Ca^{2+} mediates some PTH actions.

**Effects on Kidney.** In the kidney, PTH enhances the efficiency of Ca^{2+} reabsorption, inhibits tubular reabsorption of phosphate, and stimulates conversion of vitamin D to its biologically active form, calcitriol (Figure 61–3; see below). As a result, filtered Ca^{2+} is avidly retained, and its concentration increases in plasma, whereas phosphate is excreted, and its plasma concentration falls. Newly synthesized calcitriol interacts with specific high-affinity receptors in the intestine to increase the efficiency of intestinal Ca^{2+} absorption, thereby also increasing the plasma Ca^{2+} concentration.

**Calcium.** PTH increases tubular reabsorption of Ca^{2+} with concomitant decreases in urinary Ca^{2+} excretion. The effect occurs at distal nephron sites (Friedman, 1999). This action, along with mobilization of calcium from bone and increased absorption from the gut, increases the concentration of Ca^{2+} in plasma. Eventually, the increased glomerular filtration of Ca^{2+} overwhelms the stimulatory effect of PTH on tubular reabsorption, and hypercalciuria ensues. Conversely, reduction of serum PTH depresses tubular reabsorption of Ca^{2+} and thereby increases urinary Ca^{2+} excretion. When the plasma Ca^{2+} concentration falls below 7 mg/dl (1.75 mM), Ca^{2+} excretion decreases as the filtered load of Ca^{2+} reaches the point where the cation is almost completely reabsorbed despite reduced tubular capacity.

**Phosphate.** PTH increases renal excretion of inorganic phosphate by decreasing its reabsorption. This action is mediated by retrieval of the luminal membrane Na–P, cotransport protein rather than an effect on its activity. Patients with primary hyperparathyroidism therefore typically have low tubular phosphate reabsorption.
Cyclic AMP apparently mediates the renal effects of PTH on proximal tubular phosphate reabsorption. PTH-sensitive adenyl cyclase is located in the renal cortex, and cyclic AMP synthesized in response to the hormone affects tubular transport mechanisms. A portion of the cyclic AMP synthesized at this site, so-called nephrogenous cyclic AMP, escapes into the urine; measurement of urinary cyclic AMP is used as a surrogate for parathyroid activity and renal responsiveness.

**Other Ions.** PTH reduces renal excretion of Mg\(^{2+}\). This effect reflects the net result of increased renal Mg\(^{2+}\) reabsorption and increased mobilization of the ion from bone (Quamme, 1997). PTH increases excretion of water, amino acids, citrate, K\(^+\), increased mobilization of the ion from bone (Quamme, 1997).

**Calcitriol Synthesis.** The final step in the activation of vitamin D to calcitriol occurs in kidney proximal tubule cells. Three primary regulators govern the activity of the 25-hydroxyvitamin D\(_3\)-1α-hydroxylase that catalyzes this step: P\(_r\), PTH, and Ca\(^{2+}\) (see below for further discussion). Reduced circulating or tissue phosphate content rapidly increases calcitriol production, whereas hyperphosphatemia or hypercalcemia suppresses it. PTH powerfully stimulates calcitriol synthesis. Thus, when hypercalcemia causes a rise in PTH concentration, both the PTH-dependent lowering of circulating P\(_r\), and a more direct effect of the hormone on the 1α-hydroxylase lead to increased circulating concentrations of calcitriol.

**Integrated Regulation of Extracellular Ca\(^{2+}\) Concentration by PTH.** Even modest reductions of serum Ca\(^{2+}\) stimulate PTH secretion. For minute-to-minute regulation of Ca\(^{2+}\), adjustments in renal Ca\(^{2+}\) handling more than suffice to maintain plasma calcium homeostasis. With more prolonged hypocalcemia, the renal 1α-hydroxylase is induced, enhancing the synthesis and release of calcitriol that directly stimulates intestinal calcium absorption (Figure 61–3). In addition, delivery of calcium from bone into the extracellular fluid is stimulated. In the face of prolonged and severe hypocalcemia, new bone remodeling units are activated to restore circulating Ca\(^{2+}\) concentrations, albeit at the expense of skeletal integrity. When plasma Ca\(^{2+}\) activity rises, PTH secretion is suppressed, and tubular Ca\(^{2+}\) reabsorption decreases. The reduction in circulating PTH promotes renal phosphate conservation, and both the decreased PTH and the increased phosphate reduce calcitriol production and thereby decrease intestinal Ca\(^{2+}\) absorption. Finally, bone remodeling is suppressed. These integrated physiological events ensure a coherent response to positive or negative excursions of plasma Ca\(^{2+}\) concentration. In human beings, the importance of other hormones, such as calcitonin, to this scheme remains unsettled, but it is likely that these modulate the Ca\(^{2+}\)–parathyroid–vitamin D axis rather than serving as primary regulators.

**Vitamin D**

Vitamin D traditionally was viewed as a permissive factor in calcium metabolism because it was thought to permit efficient absorption of dietary calcium and to allow full expression of the actions of PTH. We now know that vitamin D exerts a more active role in calcium homeostasis. Vitamin D is actually a hormone rather than a vitamin; it is synthesized in mammals and, under ideal conditions, probably is not required in the diet. Receptors for the activated form of vitamin D are expressed in many cells that are not involved in calcium homeostasis, including hematopoietic cells, lymphocytes, epidermal cells, pancreatic islets, muscle, and neurons.

**History.** Vitamin D is the name applied to two related fat-soluble substances, cholecalciferol and ergocalciferol (Figure 61–4), that share the capacity to prevent or cure rickets. Prior to the discovery of vitamin D, a high percentage of urban children living in temperate zones developed rickets. Some researchers believed that the disease was due to lack of fresh air and sunshine; others claimed a dietary factor was responsible. Mellanby and Huldschinsky showed both notions to be correct; addition of cod liver oil to the diet or exposure to sunlight prevented or cured the disease. In 1924, it was found that ultraviolet irradiation of animal rations was as efficacious at curing rickets as was irradiation of the animal itself. These observations led to the elucidation of the structures of chole- and ergocalciferol and eventually to the discovery that these compounds require further processing in the body to become active. The discovery of metabolic activation is attributable primarily to studies conducted in the laboratories of DeLuca (DeLuca and Schnoes, 1976) and Kodicek (Mason et al., 1974).

**Chemistry and Occurrence.** Ultraviolet irradiation of several animal and plant sterols results in their conversion to compounds possessing vitamin D activity. The principal provitamin found in animal tissues is 7-dehydrocholesterol, which is synthesized in the skin. Exposure of the skin to sunlight converts 7-dehydrocholesterol to cholecalciferol (vitamin D\(_3\)) (Figure 61–4). Ergosterol, which is present only in plants, is the provitamin for vitamin D\(_2\) (ergocalciferol). Ergosterol and vitamin D\(_2\) differ from 7-dehydrocholesterol and vitamin D\(_3\), respectively, by the presence of a double bond between C22 and C23 and a methyl group at C24. Vitamin D\(_2\) is the active constituent of a number of commercial vitamin preparations, and is in irradiated bread and irradiated milk. In humans there is no practical difference between the antirachitic potencies of vitamin D\(_2\) and vitamin D\(_3\). Therefore, “vitamin D” will be used here as a collective term for vitamins D\(_2\) and D\(_3\).

**Human Requirements and Units.** Although sunlight provides adequate vitamin D supplies in the equatorial belt, in temperate climates insufficient cutaneous solar radiation in winter may necessitate dietary vitamin D supplementation. It was assumed that vitamin D deficiency had been eliminated as a significant problem in the United States. However, recent evidence points to low circulating levels of vitamin D with a reemergence of vitamin D–
Figure 61–4. Photobiology and metabolic pathways of vitamin D production and metabolism. Numbering for select positions discussed in the text is shown.
related rickets. Potential factors contributing to the rise in vitamin D deficiency include diminished intake of vitamin D–fortified foods owing to concerns about fat intake; reduced intake of calcium-rich foods, including milk, in adolescents and young women of reproductive age; increased use of sunscreens and decreased exposure to sunlight to reduce the risk of skin cancer and prevent premature aging owing to exposure to ultraviolet radiation; and an increased prevalence and duration of exclusive breast-feeding (the combination of human milk, a poor source of vitamin D, and the high prevalence of low circulating vitamin D levels in U.S. women, particularly African-American mothers) (Nesby-O’Dell et al., 2002; Stokstad, 2003; Holick et al., 2005).

There is no consensus regarding optimal vitamin D intake, and determination of vitamin D requirements is remarkably unsupported by clinical measurements. The recommended dietary allowance of vitamin D for infants and children is 400 IU, or 10 μg. The basis for this dose was that it approximates that in a teaspoon (5 ml) of cod liver oil, which had long been considered safe and effective in preventing rickets (Vieth, 1999). On the basis that adults require less vitamin D than infants, the adult dose was set arbitrarily at 200 IU.

There are no recommended dietary allowances for vitamin D. However, the Food and Nutrition Board of the Institute of Medicine has developed Dietary Reference Intakes (DRI) for vitamins (Institute of Medicine, 2003). In both premature and normal infants, intake of 200 units per day of vitamin D from any source is considered adequate for optimal growth. During adolescence and beyond, this amount probably is also sufficient. There is some evidence that vitamin D requirements increase during pregnancy and lactation (Hollis and Wagner, 2004), where vitamin D doses of less than 1000 IU/day may be inadequate to maintain normal circulating 25-hydroxyvitamin D concentrations. Doses of 10,000 IU/day or less of vitamin D for up to 5 months do not elevate circulating 25-hydroxyvitamin D to concentrations greater than 90 ng/ml.

Absorption, Fate, and Excretion. Both vitamins D₂ and D₃ are absorbed from the small intestine, although vitamin D₃ may be absorbed more efficiently. Most of the vitamin appears first within chylomicrons in lymph. Bile is essential for adequate absorption of vitamin D; deoxycholic acid is the major constituent of bile in this regard (see Chapter 37). The primary route of vitamin D excretion is the bile; only a small percentage is found in the urine. Patients who have intestinal bypass surgery or otherwise have severe shortening or inflammation of the small intestine may fail to absorb vitamin D sufficiently to maintain normal levels; hepatic or biliary dysfunction also may seriously impair vitamin D absorption.

Absorbed vitamin D circulates in the blood in association with vitamin D–binding protein, a specific α-globulin. The vitamin disappears from plasma with a half-life of 19 to 25 hours but is stored in fat depots for prolonged periods.

Metabolic Activation. Whether derived from diet or endogenously synthesized, vitamin D requires modification to become biologically active. The primary active metabolite of the vitamin is calcitriol [1α,25-dihydroxyvitamin D, 1,25(OH)₂D₃], the product of two successive hydroxylations of vitamin D (Figure 61–4).

25-Hydroxylation of Vitamin D. The initial step in vitamin D activation occurs in the liver, where cholecalciferol and ergocalciferol are hydroxylated in the 25-position to generate 25-OH-cholecalciferol (25-OHD, or calcifediol) and 25-OH-ergocalciferol, respectively. 25-OHD is the major circulating form of vitamin D₃, it has a biological half-life of 19 days, and normal steady-state concentrations are 15 to 50 ng/ml. Reduced extracellular Ca²⁺ levels stimulate 1α-hydroxylation of 25-OHD, increasing the formation of biologically active 1,25(OH)₂D₃. In contrast, when Ca²⁺ concentrations are elevated, 25-OHD is inactivated by 24-hydroxylation. Similar reactions occur with 25-OH-ergocalciferol. Normal steady-state concentrations of 25-OHD in human beings are 15 to 50 ng/ml, although concentrations below 25 ng/ml may be associated with increased circulating PTH and greater bone turnover.

1α-Hydroxylation of 25-OHD. After production in the liver, 25-OHD enters the circulation and is carried by vitamin D–binding globulin. Final activation to calcitriol occurs primarily in the kidney but also takes place in other sites, including keratinocytes and macrophages (Hewison et al., 2004). The enzyme system responsible for 1α-hydroxylation of 25-OHD (CYP1α, 25-hydroxyvitamin D₃-1α-hydroxylase, 1α-hydroxylase) is associated with mitochondria in proximal tubules.

Vitamin D 1α-hydroxylase is subject to tight regulatory controls that result in changes in calcitriol formation appropriate for optimal calcium homeostasis. Dietary deficiency of vitamin D, calcium, or phosphate enhances enzyme activity. 1α-Hydroxylase is potently stimulated by PTH and probably also by prolactin and estrogen. Conversely, high calcium, phosphate, and vitamin D intakes suppress 1α-hydroxylase activity. Regulation (Figure 61–5) is both acute and chronic, the latter owing to changes in protein synthesis. PTH increases calcitriol production rapidly via a cyclic AMP–dependent pathway. Hypocalcemia can activate the hydroxylase directly in addition to affecting it indirectly by eliciting PTH secretion (Bland et al., 1999). Hypophosphatemia greatly increases 1α-hydroxylase activity (Haussler and McCain, 1977; Yoshida et al., 2001). Calcitriol controls 1α-hydroxylase activity by a negative-feedback mechanism that involves a direct action on the kidney, as well as inhibition of PTH secretion. The plasma half-life of calcitriol is estimated to be between 3 and 5 days in humans.

24-Hydroxylase. Calcitriol and 25-OHD are hydroxylated to 1,24,25(OH)₃D and 24,25(OH)₂D, respectively, by another renal enzyme, 24-hydroxylase, whose expression is induced by calcitriol and suppressed by factors that stimulate the 25-OHD-1α-hydroxylase. Both 24-hydroxylated compounds are less active than calcitriol and presumably represent metabolites destined for excretion.
Physiological Functions and Mechanism of Action.

Calcitriol augments absorption and retention of Ca$^{2+}$ and phosphate. Although regulation of Ca$^{2+}$ homeostasis is considered to be its primary function, accumulating evidence underscores the importance of calcitriol in a number of other processes (see below).

Calcitriol acts to maintain normal concentrations of Ca$^{2+}$ and phosphate in plasma by facilitating their absorption in the small intestine, by interacting with PTH to enhance their mobilization from bone, and by decreasing their renal excretion. It also exerts direct physiological and pharmacological effects on bone mineralization (Suda et al., 2003).

The mechanism of action of calcitriol is mediated by the interaction of calcitriol with the vitamin D receptor (VDR). Calcitriol binds to cytosolic VDRs within target cells, and the receptor–hormone complex translocates to the nucleus and interacts with DNA to modify gene transcription. The VDR belongs to the steroid and thyroid hormone receptor supergene family (Christakos et al., 2003). Calcitriol also exerts nongenomic effects (Farach-Carson and Nemere, 2003) that may require the presence of a functional VDR (Zanello and Norman, 2004).

Intestinal Absorption of Calcium. Calcium is absorbed predominantly in the duodenum, with progressively smaller amounts in the jejunum and ileum. Studies of Ca$^{2+}$ uptake by isolated cells reflect these differences and suggest that elevated amounts of transport are likely due to greater transport by each duodenal cell. The colon also contributes to calcium absorption because ileostomy reduces absorption.

In the absence of calcitriol, calcium absorption is inefficient and proceeds in a thermodynamically passive manner through the lateral intercellular spaces (paracellular pathway). Calcitriol increases the transcellular movement of Ca$^{2+}$ from the mucosal to the serosal surface of the duodenum. Transcellular Ca$^{2+}$ movement involves three processes: Ca$^{2+}$ entry across the mucosal surface, diffusion through the cell, and energy-dependent extrusion across the serosal cell membrane. Calcium is also secreted from serosal to mucosal compartments. Thus net calcium absorption is the difference between the two oppositely oriented vectorial processes. The complex mechanisms and the proteins mediating calcium absorption are still incompletely understood (Bronner, 2003). Evidence implicates TRPV6 Ca$^{2+}$ channels in mediating mucosal calcium entry in the intestine (Nijenhuis et al., 2003). In humans, TRPV6 is expressed in the duodenum and proximal jejunum (Barley et al., 2001). A calcium-poor diet up-regulates intestinal TRPV6 expression in mice (Van Cromphaut et al., 2001). This effect is greatly reduced in VDR knockout mice, suggesting that TRPV6 mediates calcium entry and is vitamin D–dependent. Calcitriol also up-regulates the calcium-binding protein calbindin-D$_{9K}$.

Ca$^{2+}$ absorption is potently augmented by calcitriol. It is likely that calcitriol enhances all three steps involved in intestinal Ca$^{2+}$ absorption: entry across mucosal brush border membranes, diffusion through the enterocytes, and active extrusion across serosal plasma membranes (Bronner, 2003). Calcitriol up-regulates the synthesis of calbindin-D$_{9K}$ and calbindin-D$_{28K}$ and the serosal plasma membrane Ca–ATPase. Calbindin-D$_{9K}$ enhances the extrusion of Ca$^{2+}$ by the Ca–ATPase, whereas the precise function of calbindin-D$_{28K}$ is unsettled.

Mobilization of Bone Mineral. Although vitamin D–deficient animals show obvious deficits in bone mineral, there is little evidence that calcitriol directly promotes mineralization. Thus, although VDR knockout mice exhibit severely impaired bone formation and mineralization, these deficiencies can be entirely corrected by a high-calcium diet. These results support the view that the primary role of calcitriol is to stimulate intestinal absorption of calcium, which, in turn, indirectly promotes bone mineralization. Indeed, children with rickets caused by mutations of the VDR have been treated successfully with intravenous infusions of Ca$^{2+}$ and phosphate (see below). In contrast, physiological doses of vitamin D promote mobilization of Ca$^{2+}$ from bone, and large doses cause excessive bone turnover. Although calcitriol-induced bone resorption may be reduced in parathyroidectomized animals, the response is restored when hyperphosphatemia is corrected. Thus, PTH and calcitriol act independently to enhance bone resorption.
Calcitriol increases bone turnover by multiple mechanisms (see Suda et al., 2003). Mature osteoclasts apparently lack the VDR. Acting by a non-VDR mechanism, calcitriol promotes the recruitment of osteoclast precursor cells to resorption sites, as well as the development of differentiated functions that characterize mature osteoclasts.

Osteoblasts, the cells responsible for bone formation, express the VDR, and calcitriol induces their production of several proteins, including osteocalcin, a vitamin K–dependent protein that contains γ-carboxyglutamic acid residues, and interleukin-1 (IL-1), a lymphokine that promotes bone resorption (Spear et al., 1988). Thus, the current view is that calcitriol is a bone-mobilizing hormone but not a bone-forming hormone. Osteoporosis is a disease in which osteoclast responsiveness to calcitriol or other bone-resorbing agents is profoundly impaired, leading to deficient bone resorption.

**Renal Retention of Calcium and Phosphate.** The effects of calcitriol on the renal handling of Ca\(^{2+}\) and phosphate are of uncertain importance. Calcitriol increases retention of Ca\(^{2+}\) independently of phosphate. The effect on Ca\(^{2+}\) is thought to proceed in distal tubules, whereas enhanced phosphate absorption occurs in proximal tubules.

**Other Effects of Calcitriol.** It now is evident that the effects of calcitriol extend beyond calcium homeostasis. Receptors for calcitriol are distributed widely throughout the body (see Pike, 1997). Calcitriol affects maturation and differentiation of mononuclear cells and influences cytokine production and immune function (Hayes et al., 2003). One focus of research is the potential use of calcitriol to inhibit proliferation and to induce differentiation of malignant cells (see van den Bemd et al., 2000). The possibility of dissociating the hypercalcemic effect of calcitriol from its actions on cell differentiation has encouraged the search for analogs that might be useful in cancer therapy. Calcitriol inhibits epidermal proliferation and promotes epidermal differentiation and therefore is a potential treatment for psoriasis vulgaris (Kragballe and Iversen, 1993) (see Chapter 62). Calcitriol also affects the function of skeletal muscle and brain (Carswell, 1997).

**Calcitonin**

*Calcitonin* is a hypocalcemic hormone whose actions generally oppose those of PTH.

**History and Source.** Copp observed in 1962 that perfusion of canine parathyroid and thyroid glands with hypercalcemic blood caused a transient hypocalcemia that occurred significantly earlier than that caused by total parathyroidectomy. He concluded that the parathyroid glands secreted a calcium-lowering hormone (calcitonin) in response to hypercalcemia and in this way normalized plasma Ca\(^{2+}\) concentrations. The physiological relevance of calcitonin has been challenged vigorously: Calcitonin normally circulates at remarkably low levels; surgical removal of the thyroids has no appreciable effect on calcium metabolism; and conditions associated with profound elevations of serum calcitonin concentration are not accompanied by hypocalcemia (Hirsch and Baruch, 2003). The primary interest in calcitonin arises from its pharmacologic use in treating Paget’s disease and hypercalcemia and in its diagnostic use as a tumor marker for medullary carcinoma of the thyroid (see below).

The thyroid parafollicular C cells are the site of production and secretion of calcitonin. Human C cells, which are derived from neural crest ectoderm, are distributed widely in the thyroid, parathyroid, and thymus. In nonmammalian vertebrates, calcitonin is found in ultimobranchial bodies, which are separate organs from the thyroid gland.

The calcitonin gene is localized on human chromosome 11p and contains six exons (Figure 61–6). The primary transcript is alternatively spliced in a tissue-specific manner. In thyroid C cells, the calcitonin/calcitonin gene-related peptide (CGRP) pre-mRNA is processed primarily with common exons 2 and 3 to include exon 4. This leads to production of the 32-amino-acid peptide calcitonin, along with a flanking 21-amino-acid peptide called katacalcin, whose physiological significance is unknown. In neuronal cells, on the other hand, most of the calcitonin/CGRP pre-mRNA, is processed to exclude exon 4, resulting in inclusion of exons 5 and 6 with common exons 2 and 3, which ultimately gives rise to CGRP. This results in the production of the 37-amino-acid CGRP. Calcitonin is the most potent peptide inhibitor of osteoclast-mediated bone resorption and helps to protect the skeleton during periods of “calcium stress,” such as growth, pregnancy, and lactation. CGRP and the closely related peptide adrenomedullin, are potent endogenous vasodilators.

**Chemistry and Immunoreactivity.** Calcitonin is a single-chain peptide of 32 amino acids with a disulfide bridge linking the cysteine residues in positions 1 and 7 (Figure 61–7). In all species, 8 of the 32 residues are invariant, including the disulfide bridge and a carboxyl-terminal proline amid: both structural features are essential for biological activity. The residues in the middle portion of the molecule (positions 10 to 27) are more variable and apparently influence potency and/or duration of action. Calcitonins derived from salmon and eel differ from the human hormone by 13 and 16 amino acid residues, respectively, and are more potent than mammalian calcitonin. Salmon calcitonin is used therapeutically in part because it is cleared more slowly from the circulation (see below).

**Regulation of Secretion.** The biosynthesis and secretion of calcitonin are regulated by the plasma Ca\(^{2+}\) concentration. Calcitonin secretion increases when plasma Ca\(^{2+}\) is high and decreases when plasma Ca\(^{2+}\) is low. Multiple forms of calcitonin are found in plasma, including high-molecular-weight aggregates or cross-linked products. Assays for the intact monomeric peptide are now available. The circulating concentrations of calcitonin are low, normally less than 15 and 10 pg/ml for males and females, respectively. The circulating half-life of calcitonin is about 10 minutes. Abnormally elevated levels of calcitonin are characteristic of thyroid C-cell hyperplasia and medullary thyroid carcinoma.

Calcitonin secretion is stimulated by a number of agents, including catecholamines, glucagon, gastrin, and cholecystokinin, but there is little evidence for a physiological role for secretion in response to these stimuli.

**Mechanism of Action.** Calcitonin actions are mediated by the calcitonin receptor (CTR), which is a member of
the PTH/secretin subfamily of GPCRs (Lin et al., 1991). Six human CTR subtypes occur through alternative splicing of coding and noncoding exons (Galson and Goldring, 2002). These isoforms exhibit distinct ligand-binding specificity and/or signal-transduction pathways and are distributed in a tissue-specific pattern. Of the most abundant isoforms, hCTRI1 + preferentially couples with the Gs–adenylyl cyclase pathway (Gorn et al., 1995). The hCTRI1 + isoform does not couple with phospholipase C (Naro et al., 1998) and therefore does not activate protein kinase C or trigger an increase in Ca2+.

Calcitonin receptors can dimerize with modulatory proteins to create receptors with high affinity for amylin (Hay et al., 2005).

The hypocalcemic and hypophosphatemic effects of calcitonin are caused predominantly by direct inhibition of osteoclastic bone resorption. Although calcitonin inhibits the effects of PTH on osteolysis, it inhibits neither PTH activation of bone cell adenyl cyclase nor PTH-induced uptake of Ca2+ into bone. Calcitonin interacts directly with receptors on osteoclasts to produce a rapid and profound decrease in ruffled border surface area, thereby diminishing resorptive activity.

Depressed bone resorption reduces urinary excretion of Ca2+, Mg2+, and hydroxyproline. Plasma phosphate concentrations are lowered owing also to increased urinary phosphate excretion. Direct renal effects of calcitonin vary with species. Acute administration of pharmacological doses of calcitonin increases urinary calcium excretion, whereas calcitonin inhibits renal calcium excretion at physiological concentrations. In humans, calcitonin increases fractional urinary calcium excretion in a dose-dependent manner in subjects given a modest calcium load (Carney, 1997).

**BONE PHYSIOLOGY**

The skeleton is the primary structural support for the body and also provides a protected environment for hematopoiesis. It contains both a large mineralized matrix and a highly active cellular compartment.

**Figure 61–6.** Alternative splicing of calcitonin/calcitonin gene–related peptide (CGRP).

**Figure 61–7.** Comparison of calcitonins from several species. Calcitonin is a 32-amino-acid polypeptide with a disulfide bond between residues 1 and 7 and a proline-amide at the C-terminus. The figure highlights the differences in amino acid sequence between human calcitonin and calcitonins of other species; lack of an entry indicates identity with human calcitonin. Salmon calcitonin is ~20 times more potent in humans than is human calcitonin.
**Figure 61–8. The bone remodeling cycle.** Osteoclast precursors fuse and are activated to resorb a lacuna in a previously quiescent surface. These cells are replaced by osteoblasts that deposit new bone to restore the integrity of the tissue. (Adapted from Skerry and Gowen, 1995.)

**Skeletal Organization.** Because their bone turnover rates differ, it is useful to consider the appendicular, or peripheral, skeleton as separate from the axial, or central, skeleton. Appendicular bones make up 80% of bone mass and are composed predominantly of compact cortical bone. Axial bones, such as the spine and pelvis, contain substantial amounts of trabecular bone within a thin cortex. Trabecular bone consists of highly connected bony plates that resemble a honeycomb. The intertrabecular interstices contain bone marrow and fat. Alterations in bone turnover are observed first and foremost in axial bone both because bone surfaces, where bone remodeling occurs, are more densely distributed in trabecular bone and because marrow precursor cells that ultimately participate in bone turnover lie in close proximity to trabecular surfaces.

**Bone Mass.** Bone mineral density (BMD) and fracture risk in later years reflect the maximal bone mineral content at skeletal maturity (peak bone mass) and the subsequent rate of bone loss. Major increases in bone mass, accounting for about 60% of final adult levels, occur during adolescence, mainly during years of highest growth velocity. Bone acquisition is largely complete by age 17 in girls and by age 20 in boys. Inheritance accounts for much of the variance in bone acquisition; other factors include circulating estrogen and androgens, physical activity, and dietary calcium.

Bone mass peaks during the third decade, remains stable until age 50, and then declines progressively. Similar trajectories occur for men and women of all ethnic groups. The fundamental accuracy of this model has been amply confirmed for cortical bone, although trabecular bone loss at some sites probably begins prior to age 50. In women, loss of estrogen at menopause accelerates the rate of bone loss. Primary regulators of adult bone mass include physical activity, reproductive endocrine status, and calcium intake. Optimal maintenance of BMD requires sufficiency in all three areas, and deficiency in one area is not compensated by excessive attention to another.

**Bone Remodeling.** Growth and development of endochondral bone are driven by a process called modeling. Once new bone is laid down, it is subject to a continuous process of breakdown and renewal called remodeling, by which bone mass is adjusted throughout adult life (Ballock and O’Keefe, 2003). Remodeling is carried out by myriad independent “bone remodeling units” throughout the skeleton (Figure 61–8). Remodeling proceeds on bone surfaces, about 90% of which are normally inactive, covered by a thin layer of lining cells. In response to physical or biochemical signals, recruitment of marrow precursor cells to the bone surface results in their fusion into the characteristic multinucleated osteoclasts that resorb, or excavate, a cavity into the bone.

Osteoclast production is regulated by osteoblast-derived cytokines such as IL-1 and IL-6. Studies have begun to clarify the mechanisms through which osteoclast production is regulated (see Suda et al., 1999). The receptor for activating NFκB (RANK) is an osteoclast protein whose expression is required for osteoclastic bone resorption. Its natural ligand, RANK ligand (RANKL; previously called osteoclast differentiation factor), is a membrane-spanning osteoblast protein. On binding to RANK, RANKL induces osteoclast formation (Khosla, 2001) (Figure 61–9). RANKL initiates the activation of mature osteoclasts, as well as the differentiation of osteoclast precursors. Osteoblasts produce osteoprotegerin (OPG), which acts as a decoy ligand for RANKL. Under conditions favoring increased bone resorption, such as estrogen deprivation, OPG is suppressed, RANKL binds to RANK, and osteoclast production increases. When estrogen sufficiency is reestablished, OPG increases and competes effectively with RANKL for binding to RANK. In certain model systems, OPG is superior to bisphosphonates in suppressing bone resorption and hypercalcemia (Morony, et al., 2005).

Completion of the resorption phase is followed by ingress of preosteoblasts derived from marrow stroma into the base of the resorption cavity. These cells develop the characteristic osteoblastic phenotype and begin to replace the resorbed bone by elaborating new bone matrix constituents, such as collagen and osteocalcin. Once the newly formed osteoid reaches a thickness of about 20 μm, mineralization begins. A complete remodeling cycle normally requires about 6 months.
If the replacement of resorbed bone matched the amount that was removed, remodeling would not change net bone mass. However, small bone deficits persist on completion of each cycle, reflecting inefficient remodeling dynamics. Consequently, lifelong accumulation of remodeling deficits underlies the well-documented phenomenon of age-related bone loss, a process that begins shortly after growth stops. Alterations in remodeling activity represent the final pathway through which diverse stimuli, such as dietary insufficiency, hormones, and drugs, affect bone balance. Changes in hormonal milieu often lead to an increase in the activation, or birth rate, of remodeling units. Examples include hyperthyroidism, hyperparathyroidism, and hypervitaminosis D. Other factors may impair osteoblast function, such as high doses of corticosteroids or ethanol. Finally, estrogen deficiency augments osteoclastic resorptive capacity by a proapoptotic action (Manolagas et al., 2002).

At any given time, a transient deficit in bone, the remodeling space, represents sites of bone resorption that have not yet filled in. Stimuli that alter the rate of emergence of new remodeling units will either increase or decrease the remodeling space until a new steady-state is established at an increased or decreased bone mass.

## Disorders of Mineral Homeostasis and Bone

### Abnormal Calcium Metabolism

**Hypercalcemia.** Moderate elevations of the concentration of Ca\(^{2+}\) in the extracellular fluid may have no clinically detectable effects. The degree of hypercalcemia and the rate of onset of the elevation in the serum calcium concentration largely dictate the extent of symptoms. Chronic elevation of serum Ca\(^{2+}\) to 12 to 14 mg/dl (3 to 3.5 mmol/L) generally causes few manifestations, whereas an acute rise to the same levels may cause marked neuromuscular manifestations owing to an increased threshold for excitation of nerve and muscle. Symptoms include fatigue, muscle weakness, anorexia, depression, diffuse abdominal pain, and constipation.

Hypercalcemia can result from a number of conditions. Ingestion of large quantities of calcium by itself generally does not cause hypercalcemia; exceptions are hyperthyroid subjects, who absorb Ca\(^{2+}\) with increased efficiency (Benker et al., 1988), and subjects with the uncommon milk-alkali syndrome, a condition caused by concurrent ingestion of large quantities of milk and absorbable alkali, resulting in impaired renal Ca\(^{2+}\) excretion and attendant hypercalcemia.

In an outpatient setting, the most common cause of hypercalcemia is primary hyperparathyroidism, which results from hypersecretion of PTH by one or more parathyroid glands. Secondary hyperparathyroidism, in contrast, arises as a compensation for reductions of circulating Ca\(^{2+}\) and is not associated with hypercalcemia.

Symptoms and signs of primary hyperparathyroidism include fatigue, exhaustion, weakness, polydipsia, polyuria, joint pain, bone pain, constipation, depression, anorexia, nausea, heartburn, nephrothiasis, and hematuria. This condition frequently is accompanied by significant hypophosphatemia owing to the effects of PTH in diminishing renal tubular phosphate reabsorption. Some patients have renal calculi and peptic ulceration, and a few display classical parathyroid skeletal disease. However, most patients show few, if any, symptoms, and those that are present are often vague and nonspecific. Contemporary IRMA that distinguish between full-length PTH(1–84) and “intact” PTH [PTH(1–84) + PTH(1–84)] obviate many of the difficulties with previous assays and, in conjunction with an elevated serum calcium, possess a diagnostic accuracy of greater than 90% (Gao et al., 2001; Jüppner and Potts, 2002; Silverberg et al., 2003).

**Familial benign hypercalcemia** (or familial hypocalciuric hypercalcemia) is a genetic disorder generally accompanied by extremely low urinary calcium excretion. Familial benign hypercalcemia results from heterozygous mutations in the Ca\(^{2+}\)-sensing receptor (Pollak et al., 1996). Hypercalcemia usually is mild, and circulating PTH often is normal to slightly elevated. The importance of making this diagnosis lies in the fact that patients mistakenly diagnosed as having primary hyperparathyroidism may undergo surgical exploration without discovery of an adenoma and without therapeutic benefit. Patients do not experience long-term clinical consequences, except for homozygous infants, who may have severe, even lethal, hypercalcemia. Diagnosis is established by demonstrating hypercalcemia in first-degree family members and a decreased fractional excretion of calcium.

Newly diagnosed hypercalcemia in hospitalized patients is caused most often by a systemic malignancy, either with or without bony metastasis. PTH-related protein (PTHrP) is a primitive, highly conserved protein that may be abnormally expressed in malignant tissue, particularly by squamous cell and other epithelial cancers. The substantial sequence homology of the amino-terminal portion of PTHrP with that of native PTH permits it to interact with the PTH-1 receptor in target tissues, thereby causing the hypercalcemia and hypophos-
Hypocalcemia. Mild hypocalcemia [i.e., reduction in ionized serum Ca\(^{2+}\) concentrations from normal to concentrations above 3.2 mg/dl (0.8 mM), approximately equal to a total serum Ca\(^{2+}\) concentration of 8 to 8.5 mg/dl (2 to 2.1 mM)] is usually asymptomatic. Again, the rapidity of change affects the clinical picture because patients exhibit greater signs and symptoms if the hypocalcemia develops acutely. The signs and symptoms of hypocalcemia include tetany and related phenomena such as paresthesias, increased neuromuscular excitability, laryngospasm, muscle cramps, and tonic-clonic convulsions. In chronic hypoparathyroidism, ectodermal changes—consisting of loss of hair, grooved and brittle fingernails, defects of dental enamel, and cataracts—are encountered; calcification in the basal ganglia may be seen on routine skull radiographs. Psychiatric symptoms such as emotional lability, anxiety, depression, and delusions often are present.

Combined deprivation of Ca\(^{2+}\) and vitamin D, as observed with malabsorption states or dietary deficiency, readily promotes hypocalcemia. When caused by malabsorption, hypocalcemia is accompanied by low concentrations of phosphate, total plasma proteins, and magnesium. Mg\(^{2+}\) deficiency may accentuate the hypocalcemia by diminishing the secretion and action of PTH. In infants with malabsorption or inadequate calcium intake, Ca\(^{2+}\) concentrations usually are depressed, with attendant hypophosphatemia resulting in rickets.

**Hypoparathyroidism** is most often a consequence of thyroid or neck surgery but also may be due to genetic or autoimmune disorders. In hypoparathyroidism, hypocalcemia is accompanied by hyperphosphatemia, reflecting decreased PTH action on renal phosphate transport.

**Pseudohyoparathyroidism** is a diverse family of hypocalcemic and/or hyperparathyreotic disorders. Pseudohypoparathyroidism results from resistance to PTH rather than PTH deficiency; this resistance is not due to mutations of the PTH receptor but rather to mutations in G\(_\alpha\) (GNAS1), which normally mediates hormone-induced adenylyl cyclase activation (Yu et al., 1999). The variable phenotypes arising from GNAS1 defects apparently are due to different epigenetic imprinting of the maternal and paternal alleles (Levine et al., 2003). Multiple hormonal abnormalities have been associated with the GNAS1 mutation, but none is as severe as the deficient response to PTH.

Hypocalcemia is not unusual in the first several days following removal of a parathyroid adenoma. If hyperphosphatemia is also present, the condition is one of functional hypothyroidism owing to temporary failure of the remaining parathyroid glands to compensate for the missing adrenomatous tissue. In patients with parathyroid bone disease, postoperative hypocalcemia associated with hyperphosphatemia may reflect rapid uptake of calcium into bone, the “hungry bone” syndrome. In this setting, persistent, severe hypocalcemia may require administration of vitamin D and supplemental calcium for several months.

Neonatal tetany resulting from hypocalcemia sometimes occurs in infants of mothers with hyperparathyroidism; indeed, the tetany may call attention to the mother’s disorder. This problem disappears when the infant’s own parathyroid glands develop sufficiently to respond appropriately.

Hypocalcemia is associated with advanced renal insufficiency accompanied by hyperphosphatemia. Many patients with this condition do not develop tetany unless the accompanying acidosis is treated, which decreases the ionized calcium. High concentrations of phosphate in plasma inhibit the conversion of 25-hydroxycholecalciferol to 1,25-dihydroxycholecalciferol. Hypocalcemia also can occur following massive transfusions with citrated blood, which chelates calcium.

**Disturbed Phosphate Metabolism**

Dietary inadequacy very rarely causes phosphate depletion. Sustained use of antacids, however, can severely limit phosphate absorption and result in clinical phosphate depletion, manifest as malaise, muscle weakness, and osteomalacia (see Chapter 36). Osteomalacia, as described further below, is characterized by undermineralized bone matrix and may occur when sustained phosphate depletion is caused by inhibiting its absorption in the gastrointestinal tract (as with aluminum-containing antacids) or by excess renal excretion owing to PTH action.

Hyperphosphatemia is an important component of the bone disease seen in chronic renal failure. In this condition, phosphate retention is primary and reflects the degree of renal compromise. The increased phosphate level reduces the serum Ca\(^{2+}\) concentration, which, in turn, activates the parathyroid gland calcium-sensing receptor, stimulates
PTH secretion, and exacerbates the hyperphosphatemia. The continuing hyperphosphatemia may be modified by vigorous administration of aluminum hydroxide gel or calcium carbonate supplements. As discussed below, the Food and Drug Administration (FDA) recently approved therapeutic use of the calcium-sensing receptor agonist cinacalcet to suppress PTH secretion.

Disorders of Vitamin D

Hypervitaminosis D. The acute or long-term administration of excessive amounts of vitamin D or enhanced responsiveness to normal amounts of the vitamin leads to derangements in calcium metabolism. The responses to vitamin D reflect endogenous vitamin D production, tissue reactivity, and vitamin D intake. Some infants may be hyperreactive to small doses of vitamin D. In adults, hypervitaminosis D results from overtreatment of hypoparathyroidism or secondary hyperparathyroidism of renal osteodystrophy and from faddist use of excessive doses. Toxicity in children also may occur following accidental ingestion of adult doses.

The amount of vitamin D necessary to cause hypervitaminosis varies widely. As a rough approximation, continued daily ingestion of 50,000 units or more by a person with normal parathyroid function and sensitivity to vitamin D may result in poisoning. Hypervitaminosis D is particularly dangerous in patients who are receiving digoxin because the toxic effects of the cardiac glycosides are enhanced by hypercalcemia (see Chapters 33 and 34).

The initial signs and symptoms of vitamin D toxicity are those associated with hypercalcemia (see above). Since hypercalcemia in vitamin D intoxication generally is due to very high circulating levels of 25-OHD, the plasma concentrations of PTH and calcitriol typically (but not uniformly) are suppressed. In children, a single episode of moderately severe hypercalcemia may arrest growth completely for 6 months or more, and the deficit in height may never be fully corrected. Vitamin D toxicity in the fetus is associated with excess maternal vitamin D intake or extreme sensitivity and may result in congenital supravalvular aortic stenosis. In infants, this anomaly frequently is associated with other stigmata of hypercalcemia.

Vitamin D Deficiency. Vitamin D deficiency results in inadequate absorption of Ca\(^{2+}\) and phosphate. The consequent decrease of plasma Ca\(^{2+}\) concentration stimulates PTH secretion, which acts to restore plasma Ca\(^{2+}\) at the expense of bone. Plasma concentrations of phosphate remain subnormal because of the phosphaturic effect of increased circulating PTH. In children, the result is a failure to mineralize newly formed bone and cartilage matrix, causing the defect in growth known as rickets. As a consequence of inadequate calcification, bones of individuals with rickets are soft, and the stress of weight bearing gives rise to bowing of the long bones.

In adults, vitamin D deficiency results in osteomalacia, a disease characterized by generalized accumulation of undermineralized bone matrix. Severe osteomalacia may be associated with extreme bone pain and tenderness. Muscle weakness, particularly of large proximal muscles, is typical and may reflect both hypophosphatemia and inadequate vitamin D action on muscle. Gross deformity of bone occurs only in advanced stages of the disease. Circulating 25-OHD concentrations below 8 ng/ml are highly predictive of osteomalacia.

Metabolic Rickets and Osteomalacia. These disorders are characterized by abnormalities in calcitriol synthesis or response.

Hypophosphatemic vitamin D–resistant rickets, in its most common form, is an X-linked disorder (XLH) of calcium and phosphate metabolism. Calcitriol levels are inappropriately normal for the observed degree of hypophosphatemia. Patients experience clinical improvement when treated with large doses of vitamin D, usually in combination with inorganic phosphate. Even with vitamin D treatment, calcitriol concentrations may remain lower than expected. The genetic basis for XLH has been defined (HYP Consortium, 1995). The affected protein, a phosphate-regulating gene with homologies to endopeptidases on the X chromosome (PHEx), is a neutral endopeptidase. The substrate for this enzyme likely is involved in renal phosphate transport. Syndromes closely related to XLH, in which phosphate levels are altered without significant net changes in serum concentrations of calcium, PTH, or 1,25(OH)\(_{2}\)D\(_{3}\), include hereditary hypophosphatemic rickets with hypercalciuria (HHRH) and autosomal dominant hypophosphatemic rickets. The latter disorder maps to chromosome 12p13.3 (Econs et al., 1997) and is associated with mutations in the gene encoding fibroblast growth factor 23 (White et al., 2001).

Vitamin D–dependent rickets (also called vitamin D–dependent rickets type I) is an autosomal recessive disease caused by an inborn error of vitamin D metabolism involving defective conversion of 25-OHD to calcitriol owing to mutations in CYP1\(\alpha\) (1α-hydroxylase). The condition responds to physiological doses of calcitriol.

Hereditary 1,25-dihydroxyvitamin D resistance (also called vitamin D–dependent rickets type II) is an autosomal recessive disorder that is characterized by hypocalcemia, osteomalacia, rickets, and total alopecia. Mutations of the vitamin D receptor cause vitamin D–dependent rickets type II (Malloy et al., 1999). Absolute hormone resistance results from premature stop mutations or missense mutations in the zinc finger DNA-binding domain. Several missense mutations in the ligand-binding domain also have been described that result in partial or complete hormone resistance. These mutations alter ligand binding or heterodimerization with the retinoid X receptor (RXR).

Serum abnormalities include low serum concentrations of calcium and phosphate and elevated serum alkaline phosphatase activity. The hypocalcemia leads to secondary hyperparathyroidism with elevated PTH levels and hypophosphatemia. The 25(OH)–vitamin D values are normal, whereas 1,25(OH)\(_{2}\)–vitamin D levels are elevated in type II vitamin D–dependent rickets. This clinical feature distinguishes hereditary vitamin D–dependent rickets type II from CYP1\(\alpha\) deficiency (vitamin D–dependent rickets type I), where serum 1,25(OH)\(_{2}\)–vitamin D values are depressed. Children affected by vitamin D–
dependent rickets type II are refractory even to massive doses of vitamin D and calcitriol, and they may require prolonged treatment with parenteral Ca\(^{2+}\). Some remission of symptoms has been observed during adolescence, but the basis of remission is unknown.

Renal osteodystrophy (renal rickets) is associated with chronic renal failure and is characterized by decreased conversion of 25-OHD to calcitriol. Phosphate retention decreases plasma Ca\(^{2+}\) concentrations, leading to secondary hyperparathyroidism. In addition, calcitriol deficiency impairs intestinal Ca\(^{2+}\) absorption and mobilization from bone. Hypocalcemia commonly results (although in some patients, prolonged and severe hyperparathyroidism eventually may lead to hypercalcemia). Aluminum deposition in bone also may play a role in the genesis of the skeletal disease.

### SPECIFIC DISORDERS OF BONE

**Osteoporosis**

Osteoporosis is a condition of low bone mass and microarchitectural disruption that results in fractures with minimal trauma. Osteoporosis is a major and growing public health problem in developed nations. Between 30% and 50% of women and between 15% and 30% of men suffer a fracture related to osteoporosis. Characteristic sites of fracture include vertebral bodies, the distal radius, and the proximal femur, but osteoporotic individuals have generalized skeletal fragility, and fractures at sites such as ribs and long bones also are common. Fracture risk increases exponentially with age and is associated with reduced survival after any type of fracture (Center et al., 1999).

Osteoporosis can be categorized as primary or secondary. In 1948, Albright and Reifenstein concluded that primary osteoporosis included two separate entities: one related to menopausal estrogen loss and the other to aging. This concept was extended by the proposal that primary osteoporosis represents two fundamentally different conditions: type I osteoporosis, characterized by loss of trabecular bone owing to estrogen lack at menopause, and type II osteoporosis, characterized by loss of cortical and trabecular bone in men and women owing to long-term remodeling inefficiency, dietary inadequacy, and activation of the parathyroid axis with age. It is not clear, however, that these two entities are truly distinct. Although many osteoporotic women undoubtedly have experienced excessive menopausal bone loss, it may be more appropriate to consider osteoporosis as the result of multiple physical, hormonal, and nutritional factors acting alone or in concert.

Secondary osteoporosis is due to systemic illness or medications such as glucocorticoids or phenytoin. The most successful approach to secondary osteoporosis is prompt resolution of the underlying cause or drug discontinuation. Whether primary or secondary, osteoporosis is associated with characteristic disordered bone remodeling, so the same therapies can be used.

**Paget’s Disease.** Paget’s disease is characterized by single or multiple foci of disordered bone remodeling. The etiology of the disease is uncertain but is thought to be the result of infection with the measles virus of the paramyxovirus family (Kurihara et al., 2000). It affects up to 2% to 3% of the population over age 60. The primary pathologic abnormality is increased bone resorption followed by exuberant new bone formation. However, the newly formed bone is disorganized and of poor quality, resulting in characteristic bowing, stress fractures, and arthritis of joints adjoining the involved bone. Pagetic lesions contain many abnormal multinucleated osteoclasts associated with a disordered mosaic pattern of bone formation. Pagetic bone is thickened and has abnormal microarchitecture. The altered bone structure can produce secondary problems, such as deafness, spinal cord compression, high-output cardiac failure, and pain. Malignant degeneration to osteogenic sarcoma is a rare but lethal complication of Paget’s disease.

### PHARMACOLOGICAL TREATMENT OF DISORDERS OF MINERAL ION HOMEOSTASIS AND BONE METABOLISM

**Hypercalcemia.** Hypercalcemia can be life-threatening. Such patients frequently are severely dehydrated because hypercalcemia compromises renal concentrating mechanisms. Thus, fluid resuscitation with large volumes of isotonic saline must be early and aggressive (6 to 8 L/day). Agents that augment Ca\(^{2+}\) excretion, such as loop diuretics (see Chapter 28), may help to counteract the effect of plasma volume expansion by saline but are contraindicated until volume is repleted because they otherwise will aggravate volume depletion and hypercalcemia.

Corticosteroids administered at high doses (e.g., 40 to 80 mg/day of prednisone) may be useful when hypercalcemia results from sarcoidosis, lymphoma, or hypervitaminosis D (see Chapter 59). The response to steroid therapy is slow; from 1 to 2 weeks may be required before plasma Ca\(^{2+}\) concentration falls.

Calcitonin (CALCIMAR, MACALCIN) may be useful in managing hypercalcemia. Reduction in Ca\(^{2+}\) can be rapid, although “escape” from the hormone commonly occurs within several days. The recommended starting dose is 4 units/kg of body weight administered subcutaneously every 12 hours; if there is no response within 1 or 2 days, the dose may be increased to a maximum of 8 units/kg every 12 hours. If the response after 2 more days is still unsatisfactory, the dose may be increased to a maximum of 8 units/kg every 6 hours.
**Plicamycin** *(mithramycin, MITHRACIN)* is a cytotoxic antibiotic that also decreases plasma Ca\(^{2+}\) concentrations by inhibiting bone resorption. Reduction in plasma Ca\(^{2+}\) concentrations occurs within 24 to 48 hours when a relatively low dose of this agent is given (15 to 25 μg/kg of body weight) to minimize the high systemic toxicity of the drug.

Intravenous bisphosphonates *(pamidronate, zoledronate)* have proven very effective in the management of hypercalcemia *(see below for further discussion of bisphosphonates)*. These agents potently inhibit osteoclastic bone resorption. Oral bisphosphonates are less effective for treating hypercalcemia. Therefore, pamidronate *(AREDIA)* is given as an oral dose of about 30 mg/m^2 body weight) to minimize the high systemic toxicity of the drug.

**Oral bisphosphonates** *(pamidronate, zoledronate)* have proven very effective in the management of hypercalcemia *(see below for further discussion of bisphosphonates)*. These agents potently inhibit osteoclastic bone resorption. Oral bisphosphonates are less effective for treating hypercalcemia. Therefore, pamidronate *(AREDIA)* is given as an intravenous infusion of 60 to 90 mg over 4 to 24 hours. With pamidronate, resolution of hypercalcemia occurs over several days, and the effect usually persists for several weeks.

**Oral sodium phosphate** lowers plasma Ca\(^{2+}\) concentrations and may offer short-term calcemic control of some patients with primary hyperparathyroidism who are awaiting surgery. However, the risk of precipitating calcium phosphate salts in soft tissues throughout the body is of concern. In light of satisfactory responses to other agents, administration of intravenous sodium phosphate is not recommended as a treatment for hypercalcemia.

Once the hypercalcemic crisis has resolved or in patients with milder calcium elevations, therapy turns to more durable resolution of the hypercalcemic state. Parathyroidectomy remains the only definitive treatment for primary hyperparathyroidism. Specific indications for surgery have been proposed *(Bilezikian et al., 2002)*. In the hands of a skilled parathyroid surgeon, resection of a single adenoma *(about 80% of cases)* or of the hyperplastic glands *(about 15% of cases)* cures hyperparathyroidism. Complications include transient postoperative hypocalcemia, which may reflect temporary disruption of blood supply to the remaining parathyroid tissue or skeletal avidity for calcium, and permanent hypoparathyroidism. As described below, a calcium mimetic that stimulates the calcium-sensing receptor is a promising new therapy for hyperparathyroidism that may be used increasingly in the future.

Therapy of hypercalcemia of malignancy ideally is directed at the underlying cancer. When this is not possible, parenteral bisphosphonates often will maintain calcium levels within an acceptable range.

**Hypocalcemia and Other Therapeutic Uses of Calcium.** Hypoparathyroidism is treated primarily with vitamin D *(see below)*. Dietary supplementation with Ca\(^{2+}\) also may be necessary.

Calcium is used in the treatment of calcium deficiency states and as a dietary supplement. Ca\(^{2+}\) salts are specific in the immediate treatment of hypocalcemic tetany regardless of etiology. In severe tetany, symptoms are best brought under control by intravenous medication. Calcium chloride *(CaCl\(_2\);H\(_2\)O)* contains 27% Ca\(^{2+}\); it is valuable in the treatment of hypocalcemic tetany and laryngospasm. The salt is given intravenously and *must never be injected into tissues*. Injections of calcium chloride are accompanied by peripheral vasodilation and a cutaneous burning sensation. The salt usually is given intravenously in a concentration of 10% (equivalent to 1.36 mEq Ca\(^{2+}/\)ml). The rate of injection should be slow (not over 1 ml/min) to prevent cardiac arrhythmias from a high concentration of Ca\(^{2+}\). The injection may induce a moderate fall in blood pressure owing to vasodilatation. Since calcium chloride is an acidifying salt, it is usually undesirable in the treatment of the hypocalcemia caused by renal insufficiency. Calcium gluceptate injection *(a 22% solution; 18 mg or 0.9 mEq of Ca\(^{2+}/\)ml)* is administered intravenously at a dose of 5 to 20 ml for the treatment of severe hypocalcemic tetany; the injection produces a transient tingling sensation when given too rapidly. When the intravenous route is not possible, injections may be given intramuscularly in the gluteal region at a dose of up to 5 ml. A mild local reaction may result. Calcium gluconate injection *(a 10% solution; 9.3 mg of Ca\(^{2+}/\)ml)* given intravenously is the treatment of choice for severe hypocalcemic tetany. Patients with moderate-to-severe hypocalcemia may be treated by intravenous infusion of calcium gluconate at a dose of 10 to 15 mg of Ca\(^{2+}/\)kg of body weight over 4 to 6 hours. Since the usual 10-ml vial of a 10% solution contains only 93 mg Ca\(^{2+}\), many vials are needed. The intramuscular route should not be employed because abscess formation at the injection site may result.

For control of milder hypocalcemic symptoms, oral medication suffices, frequently in combination with vitamin D or one of its active metabolites. Calcium salts are acidifying, and different forms can be interchanged to avoid gastric irritation. Available Ca\(^{2+}\) salts include calcium carbonate, lactate, gluconate, phosphate, citrate, and hydroxyapatite. Calcium carbonate is prescribed most frequently, whereas calcium citrate may be absorbed more efficiently than other salts. However, absorption efficiency for most commonly prescribed calcium products is reasonable, and for many patients, cost and palatability outweigh modest differences in efficacy. Average doses for hypocalcemic patients are calcium gluconate, 15 g/day in divided doses; calcium lactate, 7.7 g plus 8 g lactose with each meal; and calcium carbonate or calcium phosphate, 1 to 2 g with meals.

Calcium carbonate and calcium acetate are used to restrict phosphate absorption in patients with chronic renal failure and oxalate absorption in patients with inflammatory bowel disease. Acute administration of calcium may be life-saving in patients with extreme hyperkalemia *(serum K\(^+\) > 7 mEq/L)*. Calcium gluconate *(10 to 30 ml of a 10% solution)* can reverse some of the cardioxic effects of hyperkalemia, providing time while other efforts are taken to lower the plasma K\(^+\) concentration.

Additional FDA-approved uses of calcium include intravenous treatment for black widow spider envenomation and management of magnesium toxicity. Use of supplemental calcium in the prevention and treatment of osteoporosis is discussed below.

**THERAPEUTIC USES OF VITAMIN D**

**Specific Forms of Vitamin D.** Calcitriol *(1,25-dihydroxycholecalciferol; CALCIJEX, ROCALTROL)* is available for oral administration or injection. Several derivatives of vitamin D *(Figure 61–10)* are of considerable experimental and therapeutic interest.
Doxercalciferol (1α-hydroxyvitamin D₂, HECTOROL) is a pro-drug that first must be activated by hepatic 25-hydroxylation to generate the biologically active compound, 1α,25-(OH)₂D₂ (Figure 61–10). The FDA has approved oral and intravenous preparations of 1α-hydroxyvitamin D₂ for use in treating secondary hyperparathyroidism, starting at 10 mg three times per week.

Dihydrotachysterol (DHT, ROXANE) is a reduced form of vitamin D₂. DHT is converted in the liver to its active form, 25-hydroxydihydrotachysterol. DHT is less than 1% as active as calcitriol in antirachitic assays but is much more effective in mobilizing bone mineral at high doses; it therefore can be used to maintain plasma Ca²⁺ in hypoparathyroidism. DHT is well absorbed from the gastrointestinal tract and maximally increases serum calcium concentration after 2 weeks of daily administration. The hypercalcemic effects typically persist for 2 weeks but can last for up to 1 month. DHT is available for oral administration in doses ranging from 0.2 to 1 mg/day (average 0.6 mg/day).

1α-Hydroxycholecalciferol (1-OHD₃, alphacalcidol; ONE-ALPHA) was introduced as a substitute for 1,25(OH)₂D₃; alphacalcidol is a synthetic vitamin D₃ derivative that is already hydroxylated in the 1α position and is rapidly hydroxylated by 25-hydroxylase to form 1,25-(OH)₂D₃. It is equal to calcitriol in assays for stimulation of intestinal absorption of Ca²⁺ and bone mineralization and does not require renal activation. It therefore has been used to treat renal osteodystrophy and is available in the United States for experimental purposes.

Ergocalciferol (calciferol, DRISDOL) is pure vitamin D₂. It is available for oral, intramuscular, or intravenous administration. Ergocalciferol is indicated for the prevention of vitamin D deficiency and the treatment of familial hypophosphatemia, hypoparathyroidism, and vitamin D–resistant rickets type II, typically in doses of 50,000 to 200,000 units/day in conjunction with calcium supplements.

Analogs of Calcitriol. Several vitamin D analogs (Figure 61–10) suppress PTH secretion by the parathyroid glands but have less or negligible hypercalcemic activity. They therefore offer a safer and more effective means of controlling secondary hyperparathyroidism.

Calcipotriol (calcipotriene) is a synthetic derivative of calcitriol with a modified side chain that contains a 22–23 double bond, a 24(S)-hydroxy functional group, and carbons 25 to 27 incorporated into a cyclopropane ring. Calcipotriol has comparable affinity with calcitriol for the vitamin D receptor, but it is less than 1% as active as calcitriol in regulating calcium metabolism. This reduced calcemic activity largely reflects the pharmacokinetics of calcipotriol (Kissmeyer and Binderup, 1991). Calcipotriol has been studied extensively as a treatment for psoriasis (see Chapter 62), although its mode of action is not known; a topical preparation (DOVONEX) is available for that purpose. In clinical trials, topical calcipotriol has been found to be slightly more effective than glucocorticoids with a good safety profile.

Paricalcitol (1,25-dihydroxy-19-norvitamin D₂, ZEMPLAR) is a synthetic calcitriol derivative that lacks the exocyclic C19 and has a vitamin D₂ rather than vitamin D₃ side chain (Figure 61–10). It reduces serum PTH levels without producing hypercalcemia or altering serum phosphorus (Martin et al., 1998). In an animal model, paricalcitol prevented or reversed PTH-induced high-turnover
bone disease (Slatopolsky et al., 2003). Paricalcitol administered intravenously is FDA approved for treating secondary hyperparathyroidism in patients with chronic renal failure.

22-Oxacalcitriol (1,25-dihydroxy-22-oxavitamin D₃, OCT, maxicalcitol, OXAROL) differs from calcitriol only in the substitution of C-22 with an oxygen atom. Oxacalcitriol has a low affinity for vitamin D–binding protein; as a result, more of the drug circulates in the free (unbound) form, allowing it to be metabolized more rapidly than calcitriol with a consequent shorter half-life. Oxacalcitriol is a potent suppressor of PTH gene expression and shows very limited activity on intestine and bone. It is a useful compound in patients with overproduction of PTH in chronic renal failure or even with primary hyperparathyroidism (Cunningham, 2004).

**Indications for Therapy with Vitamin D**

The major therapeutic uses of vitamin D may be divided into four categories: (1) prophylaxis and cure of nutritional rickets; (2) treatment of metabolic rickets and osteomalacia, particularly in the setting of chronic renal failure; (3) treatment of hypoparathyroidism; and (4) prevention and treatment of osteoporosis (discussed in the section on osteoporosis).

**Nutritional Rickets.** Nutritional rickets results from inadequate exposure to sunlight or deficiency of dietary vitamin D. The condition, once extremely rare in the United States and other countries where food fortification with the vitamin is practiced, is now increasing. Infants and children receiving adequate amounts of vitamin D–fortified food do not require additional vitamin D; however, breast-fed infants or those fed unfortified formula should receive 400 units of vitamin D daily as a supplement. The usual practice is to administer vitamin A in combination with vitamin D. A number of balanced vitamin A and D preparations are available for this purpose. Since the fetus acquires more than 85% of its calcium stores during the third trimester, premature infants are especially susceptible to rickets and may require supplemental vitamin D.

Treatment of fully developed rickets requires a larger dose of vitamin D than that used prophylactically. One thousand units daily will normalize plasma Ca²⁺ and phosphate concentrations in approximately 10 days, with radiographic evidence of healing within about 3 weeks. However, a larger dose of 3000 to 4000 units daily often is prescribed for more rapid healing, particularly when respiration is compromised by severe thoracic rickets.

Vitamin D may be given prophylactically in conditions that impair its absorption (e.g., diarrhea, steatorrhea, and biliary obstruction). Parenteral administration also may be used in such cases.

**Treatment of Osteomalacia and Renal Osteodystrophy.** Osteomalacia, distinguished by undermineralization of bone matrix, occurs commonly during sustained phosphate depletion. Patients with chronic renal disease are at risk for developing osteomalacia but also may develop a complex bone disease called renal osteodystrophy. In this setting, bone metabolism is stimulated by an increase in PTH and by a delay in bone mineralization that is due to decreased renal synthesis of calcitriol. In renal osteodystrophy, low bone mineral density may be accompanied by high-turnover bone lesions typically seen in patients with uncontrolled hyperparathyroidism or by low bone remodeling activity seen in patients with adynamic bone disease. The therapeutic approach to the patient with renal osteodystrophy depends on its specific type. In high-turnover (hyperparathyroid) or mixed high-turnover disease with deficient mineralization, dietary phosphate restriction, generally in combination with a phosphate binder, is recommended because phosphate restriction is limited by the need to provide adequate protein intake to maintain nitrogen balance. Although highly effective, aluminum is no longer used as a phosphate binder because it promotes adynamic bone disease, anemia, myopathy, and occasionally dementia. Calcium-containing phosphate binders along with calcitriol administration may contribute to oversuppression of PTH secretion and likewise result in adynamic bone disease and an increased incidence of vascular calcification. Highly effective non-calcium-containing phosphate binders have been developed. Sevelamer hydrochloride (RENAGEL), a nonabsorbable phosphate-binding polymer, effectively lowers serum phosphate concentration in hemodialysis patients, with a corresponding reduction in the calcium × phosphate product. Sevelamer hydrochloride consists of cross-linked poly[allylamine hydrochloride] that is resistant to digestive degradation. Partially protonated amines spaced one carbon from the polymer backbone chelate phosphate ions by ionic and hydrogen bonding. Side effects of sevelamer include vomiting, nausea, diarrhea, and dyspepsia. Sevelamer does not affect the bioavailability of digoxin, warfarin, enalapril, or metoprolol.

Renal osteodystrophy associated with low bone turnover (adynamic bone disease) is increasingly common and may be due to oversuppression of PTH with aggressive use of either calcitriol or other vitamin D analogs. While PTH levels generally are low (<100 pg/ml), a high PTH level does not exclude the presence of adynamic bone disease, especially with PTH assays that do not distinguish between biologically active and inactive PTH fragments (Monier-Faugere et al., 2001). Current guidelines suggest that treatment with an active vitamin D preparation is indicated if serum 25-OHD levels are less than 30 ng/ml and serum calcium is less than 9.5 mg/dl (2.37 mM). However, if 25-OHD and serum calcium levels are elevated, vitamin D supplementation should be discontinued. If the serum calcium level is less than 9.5 mg/dl, treatment with a vitamin D analog is warranted irrespective of the 25-OHD level (Eknoyan et al., 2003).

**Hypoparathyroidism.** Vitamin D and its analogs are a mainstay of the therapy of hypoparathyroidism. Dihydrotachysterol (DHT) has a faster onset, shorter duration of action, and a greater effect on bone mobilization than does vitamin D and traditionally has been a preferred agent. Calcitriol also is effective in the management of hypoparathyroidism and certain forms of pseudohypoparathyroidism in which endogenous levels of calcitriol are abnormally low. However, most hypoparathyroid patients respond to any form of vitamin D. Calcitriol may be preferred for temporary treatment of hypocalcemia while awaiting effects of a slower-acting form of vitamin D.

**Miscellaneous Uses of Vitamin D.** Vitamin D is used to treat hypophosphatemia associated with Fanconi syndrome. Large doses of vitamin D (over 10,000 units/day) are not useful in patients with osteoporosis and even can be dangerous. However, administration of 400 to 800 units/day of vitamin D to frail, elderly men and women has been shown to suppress bone remodeling, protect bone
mass, and reduce fracture incidence (see later section on osteoporosis). Clinical trials suggest that calcitriol may become an important agent for the treatment of psoriasis (Kowalzick, 2001). As such non-traditional uses of vitamin D are discovered, it will become important to develop noncalcemic analogs of calcitriol that achieve effects on cellular differentiation without the risk of hypercalcemia.

**Adverse Effects of Vitamin D Therapy**

The primary toxicity associated with calcitriol reflects its potent effect to increase intestinal calcium and phosphate absorption, along with the potential to mobilize osseous calcium and phosphate. Hypercalcemia, with or without hyperphosphatemia, commonly complicates calcitriol therapy and may limit its use at doses that effectively suppress PTH secretion. As described earlier, noncalcemic vitamin D analogs provide alternative interventions, although they do not obviate the need to monitor serum calcium and phosphorus concentrations.

Hypervitaminosis D is treated by immediate withdrawal of the vitamin, a low-calcium diet, administration of glucocorticoids, and vigorous fluid support. As noted earlier under hypercalcemia, forced saline diuresis with loop diuretics is also useful. With this regimen, the plasma Ca\(^{2+}\) concentration falls to normal, and Ca\(^{2+}\) in soft tissue tends to be mobilized. Conspicuous improvement in renal function occurs unless renal damage has been severe.

**CALCITONIN**

**Diagnostic Uses of Calcitonin**

Calcitonin is a sensitive and specific marker for the presence of medullary thyroid carcinoma (MTC), a neuroendocrine malignancy originating in thyroid parafollicular C cells. MTC can be hereditary (25%) or sporadic (75%) and is present in all patients with the multiple endocrine neoplasia type 2 (MEN2) syndromes. Because one form of MEN2 is inherited as a dominant trait, relatives of patients should be examined repeatedly by calcitonin measurements from early childhood. Because calcitonin levels may be low in early tumor stages or in premalignant C-cell hyperplasia, pentagastrin-induced calcitonin provides greater sensitivity and increased MTC detection (Karanikas et al., 2004). The identification of discrete mutations in the RET protooncogene in subjects with MEN2 offers hope that genetic screening will supplant reliance on testing serum calcitonin, which can give spurious results.

**Therapeutic Uses.** Calcitonin lowers plasma Ca\(^{2+}\) and phosphate concentrations in patients with hypercalcemia; this effect results from decreased bone resorption and is greater in patients in whom bone turnover rates are high. Although calcitonin is effective for up to 6 hours in the initial treatment of hypercalcemia, patients become refractory after a few days. This is likely due to receptor down-regulation (Takahashi et al., 1995). Use of calcitonin does not substitute for aggressive fluid resuscitation, and the bisphosphonates are the preferred agents (see above on hypercalcemia).

Calcitonin is effective in disorders of increased skeletal remodeling, such as Paget’s disease, and in some patients with osteoporosis. In Paget’s disease, chronic use of calcitonin produces long-term reductions of serum alkaline phosphatase activity and symptoms. Development of antibodies to calcitonin occurs with prolonged therapy, but this is not necessarily associated with clinical resistance. Side effects of calcitonin include nausea, hand swelling, urticaria, and rarely, intestinal cramping. Side effects appear to occur with equal frequency with human and salmon calcitonin. *Salmon calcitonin* is approved for clinical use. The latter product also is available as a nasal spray, introduced for once-daily treatment of postmenopausal osteoporosis (see below). For Paget’s disease, calcitonin generally is administered by subcutaneous injection because intranasal delivery is relatively ineffective owing to limited bioavailability. After initial therapy at 100 units/day, the dose typically is reduced to 50 units three times a week.

**BISPHOSPHONATES**

Bisphosphonates are analogs of pyrophosphate (Figure 61–11) that contain two phosphate groups attached to a geminal (central) carbon that replaces the oxygen in pyrophosphate. Because they form a three-dimensional structure capable of chelating divalent cations such as Ca\(^{2+}\), the bisphosphonates have a strong affinity for bone, targeting especially bone surfaces undergoing remodeling. Accordingly, they are used extensively in conditions characterized by osteoclast-mediated bone resorption, including osteoporosis, steroid-induced osteoporosis, Paget’s disease, tumor-associated osteolysis, breast and prostate cancer, and hypercalcemia. Recent evidence suggests that second- and third-generation bisphosphonates also may be effective anticancer drugs (see below). For a review of the basic and clinical pharmacology of bisphosphonates, see Licata (2005).

The clinical utility of bisphosphonates resides in their direct inhibition of bone resorption. First-generation bisphosphonates contain minimally modified side chains...
(R1, R2) (medronate, clodronate, and etidronate) or contain a chlorophenyl group (tiludronate) (Figure 61–11). They are the least potent and in some instances cause bone demineralization. Second-generation aminobisphosphonates (e.g., alendronate and pamidronate) contain a nitrogen group in the side chain. They are 10 to 100 times more potent than first-generation compounds. Third-generation bisphosphonates (e.g., risedronate and zoledronate) contain a nitrogen atom within a heterocyclic ring and are up to 10,000 times more potent than first-generation agents.

Bisphosphonates concentrate at sites of active remodeling. Because they are highly negatively charged, bisphosphonates are membrane impermeable but are incorporated into the bone matrix by fluid-phase endocytosis (Stenbeck and Horton, 2000). Bisphosphonates remain in the matrix until the bone is remodeled and then are released in the acid environment of the resorption lacunae beneath the osteoclast as the overlying mineral matrix is dissolved. The importance of this process for the antiresorptive effect of bisphosphonates is evidenced by the fact that calcitonin blocks the antiresorptive action.

Although bisphosphonates prevent hydroxyapatite dissolution, their antiresorptive action is due to direct inhibitory effects on osteoclasts rather than strictly physicochemical effects. The antiresorptive activity apparently involves two primary mechanisms: osteoclast apoptosis and inhibition of components of the cholesterol biosynthetic pathway.

The current model is that apoptosis accounts for the antiresorptive effect of first-generation bisphospho-
nates, whereas the inhibitory action of aminobisphosphonates proceeds through the latter mechanism. Consistent with this view, the antiresorptive effect of aminobisphosphonates such as alendronate and risedronate, but not of clodronate or etidronate, persists when apoptosis is suppressed (Halasy-Nagy et al., 2001). First-generation bisphosphonates are metabolized into a nonhydrolyzable ATP analog (AppCCLp) that accumulates within osteoclasts and induces apoptosis (Rogers, 2003). In contrast, the aminobisphosphonates such as alendronate and ibandronate directly inhibit multiple steps in the pathway from mevalonate to cholesterol and isoprenoid lipids, such as geranylgeranyl diphosphate, that are required for the prenylation of proteins that are important for osteoclast function. The potency of aminobisphosphonates for inhibiting farnesyl synthase correlates directly with their antiresorptive activity (Dunford et al., 2001).

**Available Bisphosphonates**

Several bisphosphonates are available in the United States (Figure 61–11). Etidronate sodium (DIDRONEL) is used for treatment of Paget’s disease and may be used parenterally to treat hypercalcemia. Since etidronate is the only bisphosphonate that inhibits mineralization, it has been supplanted largely by pamidronate and zoledronate for treating hypercalcemia. Pamidronate (AREDIA) is approved for management of hypercalcemia but also is effective in other skeletal disorders. Pamidronate is available in the United States only for parenteral administration. For treatment of hypercalcemia, pamidronate may be given as an intravenous infusion of 60 to 90 mg over 4 to 24 hours.

Several newer bisphosphonates have been approved for treatment of Paget’s disease. These include tiludronate (SKELID), alendronate (FOSAMAX), and risedronate (ACTONEL). Although the drug is approved only for treating hypercalcemia of malignancy, a single injection of zoledronate (ZOMETA) decreased bone turnover markers for 90 days in patients with Paget’s disease (Buckler et al., 1999). Tiludronate and the potent bisphosphonate ibandronate currently are under development for treatment of women with osteoporosis, with encouraging preliminary results.

**Absorption, Fate, and Excretion.** All oral bisphosphonates are very poorly absorbed from the intestine and have remarkably limited bioavailability (<1% (alendronate, risedronate) to 6% (etidronate tiludronate)). Thus these drugs should be administered with a full glass of water following an overnight fast and at least 30 minutes before breakfast. Oral bisphosphonates have not been used widely in children or adolescents because of uncertainty of long-term effects of bisphosphonates on the growing skeleton.

Bisphosphonates are excreted primarily by the kidneys. Adjusted doses for patients with diminished renal function have not been determined; bisphosphonates currently are not recommended for patients with a creatinine clearance of less than 30 ml/min.

**Adverse Effects.** As noted earlier, the first-generation bisphosphonate etidronate was associated with osteomalacia. This adverse effect, coupled with its relatively low efficacy, has limited its current use. Although alendronate and risedronate were well tolerated in clinical trials, some patients experience symptoms of esophagitis. Symptoms often abate when patients fastidiously take the medication with water and remain upright. Esophageal complications are infrequent when the drug is taken as described. If symptoms persist despite these precautions, use of a proton pump inhibitor at bedtime may be helpful (see Chapter 36). Both drugs may be better tolerated on a once-weekly regimen with no reduction of efficacy. Patients with active upper gastrointestinal disease should not be given oral bisphosphonates.

Mild fever and aches may attend the first parenteral infusion of pamidronate, likely owing to cytokine release. These symptoms are short-lived and generally do not recur with subsequent administration.

Zoledronate has been associated with renal toxicity, deterioration of renal function, and potential renal failure. Thus, the infusion should be given over at least 15 minutes, and the dose should be 4 mg. Patients who receive zoledronate should have standard laboratory and clinical parameters of renal function assessed prior to treatment and periodically after treatment to monitor for deterioration in renal function.

**Therapeutic Uses**

**Hypercalcemia.** The use of pamidronate in the management of malignancy-associated hypercalcemia was described earlier. Zoledronate appears to be more effective than pamidronate and at least as safe and can be infused over 15 minutes rather than 2 to 4 hours. It therefore has received FDA approval for this indication.

**Postmenopausal Osteoporosis.** Much interest is focused on the role of bisphosphonates in the treatment of osteoporosis (see “Osteoporosis,” below). Clinical trials show that treatment is associated with increased bone mineral density and protection against fracture.

**Cancer.** Bisphosphonates also may act as anticancer drugs by inhibiting the activation of cancer-associated proteins, such as Ras, through suppression of geranylgeranylation and farnesylation. Second- and third-generation bisphosphonates inhibit the proliferation of some cancer cells by preventing post-translational prenylation of Ras-related proteins. Zoledronate has been used successfully as an adjunct in treating Philadelphia chromosome–positive chronic myelogenous leukemia.
PARATHYROID HORMONE (PTH)

Continuous administration of PTH or high circulating PTH levels achieved in primary hyperparathyroidism causes bone demineralization and osteopenia. However, intermittent PTH administration promotes bone growth. Selye first described the anabolic action of PTH some 80 years ago, but this observation was largely ignored and generally forgotten. Beginning in the 1970s, studies focused on the anabolic action of PTH, culminating with FDA approval of synthetic human 34-amino-acid amino-terminal PTH fragment [hPTH(1–34), teriparatide] for use in treating severe osteoporosis (Hodsman et al., 2005). Full-length PTH(1–84) is likely to be approved in the near future; its benefits over PTH(1–34) are unclear.

Absorption, Fate, and Excretion. Pharmacokinetics and systemic actions of teriparatide on mineral metabolism are the same as for PTH. Teriparatide is administered by once-daily subcutaneous injection of 20 μg into the thigh or abdomen. With this regimen, serum PTH concentrations peak at 30 minutes after the injection and decline to undetectable concentrations within 3 hours, whereas the serum calcium concentration peaks at 4 to 6 hours after administration. Based on aggregate data from different dosage regimens, teriparatide bioavailability averages 95%. Teriparatide clearance averages 62 L/hour in women and 94 L/hour in men, which exceeds normal liver plasma flow, consistent with both hepatic and extrahepatic PTH removal. The serum half-life of teriparatide is approximately 1 hour when administered subcutaneously versus 5 minutes when administered intravenously. The longer half-life following subcutaneous administration reflects the time required for absorption from the injection site. The elimination of PTH(1–34) and full-length PTH proceeds by nonspecific enzymatic mechanisms in the liver, followed by renal excretion.

Clinical Effects. In postmenopausal women with osteoporosis, teriparatide increases BMD and reduces the risk of vertebral and nonvertebral fractures. Several laboratories have examined the effects of intermittent PTH on BMD in patients with osteoporosis. In these studies, teriparatide increased axial bone mineral, although initial reports of effects on cortical bone were disappointing. Coadministration of hPTH(1–34) with estrogen or synthetic androgen led to impressive gains in vertebral bone mass or trabecular bone. However, in some early studies there was only maintenance or even loss of cortical bone. Vitamin D insufficiency in patients at baseline or pharmacokinetic differences involving bioavailability or circulating half-life may have contributed to observed differences on cortical bone. The most comprehensive studies to date established the value of daily hPTH(1–34) administration on total BMD, with significant elevations of BMD in lumbar spine and femoral neck and with significant reductions of vertebral and nonvertebral fracture risk in osteoporotic women (Neer et al., 2001) and men (Finkelstein et al., 2003).

Candidates for teriparatide treatment include women who have a history of osteoporotic fracture, who have multiple risk factors for fracture, or who failed or are intolerant of previous osteoporosis therapy.

Adverse Effects. In rats, teriparatide increased the incidence of bone tumors, including osteosarcoma (Vahle et al., 2004). The clinical relevance of this finding is unclear, especially since patients with primary hyperparathyroidism have considerably higher elevations of serum PTH without a greater incidence of osteosarcoma. Nonetheless, teriparatide should not be used in patients who are at increased baseline risk for osteosarcoma (including those with Paget’s disease of bone, unexplained elevations of alkaline phosphatase, open epiphyses, or prior radiation therapy involving the skeleton). Full-length PTH(1–84), which is in clinical trials, has not been associated with osteosarcomas. Other adverse effects have included exacerbation of nephrolithiasis and elevation of serum uric acid levels.

CALCIUM SENSOR MIMETICS: CINACALCET

Calcimimetics are drugs that mimic the stimulatory effect of calcium to inhibit PTH secretion by the parathyroid glands. By enhancing the sensitivity of the CaSR to extracellular Ca²⁺, calcimimetics lower the concentration of Ca²⁺ at which PTH secretion is suppressed. The type II calcimimetics are phenylalkylamine derivatives that allosterically modulate the CaSR. Cinacalcet (SENSIPAR) (Figure 61–12) is FDA approved for the treatment of secondary hyperparathyroidism owing to chronic renal disease and for patients with hypercalcemia associated with parathyroid carcinoma. Cinacalcet lowers serum PTH levels in patients with normal or reduced renal function (Block et al., 2004; Barman Balfour and Scott, 2005). In clinical trials, cinacalcet at 20- to 100-mg doses lowered PTH levels in a concentration-dependent manner by 15% to 50% and serum calcium × phosphate product by 7% compared with placebo (Franceschini et al., 2003). Cinacalcet also effectively reduced PTH in patients with primary hyperparathyroidism and provided sustained normalization of serum calcium without altering bone mineral density (Shoback et al., 2003). Long-term control

Figure 61–12. Structure of cinacalcet. Cinacalcet exists as optical isomers. The R-enantiomer, which is more active, is shown.
of PTH levels was achieved during a 2-year study of cinacalcet, suggesting that resistance does not develop. There currently is insufficient information to know whether reducing serum PTH levels with cinacalcet improves outcomes such as risk of cardiovascular events, bone disease, or mortality.

Absorption, Fate, and Excretion. Cinacalcet (1R)-(–)-4-methyl-N-[3-[3-[trifluoromethyl]phenyl]propyl]-1-naphthalenemethanamine hydrochloride) exhibits first-order absorption, with maximal serum concentrations achieved 2 to 6 hours after oral administration. Maximal effects, as defined by the nadir of serum PTH, occur 2 to 4 hours after administration. After absorption, plasma concentrations of cinacalcet decrease with a half-life of 30 to 40 hours. Cinacalcet is eliminated primarily by renal excretion, with some 85% recovered in the urine after oral administration; the drug is also metabolized by multiple hepatic cytochromes, including CYP3A4, CYP2D6, and CYP1A2.

Cinacalcet is available in 30-, 60-, and 90-mg tablets. Optimal doses have not been defined. The recommended starting dose for treatment of secondary hyperparathyroidism in patients with chronic kidney disease on dialysis is 30 mg once daily, with a maximum of 180 mg/day. For treatment of parathyroid carcinoma, a starting dose of 30 mg twice daily is recommended, with a maximum of 90 mg four times daily. The starting dose is titrated upward every 2 to 4 weeks to maintain the PTH level between 150 and 300 pg/ml (secondary hyperparathyroidism) or to normalize serum calcium (parathyroid carcinoma).

Adverse Reactions. The principal adverse event with cinacalcet is hypocalcemia. Thus, the drug should not be used if the initial serum calcium concentration is less than 8.4 mg/dl; serum calcium and phosphorus concentrations should be measured within 1 week, and PTH should be measured within 4 weeks after initiating therapy or after changing dosage. Hypocalcemia can be diminished by initiating therapy with a low dose and gradually titrating it as necessary or adjusting the dose when vitamin D and/or phosphate binders are administered concomitantly. Patients on hemodialysis with low-calcium dialysate need to be monitored closely for hypocalcemia. Seizure threshold is lowered by significant reductions in serum Ca\textsuperscript{2+}, so patients with a history of seizure disorders should be monitored especially closely. Finally, adynamic bone disease may develop if the PTH level is less than 100 pg/ml, and the drug should be discontinued or the dose decreased if the PTH level falls below 150 pg/ml.

Drug Interactions. Potential drug interactions can be anticipated with drugs that interfere with calcium homeostasis or that hinder cinacalcet absorption. Based on these considerations, potentially interfering drugs may include vitamin D analogs, phosphate binders, bisphosphonates, calcitonin, glucocorticoids, gallium, and cisplatin. The other category of drug interactions is for compounds metabolized by CYPs. Caution is recommended when cinacalcet is coadministered with inhibitors of CYP3A4 (e.g., ketoconazole, erythromycin, or itraconazole), CYP2D6 (many β adrenergic receptor blockers, flecaïnide, vinblastine, and most tricyclic antidepressants), and many other drugs.

Osteoporosis is a major and growing public health problem in developed nations, causing fractures in 30% to 50% of women and 15% to 30% of men. Important reductions in fracture risk can be achieved with appropriate lifelong attention to prevention. Regular physical activity of reasonable intensity is endorsed at all ages. For children and adolescents, adequate dietary calcium is important if peak bone mass is to reach the level appropriate for genetic endowment. Attention to nutritional status (i.e., increased dietary calcium and calcium and/or vitamin D supplements) also may be required in the seventh decade and beyond. Although the administration of estrogen to women at menopause is a powerful intervention to preserve bone and protect against fracture, the detrimental effects of hormone-replacement therapy (HRT) have mandated a major reexamination on treatment options (see below and Chapter 57).

Pharmacological agents used to manage osteoporosis act by decreasing the rate of bone resorption and thereby slowing the rate of bone loss (antiresorptive therapy) or by promoting bone formation (anabolic therapy). Since bone remodeling is a coupled process, antiresorptive drugs ultimately decrease the rate of bone formation and therefore do not promote substantial gains in BMD. They nonetheless reduce fracture risk, particularly in the spine but also in the hip (for alendronate and risedronate). Increases in BMD during the first years of antiresorptive therapy represent a constriction of the remodeling space to a new steady-state level, after which BMD reaches a plateau (Figure 61–13). One consequence of this phenomenon is that therapeutic trials in osteoporosis must be of sufficient duration (i.e., at least 2 years) to determine whether an increase in BMD represents anything more than a simple reduction in remodeling space.

Pharmacologic treatment of osteoporosis is aimed at restoring bone strength and preventing fractures. The long-standing centerpiece of this approach has been antiresorptive drugs such as the bisphosphonates, estrogen, or the selective estrogen receptor modulator (SERM) raloxifene and, to some extent, calcitonin. These drugs inhibit osteoclast-mediated bone loss, thereby reducing bone turnover.

Until recently, antiresorptives were the only drugs approved in the United States for treating osteoporosis. The increase in bone density that they produce is variable
Teriparatide (40 μg) (Neer et al., 2001), PTH (25 μg) + estradiol (Lindsay et al., 1997), alendronate (10 mg) (Liberman et al., 1995), estradiol (0.625 mg/day) (Writing Group for the PEPI Trial, 1996), raloxifene (120 mg) (Ettinger et al., 1999), calcitonin (200 IU) (Reginster et al., 1995). Typical results with placebo treatment underscore the inexorable bone loss without intervention. Some of the indicated treatment interventions involved combination therapy, and absolute comparisons should not be made.

and depends on the site and the particular drug; generally, the increase is less than 10% after 3 years (Figure 61–12). This situation changed in 2002 when the FDA approved the biologically active PTH fragment PTH(1–34) (teriparatide, FORTEO) for use in treating postmenopausal women with osteoporosis and to increase bone mass in men with primary or hypogonadal osteoporosis. For a review and proposed guidelines for teriparatide/PTH use, see Hodsman et al. (2005). Therapeutic approaches likely will evolve considerably as newer treatment paradigms are developed and combinations of antiresorptive agents and PTH are introduced, and as the molecular physiology of osteoblast and osteoclast function is elucidated (Grey and Reid, 2005).

Antiresorptive Agents. Bisphosphonates. Bisphosphonates have emerged as the most effective drugs currently approved for prevention and treatment of osteoporosis. Second- and third-generation oral bisphosphonates alendronate and risedronate have sufficient potency to suppress bone resorption at doses that do not inhibit mineralization.

Alendronate is approved for prevention (5 mg daily, 35 mg once weekly) and treatment (10 mg daily, 70 mg once weekly) of osteoporosis and for the treatment of glucocorticoid-associated osteoporosis. In fact, 3-, 7-, and 10-year studies of daily treatment with alendronate established its efficacy to increase bone mineral density, decrease bone turnover, and reduce the risk of vertebral fracture among women with osteoporosis (Bone et al., 2004; Liberman et al., 1995; Tonino et al., 2000; Tucci et al., 1996). The results of 10-year daily treatment with 10 mg of alendronate (with 500 mg of supplemental calcium) reported a 14% increase of lumbar spine BMD, with smaller increments at the trochanter, total hip, and femoral neck (Bone et al., 2004). On reduction and discontinuation of treatment, BMD at the lumbar spine was maintained. Although significant decreases of BMD occurred at the total hip, femoral neck, and forearm, BMD at the lumbar spine, trochanter, total hip, and total body remained significantly above baseline values at year 10.

Alendronate conserves BMD in recently menopausal women (Hosking et al., 1998), as well as in men, and also improves BMD in patients receiving glucocorticoids (Saag et al., 1998).

For patients in whom oral bisphosphonates cause severe esophageal distress despite countermeasures, intravenous pamidronate (AREDIA) offers skeletal protection without causing adverse GI effects. For treatment of osteoporosis, pamidronate is given as a 3-hour infusion, 30 mg every 3 months. Oral pamidronate (150 or 300 mg daily) has been evaluated for treatment of postmenopausal osteoporosis. Both doses are effective; however, gastrointestinal side effects are frequent with the 300-mg dose. Oral risedronate has been approved for treatment of postmenopausal osteoporosis (5 mg daily or 35 mg once weekly) and glucocorticoid-induced osteoporosis. Risedronate improves BMD and reduces vertebral fracture incidence in postmenopausal women. Combined analysis of four placebo-controlled, randomized trials with risedronate in women with low bone density but no previous vertebral fracture displayed increases of lumbar and femoral neck BMD with a significant reduced risk of first vertebral compression fracture (Heaney et al., 2002).

Thiazide Diuretics. Although not strictly antiresorptive, thiazides reduce urinary Ca2+ excretion and constrain bone loss in patients with hypercalciuria. Whether they will prove to be useful in patients who are not hypercalciuric is not clear, but data suggest that they reduce hip fracture risk. No sustained effect is observed (Schoofs et al., 2003). Hydrochlorothiazide, 25 mg once or twice daily, may reduce urinary Ca2+ excretion substantially. Effective doses of thiazides for reducing urinary Ca2+ excretion generally are lower than those necessary for blood pressure control. For a more detailed discussion of thiazide diuretics, see Chapter 28.

Calcium. The physiological roles of Ca2+ and its use in the treatment of hypocalcemic disorders were discussed earlier. The rationale for using supplemental calcium to protect bone varies with time of life.

For preteens and adolescents, adequate substrate calcium is required for bone accretion. Controlled trials indicate that supplemental calcium promotes adolescent bone acquisition (Johnston et al., 1992), but its impact on peak bone mass is not known. Higher calcium intake during the third decade of life is positively related to
the final phase of bone acquisition (Recker et al., 1992). There is controversy about the role of calcium during the early years after menopause, when the primary basis for bone loss is estrogen withdrawal. Although little effect of calcium on trabecular bone has been reported, reduction in cortical bone loss with calcium supplementation has been observed, even in populations with high dietary calcium intake. In elderly subjects, supplemental calcium suppresses bone turnover, improves BMD, and decreases the incidence of fracture (Dawson-Hughes et al., 1997).

Patients who are unable or unwilling to increase calcium by dietary means alone may choose from many palatable, low-cost calcium preparations. As noted previously, numerous oral calcium preparations are available, the most frequently prescribed being carbonate. Traditional dosing of calcium is about 1000 mg/day, nearly the amount present in a quart of milk. Added to the 500 to 600 mg of dietary calcium that typifies the diet of elderly men and women, this provides a total daily intake of about 1500 mg. More may be necessary to overcome endogenous intestinal calcium losses, but daily intakes of 2000 mg or more frequently are reported to be constipating. Calcium supplements are taken most often with meals to improve absorption.

**Vitamin D and Its Analogs.** Modest supplementation with vitamin D (400 to 800 IU/day) may improve intestinal Ca\(^{2+}\) absorption, suppress bone remodeling, and improve BMD in individuals with marginal or deficient vitamin D status. Although supplemental vitamin D appeared to reduce fracture incidence in several trials, a prospective study found that neither dietary calcium nor vitamin D intake was of major importance for the primary prevention of osteoporotic fractures in women (Michaelsson et al., 2003). Nonetheless, because women commonly consume less than the recommended intake of vitamin D, use of supplemental vitamin D or increased consumption of such vitamin D–rich foods as dark fish may be prudent.

The use of calcitriol to treat osteoporosis is distinct from ensuring vitamin D nutritional adequacy. Here, the rationale is to suppress parathyroid function directly and reduce bone turnover. Calcitriol and the polar vitamin D metabolite 1\(\alpha\)-hydroxycholecalciferol are used frequently in Japan and other countries, but experience in the United States has been mixed. Higher doses of calcitriol appear to be more likely to improve BMD, but at the risk of hypercalciumia and hypercalcemia; therefore, close scrutiny of patients and dose modification are required. Restriction of dietary calcium may reduce toxicity during calcitriol therapy (Gallagher and Goldgar, 1990). A low incidence of hypercalcemic and hypercalcemic complications of therapy in Japan may reflect relatively poor calcium intakes in that country.

**Estrogen.** There is an unambiguous relationship between estrogen deficiency and osteoporosis. Postmenopausal status or estrogen deficiency at any age significantly increases a patient’s risk for osteoporosis and fractures. Likewise, overwhelming evidence supports the positive impact of estrogen replacement on the conservation of bone and protection against osteoporotic fracture after menopause (Rosen and Kessenich, 1997) (see Chapter 57). The outcome of the Women’s Health Initiative (WHI) studies, however, has strikingly altered the view of the therapeutic use of HRT for long-term prevention or treatment of osteoporosis. Significantly increased risks of heart disease and breast cancer were found (Anderson et al., 2004; Cauley et al., 2003). The consensus among experts now is to reserve HRT only for the short-term relief of vasomotor symptoms associated with menopause. HRT should be limited to osteoporosis prevention in women with significant ongoing vasomotor symptoms who are not at an increased risk for cardiovascular disease. An annual individualized risk-benefit reassessment should be performed on these patients.

**Selective Estradiol Receptor Modulators (SERMs).** Considerable work has been undertaken to develop estrogenic compounds with tissue-selective activities. One of these, raloxifene (EVISTA), acts as an estrogen agonist on bone and liver, is inactive on the uterus, and acts as an antiestrogen on the breast (see Chapter 57). In postmenopausal women, raloxifene stabilizes and modestly increases BMD and has been shown to reduce the risk of vertebral compression fracture (Ettinger et al., 1999). Raloxifene is approved for both the prevention and treatment of osteoporosis. With the decreased use of estrogen for treating osteoporosis, the SERM raloxifene would seem to be an ideal alternative to HRT because raloxifene reduces the risk of vertebral fractures (albeit without a positive effect on nonvertebral fractures), breast cancer, and coronary events (coronary death, nonfatal myocardial infarction, and hospitalized acute coronary syndromes other than myocardial infarction) (Clemett and Spencer, 2000). The major drawback of raloxifene is that it can worsen vasomotor symptoms.

**Calcitonin.** Calcitonin inhibits osteoclastic bone resorption and modestly increases bone mass in patients with osteoporosis (Civitelli et al., 1988); the largest increases occurred in patients with high intrinsic rates of bone turnover. One study showed that calcitonin nasal spray (200 units/day) reduced the incidence of vertebral compression fractures by about 40% in osteoporotic women (Chesnut et al., 2000).

**Combination Therapies**

Because teriparatide stimulates bone formation, whereas bisphosphonates reduce bone resorption, it was predicted
that therapy combining the two would enhance the effect on BMD more than treatment with either one alone. However, addition of alendronate to PTH treatment provided no additional benefit for BMD and reduced the anabolic effect of PTH in both women and men (Black et al., 2003; Body et al., 2002; Finkelstein et al., 2003). Sequential treatment with PTH(1–84) followed by alendronate increased vertebral BMD to a greater degree than alendronate or estrogen alone (Rittmaster et al., 2000). Recent work underscores the beneficial action of alendronate in consolidating the gains in lumbar spine BMD achieved by antecedent teriparatide treatment in men.

Paget’s Disease. Although most patients with Paget’s disease require no treatment, factors such as severe pain, neural compression, progressive deformity, hypercalcaemia, high-output congestive heart failure, and repeated fracture risk are considered indications for treatment. Bisphosphonates and calcitonin decrease the elevated biochemical markers of bone turnover, such as plasma alkaline phosphatase activity and urinary excretion of hydroxyproline. An initial course of bisphosphonate typically is given once daily or once weekly for 6 months. With treatment, most patients experience a decrease in bone pain over several weeks. Such treatment may induce long-lasting remission. If symptoms recur, additional courses of therapy can be effective. When etidronate is given at higher doses (10 to 20 mg/kg per day) or continuously for longer than 6 months, there is a substantial risk for osteomalacia. At lower doses (5 to 7.5 mg/kg per day), focal osteomalacia has been observed occasionally. Defective mineralization has not been observed with other bisphosphonates or with calcitonin.

Choice of optimal therapy for Paget’s disease varies among patients. Bisphosphonates are the standard therapy. Intravenous pamidronate induces long-term remission following a single infusion. Zoledronate seems to exhibit greater response rates and a longer median duration of complete response (Major et al., 2001). Compared with calcitonin, bisphosphonates have the advantage of oral administration, lower cost, lack of antigenicity, and generally fewer side effects. Resistance to calcitonin develops in most patients. However, calcitonin is highly reliable and may have a distinct skeletal analgesic property. Methramycin (plicamycin) has been used in difficult cases of Paget’s disease that do not respond to bisphosphonates or calcitonin. Therapeutic utility of this agent is limited by a high potential for hemorrhagic and other toxicities, and it is not generally recommended.

**FLUORIDE**

*Fluoride* is discussed because of its toxic properties and its effect on dentition and bone.

**Absorption, Distribution, and Excretion.** Human beings obtain fluoride predominantly from the ingestion of plants and water, with most absorption taking place in the intestine. The degree of fluoride absorption correlates with its water solubility. Relatively soluble compounds, such as sodium fluoride, are absorbed almost completely, whereas relatively insoluble compounds, such as cryolite (Na₃AlF₆) and the fluoride found in bone meal (fluoroapatite) are absorbed poorly. A second route of absorption is through the lungs, and inhalation of fluoride present in dusts and gases constitutes the major route of industrial exposure.

Fluoride is distributed widely in organs and tissues but is concentrated in bone and teeth, and the skeletal burden is related to intake and age. Bone deposition reflects skeletal turnover; growing bone shows greater deposition than mature bone.

The kidneys are the major site of fluoride excretion. Small amounts of fluoride also appear in sweat, milk, and intestinal secretions; in a very hot environment, sweat can account for nearly 50% of total fluoride excretion.

**Pharmacological Actions and Uses.** Because it is concentrated in the bone, the radionuclide ¹⁸F has been used in skeletal imaging. Sodium fluoride enhances osteoblast activity and increases bone volume. These effects may be bimodal, with low doses stimulating and higher doses suppressing osteoblasts; if true, this may account for the poorly mineralized and mechanically defective bone seen in some studies. In doses of 30 to 60 mg/day, fluoride increases trabecular bone mineral density in many, but not all, patients. In one controlled trial, fluoride increased lumbar spine density (cancellous bone) but decreased cortical bone mineral density; these changes were associated with a significant increase in peripheral fractures and stress fractures (Riggs et al., 1990). In one study, sustained-release fluoride, which provided lower blood fluoride levels, increased bone mineral density and decreased fractures (Pak et al., 1994). Intermittent courses of slow-release fluoride also have been evaluated. When the total fluoride dose was kept constant (Balena et al., 1998), there was no difference in outcome between continuous and intermittent fluoride treatment; notably, both regimens increased cancellous and trabecular thickness to the same extent. Unfortunately, increased bone mass is not synonymous with increased bone strength (Riggs et al., 1990). Thus, the apparent effects of fluoride in osteoporosis are slight compared with those achieved with PTH or other agents.

Other pharmacological actions of fluoride can be classified as toxic, as described below. Fluoride inhibits several enzyme systems and diminishes tissue respiration and anaerobic glycolysis.

**Acute Poisoning.** Acute fluoride poisoning usually results from accidental ingestion of fluoride-containing insecticides or rodenticides. Initial symptoms (salivation, nausea, abdominal pain, vomiting, and diarrhea) are secondary to the local action of fluoride on the intestinal mucosa. Systemic symptoms are varied and severe: increased irritability of the central nervous system consistent with the Cu²⁺-binding effect of fluoride and the resulting hypocalcemia; hypertension, presumably owing to central vasomotor depression as well as direct cardiototoxicity; and stimulation and then depression of respiration. Death can result from respiratory paralysis or cardiac failure. The lethal dose of sodium fluoride for human beings is about 5 g, although there is considerable variation. Treatment includes the intravenous administration of glucose in saline and gastric lavage with lime water (0.15% calcium hydroxide solution) or other Ca²⁺ salts to precipitate the fluoride. Calcium gluconate is given intravenously for tetany; urine volume is kept high with vigorous fluid resuscitation.

**Chronic Poisoning.** In human beings, the major manifestations of chronic ingestion of excessive fluoride are osteosclerosis and mottled enamel. Osteosclerosis is characterized by increased bone density secondary both to elevated osteoblastic activity and to the
replacement of hydroxyapatite by the denser fluoroapatite. The degree of skeletal involvement varies from changes that are barely detectable radiologically to marked cortical thickening of long bones, numerous exostoses scattered throughout the skeleton, and calcification of ligaments, tendons, and muscle attachments. In its severest form, it is a disabling and crippling disease.

Mottled enamel, or dental fluorosis, was first described more than 60 years ago. In very mild mottling, small, opaque, paper-white areas are scattered irregularly over the tooth surface. In severe cases, discrete or confluent, deep brown- to black-stained pits give the tooth a corroded appearance. Mottled enamel results from a partial failure of the enamel-forming ameloblasts to elaborate and lay down enamel. Since mottled enamel is a developmental injury, fluoride ingestion following the eruption of teeth has no effect. Mottling is one of the first visible signs of excess fluoride intake during childhood. Continuous use of water containing about 1 ppm of fluoride may result in very mild mottling in 10% of children; at 4 to 6 ppm the incidence approaches 100%, with a marked increase in severity. Severe dental fluorosis formerly occurred in regions where local water supplies had a very high fluoride content (e.g., Pompeii, Italy, and Pike’s Peak, Colorado). Current regulations in the United States require lowering the fluoride content of the water supply or providing an alternative source of acceptable drinking water for affected communities. Sustained consumption of water with a fluoride content of 4 mg/L (4 ppm) is associated with deficits in cortical bone mass and increased rates of bone loss over time (Sowers et al., 1991).

Fluoride and Dental Caries. After a new water supply was established, children in Bauxite, Arkansas, had a much higher incidence of caries than those who had been exposed to the former fluoride-containing water. Subsequent studies established definitely that supplementation of water fluoride content to 1.0 ppm is a safe and practical intervention that substantially reduces the incidence of caries in permanent teeth.

There are partial benefits for children who begin drinking fluoridated water at any age; however, optimal benefits are obtained at ages before permanent teeth erupt. Topical application of fluoride solutions by dental personnel appears to be particularly effective on newly erupted teeth and can reduce the incidence of caries by 30% to 40%. Dietary fluoride supplements should be considered for children younger than age 12 years whose drinking water contains less than 0.7 ppm fluoride. Conflicting results have been reported from studies of fluoride-containing toothpastes.

Adequate incorporation of fluoride into teeth hardens the outer layers of enamel and increases resistance to demineralization. Fluoride deposition apparently involves exchange with hydroxyl or citrate anions in the enamel apatite crystal surface. The mechanism by which fluoride prevents caries is not completely understood. There is no convincing evidence that fluoride from any source reduces the development of caries after the permanent teeth are completely formed (usually about age 14).

The fluoride salts usually employed in dentifrices are sodium fluoride and stannous fluoride. Sodium fluoride also is available in a variety of preparations for oral and topical use, including tablets, drops, rinses, and gels.

Since its inception, regulation of the fluoride concentration of community water supplies periodically has encountered vocal opposition, including allegations of putative adverse health consequences of fluoridated water. Careful examination of these issues indicates that cancer and all-cause mortalities do not differ significantly between communities with fluoridated and nonfluoridated water (Richmond, 1985).

CLINICAL SUMMARY

Increasing evidence supports the concept that regular physical activity, adequate calcium intake, and lifestyle changes have a positive impact on bone remodeling, constrain bone loss, and reduce fracture risk. Antiresorptive agents such as bisphosphonates, estrogen, selective estrogen response modulators (SERMs), and calcium, will slow bone resorption. Recombinant human PTH has been approved for the treatment of osteoporosis and provides significant intervention for restoring normal bone mass.

Cinacalcet, a drug that acts directly on the parathyroid calcium-sensing receptor, also has been approved, providing a novel approach to decreasing PTH secretion in secondary hyperparathyroidism and parathyroid carcinoma. Improved assays for measuring biologically active and inactive forms of PTH likely will facilitate the diagnosis and treatment of diseases associated with PTH resistance.

Estrogen-replacement therapy, once a mainstay treatment for osteoporosis in women, has been curtailed by the findings of the Women’s Health Initiative: Despite estrogen’s beneficial effects on bone and fracture risk, alone or in combination with progesterone, estrogen promotes an array of serious adverse cardiovascular consequences. The FDA now recommends that estrogen be reserved for women at significant risk of osteoporosis who cannot take other medications.

BIBLIOGRAPHY

The skin has many essential functions, including protection, thermoregulation, immune responsiveness, biochemical synthesis, sensory detection, and social and sexual communication. Therapy to correct dysfunction in any of these activities may employ chemical agents that can be delivered systemically, intraleesionally, or topically and physical agents to which the skin can be exposed, including ultraviolet and ionizing radiation.

A unique aspect of dermatological pharmacology is the direct accessibility of the skin as a target organ for diagnosis and treatment (Figure 62–1). Topical agents are employed alone or in conjunction with phototherapy and/or systemic medications in the management of most dermatological conditions. Therapeutic agents can reach epidermal keratinocytes and immunocompetent cells in the epidermis and the underlying dermis that are involved in the pathogenesis of numerous cutaneous diseases. Topical agents can be applied directly to the skin but must penetrate into the tissue to achieve efficacy. Appropriate use of topical agents requires an appreciation of the factors that influence percutaneous absorption.

Antibacterial, antiviral, and antifungal agents are employed widely both topically and systemically. Oral antimalarial, cytotoxic, and immunosuppressive agents and antihistamines frequently are used for treatment of dermatological diseases. Calcipotriene, a vitamin D analog, is used topically for psoriasis. Ultraviolet radiation therapy is a frequent mode of treatment that can be administered independently or in combination with photosensitizers. The pathogenetic role of ultraviolet radiation in cutaneous cancers has led to the development of sunscreens to reduce or prevent premalignant and malignant skin lesions. An improved understanding of the pathogenesis of immunologic disorders has led to a number of novel biological agents that hold considerable promise to match the efficacy of glucocorticoids and other immunosuppressive agents in dermatologic diseases, possibly with fewer serious adverse effects.

The skin acts as a two-way barrier to prevent absorption or loss of water and electrolytes. The barrier resides in the outermost layer of the epidermis, the stratum corneum, as evidenced by approximately equal rates of penetration of chemicals through isolated stratum corneum or whole skin. Having lost their nuclei and cytoplasmic organelles, the corneocytes of the stratum corneum are nonviable. The cells are flattened, and the fibrous keratins are aligned into disulfide cross-linked macrofibers in association with filaggrin, the major protein component of the keratoxylin granule. Each cell develops a cornified enve-
lopes resulting from cross-linking of involucrin and keratohyalin, forming an insoluble exoskeleton that acts as a rigid scaffold for the internal keratin filaments. The intercellular spaces are filled with hydrophobic lamellar lipids derived from membrane-coating granules. The combination of hydrophilic cornified cells in hydrophobic intercellular material provides a barrier to both hydrophilic and hydrophobic substances (Ebling, 1993). In dermatological diseases, the thickened epidermis may further diminish the penetration of pharmacological agents into the dermis.

**Figure 62–1. Skin as a pharmacological target.** The skin is a multicellular organ containing numerous indigenous cells and structures as well as circulating cells that are potential targets for pharmacological intervention (black arrows). UVB, ultraviolet radiation (290–320 nm); PUVA, psoralen activated by UVA radiation (320–400 nm).

**DRUG DELIVERY IN DERMATOLOGICAL DISEASES**

**Topical Preparations**

Molecules can penetrate the skin by three routes: through intact stratum corneum, through sweat ducts, or through the sebaceous follicle. The surface of the stratum corneum presents more than 99% of the total skin surface available for percutaneous drug absorption. Passage through this outermost layer is the rate-limiting step for percutaneous absorption. The major steps involved in percutaneous absorption include the establishment of a concentration gradient, which provides the driving force for drug movement across the skin; release of drug from the vehicle (partition coefficient); and drug diffusion across the layers of the skin (diffusion coefficient). Preferable characteristics of topical drugs include low molecular mass (600 Da), adequate solubility in oil and water, and a high partition coefficient (Barry, 2004). Except for very small particles, water-soluble ions and polar molecules do not penetrate intact stratum corneum. The relationship of these factors to one another is summarized in the following equation:

\[
J = C_{veh} \cdot K_m \cdot D/x
\]

where \( J \) is the rate of absorption, \( C_{veh} \) is the concentration of drug in vehicle, \( K_m \) is the partition coefficient, \( D \) is the diffusion coefficient, and \( x \) is the thickness of stratum corneum (Piaquadio and Kligman, 1998).

**Metabolism**

The viable epidermis contains a variety of enzyme systems capable of metabolizing drugs that reach this compartment, including CYPs, epoxide hydrolase, transferases such as N-acetyl-transferases, and diverse enzymes including glucuronid transferases and sulfatases (Baron et al., 2001; Du et al., 2004). A specific CYP isoform, CYP26A1, metabolizes retinoic acid and may control its level in the skin (White et al., 1997; Baron et al., 2001). In addition, transporter proteins that influence influx (OATP) or efflux (MRD and LRD) of certain xenobiotics are present in human keratinocytes (Baron et al., 2001). While substrate turnover is considerably less than that for hepatic CYPs, these enzymes influence concentrations of xenobiotics in the skin.

**General Guidelines for Topical Therapy**

**Dosage.** An amount of topical medication sufficient to cover affected body surfaces in repeated applications must be dispensed to the patient. A general rule is that approximately 30 g is required to cover the body surface.
Regional Anatomic Variation. Permeability generally is inversely proportional to the thickness of the stratum corneum. Drug penetration is higher on the face, in intertriginous areas, and especially in the perineum. Consequently, the skin in these regions may be more susceptible to irritant and allergic contact reactions. Skin sites that are naturally occluded by apposing surfaces, such as the axillae, groin, and inframammary areas, also may be vulnerable to drug-related toxicity such as atrophy from potent topical glucocorticoids.

Altered Barrier Function. In many dermatological diseases, such as psoriasis, the stratum corneum is abnormal, and barrier function is compromised. In these settings, percutaneous absorption may be increased to the point that standard drug doses can result in systemic toxicity (e.g., hypothalamic–pituitary–adrenal axis suppression) that standard drug doses can result in systemic absorption of potent topical glucocorticoids.

Hydration. Drug absorption is increased with hydration, defined as an increase in the water content of the stratum corneum that is produced by inhibiting transepidermal loss of water. Methods of hydration include occlusion with an impermeable film, application of lipophilic occlusive vehicles such as ointments, and soaking dry skin before occlusion.

Vehicle. Many factors influence the rate and extent to which topical medications are absorbed. Most topical medications are incorporated into bases or vehicles that are applied directly to the skin. The chosen vehicle can influence drug absorption and provide therapeutic efficacy; for example, an ointment is more occlusive and has superior emollient properties than a cream or a lotion base.

Newer vehicles include liposomes and microgel formulations. Liposomes are concentric spherical shells of phospholipids in an aqueous medium that may enhance percutaneous absorption. Variations in size, charge, and lipid content can influence liposome function substantially. Liposomes penetrate compromised epidermal barriers more efficiently (Korting et al., 1991). Microgels are polymers that may enhance solubilization of certain drugs, thereby enhancing penetration and diminishing irritancy.

Transfersomes are a drug-delivery technology based on highly deformable, ultraflexible lipid vesicles that penetrate the skin when applied nonocclusively (Barry, 2004). Finally, pressure waves generated by intense laser radiation can permeabilize the stratum corneum and may provide a novel system for transdermal drug delivery.

Age. Children have a greater ratio of surface area to mass than adults, so a given amount of topical drug results in a greater systemic dose. Based on transepidermal water loss and percutaneous absorption studies, term infants seem to possess a stratum corneum with barrier properties comparable with adults.

Application Frequency. Topical agents often are applied twice daily. For certain drugs, once-daily application of a larger dose may be equally effective as more frequent applications of smaller doses. The stratum corneum may act as a drug reservoir that allows gradual penetration into the viable skin layers over a prolonged period. Intermittent pulse therapy—treatment for several days or weeks alternating with treatment-free periods—may prevent development of tachyphylaxis associated with drugs such as topical glucocorticoids.

Intralesional Administration. Intralesional drug administration is used mainly for inflammatory lesions but also can be used for treatment of warts and selected neoplasms. Medications injected intralesionally have the advantages of direct contact with the underlying pathologic process, no first-pass metabolism, and the formation of a slowly absorbed depot of drug. In considering the use of intralesional medications, it is important to be cognizant of the possibility of systemic absorption of the medication.

Systemic Administration. Systemic administration of medication in dermatology usually involves oral ingestion but also can involve intramuscular (e.g., methotrexate and glucocorticoids), intravenous (e.g., immunoglobulin and alefacept), or subcutaneous administration (e.g., efalizumab and etanercept).

**GLUCOCORTICOIDS**

Glucocorticoids are prescribed frequently for their immunosuppressive and antiinflammatory properties. They are administered locally, through topical and intralesional routes, and systemically, through intramuscular, intravenous, and oral routes. Mechanisms of glucocorticoid action are numerous, as discussed in Chapter 59. These include apoptosis of lymphocytes, inhibitory effects on the arachidonic acid cascade, depression of production of many cytokines, and myriad effects on inflammatory cells.

Shortly after the synthesis of hydrocortisone in 1951, topical glucocorticoids were recognized as effective agents for the treatment of skin disease. With the development of appropriate vehicles, these agents rapidly became the mainstay of therapy for many inflammatory skin diseases.

Topical glucocorticoids have been grouped into seven classes in order of decreasing potency (Table 62–1); many of the more potent drugs have a fluorinated hydrocortisone backbone. Potency traditionally is measured using a vasoconstrictor assay in which an agent is applied to skin under occlusion, and the area of skin blanching is assessed. Vasoconstriction-induced blanching can be readily quantified by this methodology, which has been verified using laser–Doppler perfusion imaging (Sommer et al. ...
Other assays of glucocorticoid potency involve suppression of erythema and edema after experimentally induced inflammation and the psoriasis bioassay, in which the effect of steroid on psoriatic lesions is quantified.

Therapeutic Uses. Many inflammatory skin diseases respond to topical or intralesional administration of glucocorticoids. Absorption varies among body areas; the steroid is selected on the basis of its potency, the site of involvement, and the severity of the skin disease. Often, a

</table>

*Class 1 is most potent; class 7 is least potent. Adapted from Arndt, K.A. *Manual of Dermatologic Therapeutics*, 4th ed. Little, Brown, and Company, Boston, 1989, p. 234, with permission.

*al., 1998*
more potent steroid is used initially, followed by a less potent agent. Most practitioners become familiar with one glucocorticoid in each class so as to select the appropriate strength of drug. Twice-daily application is sufficient, and more frequent application does not improve response (Yohn and Weston, 1990). In general, only nonfluorinated glucocorticoids should be used on the face or in occluded areas such as the axillae or groin.

Intralesional preparations of glucocorticoids include insoluble preparations of triamcinolone acetonide (KENALOG-10 and others) and triamcinolone hexacetonide (KENOLOG-40 AND ARISTOSPAN), which solubilize gradually and therefore have a prolonged duration of action.

**Toxicity and Monitoring.** Chronic use of class I topical glucocorticoids can cause skin atrophy, striae, telangiectasias, purpura, and acneiform eruptions. Because perioral dermatitis and rosacea can develop after the use of fluorinated glucocorticoids can cause skin atrophy, striae, telangiectasias, purpura, and acneiform eruptions. Because perioral dermatitis and rosacea can develop after the use of fluorinated glucocorticoids should be used on the face or in occluded areas such as the axillae or groin.

**Systemic Glucocorticoids**

**Therapeutic Uses.** Systemic glucocorticoid therapy is used for severe dermatological illnesses. In general, it is best to reserve this method for allergic contact dermatitis to plants (e.g., poison ivy) and for life-threatening vesiculobullous dermatoses such as pemphigus vulgaris and bullous pemphigoid. Chronic administration of oral glucocorticoids is problematic, given the side effects associated with their long-term use (see Chapter 59).

Daily morning dosing with prednisone generally is preferred, although divided doses are used occasionally to enhance efficacy. Fewer side effects are seen with alternate-day dosing, and if required for chronic use, prednisone is tapered to every other day as soon as it is practical. Pulse therapy using large intravenous doses of methylprednisolone sodium succinate (SOLU-MEDROL) is an option for severe resistant pyoderma gangrenosum, pemphigus vulgaris, systemic lupus erythematosus with multisystem disease, and dermatomyositis (Werth, 1993). The dose usually is 0.5 g to 1 g given over 2 to 3 hours. More rapid infusion has been associated with increased rates of hypotension, electrolyte shifts, and cardiac arrhythmias.

**Toxicity and Monitoring.** Oral glucocorticoids have numerous systemic effects, as discussed in Chapter 59. Most side effects are dose-dependent. Long-term use is associated with a number of complications, including psychiatric problems, cataracts, myopathy, osteoporosis, avascular bone necrosis, glucose intolerance or overt diabetes mellitus, and hypertension. In addition, psoriatic patients treated with parenteral or topical glucocorticoids may have a pustular flare, particularly if the steroid is tapered rapidly.

---

**RETINOIDS**

*Retinoids* include natural compounds and synthetic derivatives of retinol that exhibit vitamin A activity. Retinoids have many important functions throughout the body, including roles in vision, regulation of cell proliferation and differentiation and bone growth, immune defense, and tumor suppression (Chandraratna, 1998). Because vitamin A affects normal epithelial differentiation, it was investigated as a treatment for cutaneous disorders but was abandoned initially because of unfavorable side effects. Molecular modifications yielded compounds with vastly improved margins of safety. First-generation retinoids include retinol, tretinoin (all-trans-retinoic acid), isoretinoin (13-cis-retinoic acid), and altretinoin (9-cis-retinoic acid). Second-generation retinoids, also known as aromatic retinoids, were created by alteration of the cyclic end group and include acitretin. Third-generation retinoids contain further modifications and are called *arotinoids*. Members of this generation include tazarotene and bexarotene. Adapalene, a derivative of naphthoic acid with retinoid-like properties, does not fit precisely into any of the three generations.

Retinoic acid (RA) exerts its effects on gene expression by activating two families of receptors—*retinoic acid receptors* (RARs) and the *retinoid X receptors* (RXRs)—that are members of the thyroid/steroid hormone receptor superfamily (Winterfield *et al.*, 2003). Retinoids (ligands) bind transcription factors (nuclear receptors), and the ligand–receptor complex then binds to the promoter regions of target genes to regulate their expression (Saurat, 1999). The gene products formed contribute to the desirable pharmacological effects of these drugs and their unwanted side effects (Shroot, 1998). Additional complexity arises because each receptor has three isoforms (α, β, and γ) that form homo- and heterodimers. Retinoid-responsive tissues express one or more RAR and RXR subtypes in various combinations that determine activity locally (Petkovich, 2001). Human skin contains mainly RARα and RARβ.

First- and second-generation retinoids can bind to several retinoid receptors because of the flexibility imparted by
their alternating single and double bonds. This relative lack of receptor specificity may lead to greater side effects. The structures of third-generation retinoids are much less flexible than those of earlier-generation retinoids and therefore interact with fewer retinoid receptors (Chandraratna, 1998).

Acute retinoid toxicity is similar to vitamin A intoxication. Side effects of retinoids include dry skin, nosebleeds from dry mucous membranes, conjunctivitis, and hair loss. Less frequently, musculoskeletal pain, pseudotumor cerebri, and mood alterations occur. Oral retinoids are potent teratogens and cause severe fetal malformations. Because of this, systemic retinoids should be used with great caution in females of childbearing potential.

Retinoids are used in the treatment of diverse diseases and are effective in the treatment of inflammatory skin disorders, skin malignancies, hyperproliferative disorders, photoaging, and many other disorders. Topical retinoids can normalize disordered keratinization in sebaceous follicles and reduce inflammation, and they may enhance the penetration of other topical medications. Specific retinoids and their uses in the treatment of dermatologic disorders are discussed below.

**Tretinoin**

Tretinoin (RETIN-A, others) has been used in the treatment of acne vulgaris for almost four decades. A primary use for tretinoin is to reduce the hyperkeratinization that leads to microcomedone formation, the initial lesion in acne. Follicular corneocytes become less cohesive as a result of shedding of desmosomes, decreasing tonofilaments and increasing keratinocyte autolysis and intracellular deposition of glycogen (Wolff et al., 1975).

In addition to treating acne, tretinoin improves photodamaged human skin (Kligman et al., 1986). Epidermal effects include increased epidermal and granular layer thickness, decreased melanocytic activity, and increased secretion of a glycosaminoglycan-like substance into the intercellular space. In the dermis, blood vessel vasodilation and angiogenesis and increased papillary dermal collagen synthesis have been documented. Clinically, this translates to modest attenuation of fine and coarse wrinkling, smoother texture, increased pinkness, and diminished hyperpigmentation (Green et al., 1993). In clinical trials, wrinkling, mottled hyperpigmentation, and roughness improved in most patients treated with retinoids, a response rate roughly twice that of control subjects who used sunscreens and emollients (Stern, 2004). Ultraviolet radiation also activates growth factor and cytokine receptors on epidermal keratinocytes and dermal cells. These receptors stimulate mitogen-activated protein kinases (MAP kinases), which, in turn, induce c-Jun expression. This transcription factor heterodimerizes with c-Fos to form activated AP-1 complexes that induce the transcription of metalloproteinases that degrade dermal collagens and other proteins (Fisher and Voorhees, 1998).

Tretinoin is approved for the treatment of acne vulgaris and as an adjunctive agent for treating photoaging. Topical preparations contain from 0.01% to 0.1% tretinoin in cream, gel, and solution formulations. Initiation of therapy with lower-strength preparations and progression to higher strengths may be useful because individual sensitivity is unpredictable. Tretinoin formulations with a cream base are indicated for dry skin, whereas gel-based formulations are indicated for oily skin. The medication is applied once daily before bedtime to minimize photodegradation. Maximum clinical response in acne may require several months, and maintenance therapy is necessary. A formulation of tretinoin with active drug incorporated into microsponges (RETIN-A MICRO) has been developed (Gollnick and Krautheim, 2003). The microsponges not only decrease irritation by slowing the release of the medication but also may enhance efficacy by targeting delivery to the sebaceous follicle (Webster, 1998).

A 0.5% emollient cream formulation of tretinoin (RENOVA) is one formulation approved for treatment of photoaged skin. Nightly application produces maximum response within 1 year, and application once to three times weekly is said to maintain improvement (Green et al., 1993). Treatment must be combined with a rigorous program of photoprotection, including sunscreens, sun avoidance, and photoprotective clothing.

**Adapalene**

Adapalene (DIFFERIN), a derivative of naphthoic acid, is a synthetic retinoid-like compound that is available in solution, cream, and gel formulations for topical use. In addition to displaying typical retinoid effects, it also has anti-inflammatory properties. Adapalene has similar efficacy to tretinoin, but unlike tretinoin, it is stable in sunlight (Weiss and Shavin, 1998) and tends to be less irritating. The structure for adapalene is shown below.
Tazarotene

Tazarotene (TAZORAC) is a third-generation retinoid approved for the treatment of psoriasis and acne vulgaris (Duvic and Marks, 1998). This retinoid binds to all three RARs. In mice, tazarotene blocks ornithine decarboxylase activity, which is associated with cell proliferation and hyperplasia. In cell culture, it suppresses markers of epidermal inflammation and inhibits cornification of the keratinocyte.

Tazarotene gel, applied once daily to dry skin, may be used as monotherapy or in combination with other medications, such as topical corticosteroids, for the treatment of localized plaque psoriasis. This is the first topical retinoid approved by the Food and Drug Administration (FDA) for the treatment of psoriasis. Side effects of burning, itching, and skin irritation are relatively common, and patients should avoid sun exposure.

Alitretinoin

Alitretinoin (PANRETIN) is a retinoid that binds all types of retinoid receptors and is approved only for treatment of the skin manifestations of Kaposi’s sarcoma. Approximately 50% of patients in an open-label trial responded positively to topical application of this drug (Walmsley et al., 1999).

Toxicity and Monitoring. Adverse effects of all topical retinoids include erythema, desquamation, burning, and stinging. These effects often decrease spontaneously with time and are lessened by concomitant use of emollients. Photosensitivity can occur as a result of epidermal thinning, with a resulting greater potential for phototoxic reactions such as sunburn. Although there is little systemic absorption of tretinoin and no alteration in plasma vitamin A levels with its use as a topical agent, most physicians do not prescribe tretinoin during pregnancy, and the FDA lists it as category X for pregnant women.

Isotretinoin

Oral isotretinoin (ACCUTANE) is approved for the treatment of severe nodulocystic acne vulgaris. The drug has remarkable efficacy in severe acne and may induce prolonged remissions after a single course of therapy. It normalizes keratinization in the sebaceous follicle, reduces sebocyte number with decreased sebum synthesis, and reduces Propionibacterium acnes, the organism that produces inflammation in acne (Layton and Cunliffe, 1992; Harper and Thiboutot, 2003).

Therapeutic Uses. Isotretinoin is administered orally. The recommended dose is 0.5 to 2 mg/kg per day for 15 to 20 weeks. Lower doses are effective but are associated with shorter remissions. The cumulative dose also is important, so smaller doses for longer periods can be used to achieve a total dose in the range of 120 mg/kg (Smith, 1999). Approximately 40% of patients will relapse, usually within 3 years of therapy, and may require retreatment (Layton et al., 1993). Preteens and patients with acne conglobata or androgen excess are at increased risk of relapse. However, mild relapses may respond to conventional management with topical and systemic antiacne agents.

Isotretinoin is prescribed for severe, recalcitrant nodular acne, moderate acne unresponsive to oral antibiotics, and acne that produces scarring. It also is used commonly for other related disorders, such as gram-negative folliculitis, acne rosacea, and hidradenitis suppurativa (Leyden, 1988).

Toxicity and Monitoring. A consensus statement regarding the safe and optimal use of isotretinoin has been published (Goldsmith et al., 2004). Dose-dependent adverse effects on the skin and mucous membranes are observed most commonly, including cheilitis, mucous membrane dryness, epistaxis, dry eyes, blepharoconjunctivitis, erythematous eruptions, and xerosis. Alteration of epidermal surfaces may facilitate Staphylococcus aureus colonization and, rarely, subsequent infection. Hair loss, exuberant granulation tissue formation, photosensitivity, and dark adaptation dysfunction are rarer occurrences.

Systemic side effects generally are less significant with short-term therapy. Transitory elevations in serum transaminases occur rarely. Hyperlipidemia is frequent, with 25% of patients developing increased triglyceride levels and, less frequently, increased cholesterol and low-density lipoproteins and decreased high-density lipoproteins (Bershad et al., 1985). Myalgia and arthralgia are common complaints. Headaches occur and rarely are a symptom of pseudotumor cerebri. Use of isotretinoin concomitantly with tetracycline antibiotics may increase the risk of pseudotumor cerebri. Controversy exists regarding the potential linking of isotretinoin to depression, suicidal thoughts, and suicide. Epidemiological studies to date have not shown an association between isotretinoin and depression or suicide, perhaps because acne itself may be a risk factor for depression. Some physicians have proposed a causal relationship with mood changes and depression in a limited number of patients. These uncontrolled clinical observations have not been examined in a rigorous, prospective manner. In addition, there is a paucity of data on the effect of retinoids on adult brain function (Goldsmith et al., 2004). Long-term therapy may produce skeletal side effects, including diffuse idiopathic skeletal hyperostoses, extraskeletal ossification (particularly at tendinous
insertions), and premature epiphyseal closure in children (DiGiovanna, 2001).

Teratogenicity is a major problem; it occurs if the drug is given within the first 3 weeks of gestation and is not dose-related. Teratogenic effects include CNS, cardiac, thymus, and craniofacial abnormalities. Spontaneous abortion occurs in one-third of patients (Lammer et al., 1985). Pregnancy is an absolute contraindication to the use of isotretinoin. Females of childbearing potential should initiate therapy at the beginning of a normal menstrual period after giving informed consent and obtaining two negative pregnancy tests. Two forms of birth control (one of which must be surgical or hormonal) must be practiced during therapy and for 1 month both before beginning therapy and after completion of therapy; pregnancy tests should be repeated monthly. Patients should not donate blood for transfusion for at least 3 years following discontinuation of therapy or at any time for at least 3 years following discontinuation of therapy.

The same precautions regarding blood donation described earlier for isotretinoin should be followed. Laboratory monitoring should include a baseline pregnancy test in all female patients and a complete blood count, lipid profile, and hepatic profile in all patients. Serial follow-up of laboratory tests should be conducted every 1 to 2 weeks until stable and thereafter as clinically indicated.

Bexarotene

Bexarotene (TARGRETIN) is a retinoid that selectively binds RXRs. Bexarotene has been used in patients with cutaneous T-cell lymphoma with a suggested dose of 300 mg/m² per day. Because it is metabolized by CYP3A4, inhibitors of CYP3A4 (e.g., imidazole antifungals and macrolide antibiotics) will increase and inducers of the CYP3A4 system will decrease plasma levels of bexarotene. Side effects include lipid abnormalities, hypothyroidism secondary to a reversible RXR-mediated suppression of TSH gene expression (Sherman, 2003), pancreatitis, leukopenia, and gastrointestinal symptoms. Blood lipids and thyroid function should be measured before initiating therapy and periodically thereafter.

Cancer Chemoprevention with Retinoids. The association of vitamin A deficiency with squamous metaplasia, increased cell proliferation, hyperkeratosis, and carcinoma suggested that retinoids might be valuable in the treatment and prevention of cutaneous premalignant and malignant disorders. Clinical trials indicate that retinoids have significant activity in the reversal of oral, skin, and cervical premalignancies and in the prevention of head and neck, lung, and skin primary tumors. As with the treatment of other dermatological diseases, individual retinoids show selectivity in tumor prevention and treatment.

Systemic and topical retinoids have been used successfully to treat premalignant skin conditions and may have a role in chemoprevention of skin malignancies. High-dose isotretinoin (2 mg/kg per day) has suppressed skin cancers in patients with increased risk of skin malignancy from congenital disorders such as xeroderma pigmentosa and nevoid basal cell carcinoma syndrome. To achieve an anticancer effect, toxic doses of retinoids generally are required. Acitretin at a dose of 25 mg/day or more appears to reduce the risk of skin cancer by about 25% among patients with psoriasis who are at high risk for squamous cell carcinoma because of prior use of 8-methoxypsoralen and ultraviolet radiation or other carcinogenic modalities for psoriasis (Nijsten and Stern, 2003). Tretinoin cream applied once or twice daily decreased the size and number of actinic keratoses by 50% in one multicenter study.

**Acitretin**

Acitretin (SORIATANE) is the major metabolite of etretinate, an aromatic retinoid that formerly was approved for psoriasis but withdrawn from the market because of its undesirable pharmacokinetics. Acitretin has an elimination half-life of 2 to 3 days.

Acitretin is readily esterified in vivo to produce etretinate, especially in the presence of ethanol (Katz et al., 1999). The optimal dosing range for acitretin in adults is 25 to 50 mg/day, providing efficacy with an acceptable level of side effects. Improvement of plaque psoriasis requires up to 3 to 6 months for optimal results. As monotherapy, acitretin has an overall rate of complete remission of less than 50% (Ling, 1999); response rates are higher when the drug is combined with other modalities (Lebwohl, 1999; Lebwohl et al., 2004). At doses of 10 to 25 mg/day, both pustular and erythrodermic psoriasis usually respond more rapidly than common plaque psoriasis. Excellent control of these conditions usually can be achieved with acitretin (Goldfok and Ellis, 1998). Common side effects include dry skin and mucous membranes, xerophthalmia, and hair thinning. Less frequently, arthralgias and decreased night vision have been noted. Serious side effects (e.g., hepatotoxicity or pseudotumor cerebri) are rare (Katz et al., 1999). Acitretin is a potent teratogen and should not be used by females who intend to become pregnant during therapy or at any time for at least 3 years following discontinuation of therapy.
High doses of isotretinoin produce partial regression of multiple basal cell carcinomas (Peck et al., 1988) but are more effective in suppressing the formation of new tumors, as demonstrated in patients with xeroderma pigmentosum (Kraemer et al., 1988). Isotretinoin also prevents second primary tumors in patients who have had a previous squamous cell carcinoma of the head and neck (Hong et al., 1990). Isotretinoin also is effective for oral leukoplakia (Hong et al., 1986). Topical tazarotene has shown efficacy in some basal cell carcinomas (Peris et al., 1999). Cutaneous T-cell lymphoma has been shown to respond to several types of topical and systemic retinoids, including bexarotene (Zhang and Duvic, 2003). The benefits of long-term retinoid use in malignant lymphomas such as cutaneous T-cell lymphoma must be balanced by appreciation of retinoid toxicity and the chronicity of the disease.

β-Carotene. β-Carotene (SOLATENE, others) is a precursor of vitamin A that is present in green and yellow vegetables. The drug is used in dermatology to reduce skin photosensitivity in patients with erythropoietic protoporphyria. The mechanism of action is controversial but may involve an antioxidant effect that decreases the production of free radicals or singlet oxygen (Harber and Bickers, 1989). While this concept has led to the use of β-carotene as a chemopreventative agent, current evidence indicates that this compound has no discernible cancer chemoprevention effects in human skin cancer (Darlington et al., 2003).

**PHOTOCHEMOTHERAPY**

Electromagnetic radiation is defined by its wavelength and frequency; for convenience, it can be classified into different regions based on its photon energy. For therapeutic purposes, dermatologists are most concerned with the ultraviolet (UV) B (290 to 320 nm), A-I (320 to 340 nm), and A-II (340 to 400 nm) portions of the solar spectrum. UVC (100 to 290 nm) is absorbed by stratospheric ozone, does not reach earth’s surface, and is no longer used therapeutically. UVB is the most erythrogenic and melanogenic type of radiation. It is the major action spectrum for sunburn, tanning, skin cancer, and photoaging. The longer wavelengths of UVA are a thousand times less erythrogenic than UVB; however, they penetrate more deeply into the skin and contribute substantially to photoaging and photosensitivity diseases. They also enhance UVB-induced erythema and increase the risk of skin carcinogenesis. Visible radiation may augment the severity of some photosensitive eruptions. Electromagnetic radiation has proven to be highly efficacious in the treatment of numerous dermatologic diseases (Scheinfeld and Deleo, 2003; Lebwohl et al., 2004). Phototherapy and photochemotherapy are treatment methods in which ultraviolet or visible radiation is used to induce a therapeutic response either alone or in the presence of a photosensitizing drug. Phototherapy using broad-band (290 to 320 nm) or narrow-band (311 to 313 nm) UVB or high-dose UVA-I is efficacious in selected dermatological diseases. To be effective, the incident radiation must be absorbed by a target or chromophore in the skin—which in phototherapy is endogenous and in photochemotherapy must be administered exogenously. Patients treated with these modalities should be monitored for concomitant use of other potential photosensitizing medications before initiation of therapy. Such drugs include phenothiazines, thiazides, sulfonamides, nonsteroidal antiinflammatory agents, sulfonylureas, tetracyclines, and benzodiazepines.

**PUVA: Psoralens and UVA**

Photochemotherapy with psoralen-containing plant extracts was employed for the treatment of vitiligo in Egypt and India as early as 1500 B.C. Orally administered 8-methoxypsoralen followed by UVA (PUVA) is FDA approved for the treatment of vitiligo, psoriasis, and cutaneous T-cell lymphoma.

**Chemistry.** Psoralens belong to the furocoumarin class of compounds, which are derived from the fusion of a furan with a coumarin. They occur naturally in many plants, including limes, lemons, figs, and parsnips. Two psoralens, 8-methoxypsoralen (methoxsalen) and 4, 5, 8-trimethylpsoralen (trioxsalen, TRISORALEN) are available in the United States. Methoxsalen is used primarily because of its superior gastrointestinal absorption. Structures of the two psoralens are:

![Methoxsalen](image1)

![Trioxsalen](image2)

**Pharmacokinetics.** The psoralens are absorbed rapidly after oral administration. Photosensitivity typically is maximal 1 to 2 hours after ingestion of methoxsalen. There is significant but saturable first-pass elimination in the liver, which may account for variations in plasma levels among individuals after a standard dose. Methoxsalen has a serum half-life of approximately 1 hour, but the skin remains sensitive to light for 8 to 12 hours. Despite widespread drug distribution throughout the body, it is photoactivated only in the skin where the UVA penetrates.

**Mechanism of Action.** The mechanism by which PUVA induces photosensitivity is not known. The action spectrum for oral PUVA is between 320 and 400 nm. Two distinct photoreactions take place. Type I reactions involve the oxygen-independent formation of mono- and bifunctional adducts in DNA. Type II reactions are oxygen-dependent and involve sensitized transfer of energy to molecular oxygen. The therapeutic effects of PUVA in psoriasis may result from a decrease in DNA-dependent proliferation after adduct formation. Perhaps more important, PUVA can alter cytokine profiles and cause immunocyte apoptosis, thereby interrupting immunopathologic processes (Godar, 1999).

PUVA promotes melanogenesis in normal skin. Increased pigmentation results from augmented transfer...
of melanosomes from melanocytes to keratinocytes; however, there is no change in the size of melanosomes or in their distribution pattern.

**Therapeutic Uses.** Methoxsalen is supplied in soft gelatin capsules (OXSORALEN-ULTRA) and hard gelatin capsules (8-MOP). The dose is 0.4 mg/kg for the soft capsule and 0.6 mg/kg for the hard capsule taken 1.5 to 2 hours before UVA exposure. A lotion containing 1% methoxsalen (OXSORALEN) also is available for topical application. It can be diluted for use in bath water to minimize systemic absorption. The risk of phototoxicity is increased with topical PUVA therapy. In U.S. and European multicenter cooperative studies of PUVA for the treatment of psoriasis, initial clearance rates approaching 90% were achieved (Melski et al., 1977; Henseler et al., 1981). Relapse occurs within 6 months of cessation of treatment in many patients, which has prompted efforts to design maintenance protocols.

PUVA also is used to repigment the leukoderma of vitiligo. Success rates are highest in young individuals with recent onset of disease involving nonacral areas. Localized vitiligo can be treated with topical PUVA and more extensive disease with systemic administration. PUVA also is employed in the treatment of cutaneous T-cell lymphoma, atopic dermatitis, alopecia areata, lichen planus, urticaria pigmentosa, and as a preventive modality in some forms of photosensitivity.

**Toxicity and Monitoring.** The major acute side effects of PUVA include nausea, blistering, and painful erythema. PUVA-induced redness and blistering generally peak within 48 to 72 hours.

Chronic PUVA therapy accelerates photoaging and the development of actinic keratoses, nonmelanoma skin cancer, and melanoma. Squamous cell carcinomas occur at 10 times the expected frequency. In patients receiving 250 or more treatments, there is an increased risk of melanoma. Careful monitoring of patients for cutaneous carcinoma therefore is essential.

**Photopheresis.** Extracorporeal photopheresis (ECP) is a form of pheresis therapy that has proven effective in the treatment of cutaneous T-cell lymphoma (Edelson et al., 1987). After oral administration of methoxsalen, leukocytes are separated from whole blood using an extracorporeal pheresis device and then exposed to UVA radiation. The irradiated cells then are returned to the patient. Multiple mechanisms probably contribute to the effectiveness of this procedure. ECP simultaneously and efficiently induces apoptosis of disease-causing T cells and con-
Incoherent (nonlaser) and laser light sources have been used for PDT. The wavelengths chosen must include those within the action spectrum of protoporphyrin and ideally those that permit maximum skin penetration. Light sources in use emit energy predominantly in the blue portion (maximum porphyrin absorption) or the red portion (better tissue penetration) of the visible spectrum. Nonhypertrophic actinic keratoses (Piacquadio et al., 2004) and superficial basal cell carcinomas and Bowen's disease seem to respond best to PDT. Topical ALA products for PDT approved by the FDA include LEVULAN KERASTICK, BLU-U blue light, and METVIX.

**ANTIHISTAMINES**

Histamine is a potent vasodilator, bronchial smooth muscle constrictor, and stimulant of nociceptive itch nerves (Repka-Ramirez and Baraniuk, 2002). In addition to histamine, multiple chemical itch mediators can act as pruritogens on C-fibers, including neuropeptides, prostaglandins, serotonin, acetylcholine, and bradykinin (Stander et al., 2003). Furthermore, new receptor systems such as vanilloid, opioid, and cannabinoid receptors on cutaneous sensory nerve fibers that may modulate itch offer novel targets for antipruritic therapy.

Histamine is in mast cells, basophils, and platelets. Human skin mast cells express H<sub>1</sub>, H<sub>2</sub>, and H<sub>4</sub> receptors but not H<sub>3</sub> receptors (Lippert et al., 2004). H<sub>1</sub> and H<sub>2</sub> receptors are involved in wheal formation and erythema, whereas only H<sub>1</sub> receptor agonists cause pruritus. Complete blockade of H<sub>1</sub> receptors does not totally relieve itching, and combinations of H<sub>1</sub> and H<sub>2</sub> blockers may be superior to H<sub>1</sub> blockers alone.

Oral antihistamines, particularly H<sub>1</sub>-receptor antagonists, have some anticholinergic activity and are sedating (see Chapter 24), making them useful for the control of pruritus. First-generation sedating H<sub>1</sub>-receptor antagonists include hydroxyzine hydrochloride (ATARAX), which is given in a dose of 0.5 mg/kg every 6 hours; diphenhydramine (BENADRYL; others); promethazine (PHENERGY); and cyproheptadine (PERIACTIN). Doxepin (ADAPIN, SINEQUAN), which has tricyclic antidepressant and sedative antihistamine effects (see Chapter 17), is a good alternative for severe pruritus. A topical formulation of doxepin also is available as a 5% cream (ZONALON), which can be used in conjunction with low- to moderate-potency topical glucocorticoids. The systemic effect from topical doxepin is comparable with that of low-dose oral therapy.

Second-generation H<sub>1</sub>-receptor antagonists lack anticholinergic side effects and are described as nonsedating largely because they do not cross the blood–brain barrier. They include cetirizine (ZYRTEC), loratadine (CLARITIN), desloratadine (CLARINEX), and fexofenadine hydrochloride (ALLEGRA). While second-generation nonsedating H<sub>1</sub>-receptor blockers are as effective as the first-generation H<sub>1</sub> blockers (Monroe, 1993), they are metabolized by CYP3A4 and, to a lesser extent, by CYP2D6 and should not be coadministered with medications that inhibit these enzymes (e.g., imidazole antifungals and macrolide antibiotics).

H<sub>2</sub>-receptor blockers include cimetidine (TAGAMET), ranitidine (ZANTAC), famotidine (PEPCID), and nizatidine (AXID). Besides their use in combination with H<sub>1</sub>-receptor blockers for pruritus, the H<sub>2</sub>-receptor blockers have immunomodulating effects, and this property has been exploited in children to treat warts (Orlow and Paller, 1993).

**ANTIMICROBIAL AGENTS**

**Antibiotics**

These drugs are used commonly to treat superficial cutaneous infections (pyoderma) and noninfectious diseases. Topical agents are very effective for the treatment of superficial bacterial infections and acne vulgaris. Systemic antibiotics also are prescribed commonly for acne and for deeper bacterial infections. The pharmacology of individual antibacterial agents is discussed in Section VIII, Chemotherapy of Microbial Diseases. Only the topical and systemic antibacterial agents principally used in dermatology are discussed here.

Acne vulgaris is the most common dermatologic disorder treated with either topical or systemic antibiotics. The anaerobe Propionibacterium acnes is a component of normal skin flora that proliferates in the obstructed, lipid-rich lumen of the pilosebaceous unit, where O<sub>2</sub> tension is low. P. acnes generates free fatty acids that are irritants and may lead to microcomedo formation and result in the inflammatory lesions of acne. Suppression of cutaneous...
Resistant strains of *P. acnes* are emerging that may respond to judicious use of retinoids in combination with antibiotics (Leyden, 2001). Commonly used topical antimicrobials in acne include tetracycline (SUMYCIN, others), clindamycin (CLEOCIN), and benzoyl peroxide and antibiotic–benzoyl peroxide combinations (BENZAMYCIN, BENZACLIN, others). Other antimicrobials used in treating acne include sulfacetamide (KLARON), sulfacetamide/sulfur combinations (SULFACET-R), metronidazole (METROCLEAR, METROGEL, NORITATE), and azelaic acid (AZELEX). Systemic therapy is prescribed for patients with more extensive disease and acne that is resistant to topical therapy. Effective agents include tetracycline (SUMYCIN, others), minocycline (MINOCIN, others), erythromycin (ERYC, others), clindamycin (CLEOCIN), and trimethoprim–sulfamethoxazole (BACTRIM, others). Antibiotics usually are administered twice daily, and doses are tapered after control is achieved. Tetracycline is the most commonly employed antibiotic because it is inexpensive, safe, and effective. The initial daily dose is usually 1 g in divided doses. Although tetracycline is an antimicrobial agent, its efficacy in acne may be more dependent on its antiinflammatory activity.

Minocycline has better gastrointestinal absorption than tetracycline and may be less photosensitizing than either tetracycline or doxycycline. Side effects of minocycline include dizziness and hyperpigmentation of the skin and mucosa, serum-sickness-like reactions, and drug-induced lupus erythematosus. With all the tetracyclines, vaginal candidiasis is a common complication that is readily treated with local administration of antifungal drugs.

In healthy individuals taking oral antibiotics for acne, laboratory monitoring is not necessary. Orally administered antibiotics also may be indicated in other noninfectious conditions, including acne rosacea, perioral dermatitis, hidradenitis suppurativa, autoimmune blistering diseases, sarcoidosis, and pyoderma gangrenosum (Carter, 2003).

**Cutaneous Infections.** Gram-positive organisms, including *Staphylococcus aureus* and *Streptococcus pyogenes*, are the most common cause of pyoderma. Skin infections with gram-negative bacilli are rare, although they can occur in diabetics and patients who are immunosuppressed; appropriate parenteral antibiotic therapy is required for their treatment.

Topical therapy frequently is adequate for impetigo, the most superficial bacterial infection of the skin caused by *S. aureus* and *S. pyogenes*. *Pseudomonas aeruginosa* (MUPIROCIN, BACTROBAN), produced by *Pseudomonas fluorescens*, is effective for such localized infections. It inhibits protein synthesis by binding to bacterial isoleucyl-tRNA synthetase. Mupirocin is highly active against staphylococci and all streptococci except those of group D. It is less active against gram-negative organisms, but it has *in vitro* activity against *Haemophilus influenzae*, *Neisseria gonorrhoeae*, *Pasteurella multocida*, *Moraxella catarrhalis*, and *Bordetella pertussis*. Mupirocin is inactive against normal skin flora (Leyden, 1992). Its antibacterial activity is enhanced by the acid pH of the skin surface. Mupirocin is available as a 2% ointment or cream (BACTODERM, BACTROBAN, BACTROBAN NASAL, EISMYCIN) and is applied three times daily.

Topical therapy often is employed for prophylaxis of superficial infections caused by wounds and injuries. Neomycin is active against staphylococci and most gram-negative bacilli. It may cause allergic contact dermatitis, especially on disrupted skin. Bacitracin inhibits staphylococci, streptococci, and gram-positive bacilli. Polymyxin B is active against aerobic gram-negative bacilli. Bacitracin and polymyxin B are combined in a number of over-the-counter preparations.

Deeper bacterial infections of the skin include folliculitis, erysipelas, cellulitis, and necrotizing fasciitis. Since streptococcal and staphylococcal species also are the most common causes of deep cutaneous infections, *penicillins* (especially β-lactamase-resistant β-lactams) and *cephalosporins* are the systemic antibiotics used most frequently in their treatment (Carter, 2003) (see Chapter 44). A growing concern is the increased incidence of skin and soft tissue infections with hospital- and community-acquired methicillin-resistant *S. aureus* (MRSA) and drug-resistant pneumococci. Infection with community-acquired MRSA often is susceptible to trimethoprim–sulfamethoxazole (Cohen and Grossman, 2004).

Novel antibacterial agents such as linezolid, quinupristin–dalfopristin, and daptomycin (see Chapter 46) have been approved for the treatment of complicated skin and skin-structure infections (Schweiger and Weinberg, 2004).

**Antifungal Agents**

Fungal infections are among the most common causes of skin disease in the United States, and numerous effective topical and oral antifungal agents have been developed. *Griseofulvin*, topical and oral *imidazoles*, *triazoles*, and *allylamines* are the most effective agents available. The pharmacology, uses, and toxicities of antifungal drugs are discussed in Chapter 48. This section will address the management of common cutaneous fungal diseases. Recommendations for cutaneous antifungal therapy are summarized in Table 62–2.

The azoles *miconazole* (MICATIN, others) and econazole (SPECTRAZOLE, others) and the allylamines *naftifine* (NAFTIN) and *terbinafine* (LAMISIL, others) are effective topical agents for the treatment of localized tinea corporis and uncomplicated tinea pedis. Topical therapy with the azoles is preferred for localized cutaneous candidiasis and tinea versicolor.

Systemic therapy is necessary for the treatment of tinea capitis. Oral *griseofulvin* (FULVICIN V/F, P/G, others) has been the traditional medication for treatment of tinea capitis. Oral *terbinafine* is a safe and effective alternative to griseofulvin in treating tinea capitis in children (Moosavi et al., 2001).
Tinea Pedis. Topical therapy with the azoles and allylamines is effective for tinea pedis. Macerated toe web disease may require the addition of antibacterial therapy. Econazole nitrate, which has a limited antibacterial spectrum, can be useful in this situation. Systemic therapy with griseofulvin, terbinafine, or itraconazole (SPORANOX, others) is used for more extensive tinea pedis. It should be recognized that long-term topical therapy may be necessary in some patients after courses of systemic antifungal therapy.

Onychomycosis. Fungal infection of the nails is caused most frequently by dermatophytes and Candida. Mixed infections are common. The nail must be cultured or clipped for histological examination before initiating therapy because up to a third of dystrophic nails that appear clinically to be onychomycosis are actually due to psoriasis or other conditions.

Systemic therapy is necessary for effective management of onychomycosis. Treatment of onychomycosis of toenails with griseofulvin for 12 to 18 months produces a cure rate of 50% and a relapse rate of 50% after 1 year. Terbinafine and itraconazole offer significant potential advantages. They quickly produce high drug levels in the nail, which persist after therapy is discontinued. Additional advantages include a broader spectrum of coverage with itraconazole and few drug interactions with terbinafine. Treatment of toenail onychomycosis requires 3 months with terbinafine (250 mg/day) or itraconazole (pulsed dosing 1 week per month for 3 months). Cure rates of 75% or greater have been achieved with both drugs (Gupta et al., 1994a, 1994b; Darkes et al., 2003).

Ciclopirox topical (PENLAC) solution is a nail lacquer that is FDA approved for the treatment of onychomycosis but demonstrates low complete cure rates (5.5% to 8.5%).

Antiviral Agents

Viral infections of the skin are very common and include verrucae [human papillomavirus (HPV)], herpes simplex (HSV), condyloma acuminatum (HPV), molluscum contagiosum (poxvirus), and chicken pox [varicella-zoster virus (VZV)]. Acyclovir (ZOVIRAX), famciclovir (FAM-VIR), and valacyclovir (VALTREX) frequently are used systemically to treat herpes simplex and varicella infections (see Chapter 49). Cidofovir (VISTIDE) may be useful in treating acyclovir-resistant HSV or VZV and other cutaneous viral infections (Anonymous, 2002a). Topically, acyclovir, docosanol (ABREVA), and penciclovir (DENAVIR) are available for treating mucocutaneous HSV. Podophyllin (25% solution) and podofilox (CONDYLOX; 0.5% solution) are used to treat condylomata. The immune response modifier imiquimod (ALDARA) is discussed below. Interferons $\alpha$-2b (INTRON-A), $\alpha$-n1 (not commercially available in the United States), and $\alpha$-n3 (ALFERON N) may be useful for treating refractory or recurrent warts (Carter et al., 2004).

Agents Used to Treat Infestations

Infestations with ectoparasites such as body lice and scabies are common throughout the world. These conditions have a significant impact on public health in the form of disabling pruritus, secondary infection, and in the case of the body louse, transmission of life-threatening illnesses such as typhus. Topical and oral medications are available to treat these infestations.

Perhaps the best known anti-ectoparasitic medication is 1% $\gamma$-benzene hexachloride lotion, also known as lindane. Its chemical structure is:

Table 62–2

Recommended Cutaneous Antifungal Therapy
Lindane has been used as a commercial insecticide as well as a topical medication. It is highly effective in the treatment of ectoparasites. Neurotoxicity, although a concern with the use of lindane, is a rare side effect when the medication is used correctly. However, the FDA has defined lindane as a second-line drug in treating pediculosis and scabies and has highlighted the potential for neurotoxicity in children and adults weighing less than 110 pounds (FDA, 2003). The lotion is applied in a thin layer from the neck down, left in place for 8 to 12 hours or overnight, and removed by thorough washing at the end of the 8- to 12-hour period. The treatment may be repeated in 1 week. To avoid problems with neurotoxicity, the lotion should be applied only in a thin coat to dry skin, should not be applied immediately after bathing, and should be kept away from the eyes, mouth, and open cuts or sores. A 1% lindane shampoo also is available for head and body lice.

A second topical agent that is very useful in the treatment of ectoparasites is permethrin. Its structure is:

Permethrin is a synthetic derivative of the insecticide pyrethrum, which was obtained originally from Chrysanthemum cinerariaefolium. Neurotoxicity associated with this compound is extremely rare. A 5% cream (ACTICIN, ELIMITE, others) is available for the treatment of scabies. This is used as an 8- to 12-hour or overnight application. A 1% permethrin cream rinse (NIX) also is available for the treatment of lice.

Ivermectin (STROMECTOL), an anthelmintic drug (see Chapter 41) used traditionally to treat onchocerciasis, also is effective in the off-label treatment of scabies. Its structure is:

Because ivermectin does not cross the blood–brain barrier, there is no major CNS toxicity. Ivermectin, available as a 6-mg tablet, is given at a dose of 250 to 400 μg/kg, which is repeated in a week. Cure rates of 70% after one dose and 95% after two doses given 2 weeks apart have been achieved (Usha et al., 2000). For treatment of scabies outbreaks in large groups, this drug has obvious advantages as compared with topical therapy.

Other, less effective topical treatments for scabies include 10% crotamiton cream and lotion (EURAX) and 5% precipitated sulfur in petrolatum. Crotamiton and sulfur typically are considered for use in patients in whom lindane or permethrin may be contraindicated.

**ANTIMALARIAL AGENTS**

The major antimalarials used commonly in dermatology include chloroquine (ARALEN), hydroxychloroquine (PLAQUENIL), and to a lesser extent, quinacrine (no longer available in the United States); all three drugs are useful because of their antiinflammatory effects, especially in connective tissue disorders and photosensitivity diseases (see Chapter 39).

The mechanism of action of antimalarials is controversial, but there are immunological and antiinflammatory effects. Likely mechanisms of action include inhibition of phospholipase A2, inhibition of platelet aggregation, a range of lysosomal effects (e.g., an increase in pH, membrane stabilization, and inhibition of release and activity of lysosomal enzymes), inhibition of phagocytosis, an increase in intracellular pH in cytoplasmic vacuoles leading to decreased stimulation of autoimmune CD4+ T cells, decreased cytokine release from lymphocytes and stimulated monocytes, inhibition of immune complex formation, and antioxidant activity (Van Beek and Piette, 2001; Callen and Camisa, 2001). In patients with porphyria cutanea tarda, chloroquine and hydroxychloroquine bind to porphyrins and/or iron to facilitate their hepatic clearance. The ability to bind to melanin and other pigments may contribute to the retinal toxicity seen occasionally when antimalarial agents are used.
Therapeutic Uses. FDA-approved dermatological uses of hydroxychloroquine include treatment of discoid and systemic lupus erythematosus. Unapproved but first-line uses include treatment of dermatomyositis, porphyria cutanea tarda, polymorphous light eruption, sarcoidosis, eosinophilic fascitis, lymphocytic infiltrate of Jessner, lymphocytoma cutis, solar urticaria, granuloma annulare, and some forms of panniculitis.

The usual doses of antimalarials are hydroxychloroquine, 200 mg twice a day; chloroquine, 250 to 500 mg/day; and quinacrine, 100 to 200 mg/day. Usually, hydroxychloroquine is started first, and if no improvement is noted in 3 months, quinacrine is added. Alternatively, chloroquine is used as a single agent. Dosing should be adjusted for low-weight individuals so that chloroquine dosing is 2.5 mg/kg per day and hydroxychloroquine is 6.5 mg/kg per day. Antimalarial agents are the treatment of choice for widespread forms of cutaneous lupus that do not respond to topical glucocorticoids and sunscreens. Clinical improvement may be delayed for several months.

Porphyria cutanea tarda, characterized by fluid-filled vesicles and bullae on sun-exposed areas, can be either genetic or associated with alcohol abuse or hepatitis C. Although the associated iron overload is treated with phlebotomy, the dermatologic manifestations sometimes are treated with antimalarial agents. These patients require reduced doses because of the potential for hepatotoxicity, as manifested by elevated transaminase levels, and the rapid excretion of large amounts of uroporphyrins in the urine that can occur with usual doses. Low-dose twice-weekly administration is effective and avoids these side effects.

Toxicity and Monitoring. The toxic effects of antimalarial agents are described in Chapter 39. The incidence of retinopathy from chloroquine and hydroxychloroquine is low, as long as the doses are within the above-mentioned guidelines and the medication is used for less than 10 years in patients with normal renal function (Callen and Camisa, 2001).

Quinacrine does not cause retinopathy. Current recommendations for ophthalmological supervision may be overly cautious, and eye examinations every 6 months or even yearly after a baseline examination probably are sufficient, provided dosing guidelines are followed. Although caution is required, there is evidence that antimalarial agents probably are safe in pregnancy and in children (Parke, 1993; Callen and Camisa, 2001).

Cytotoxic and immunosuppressant drugs are used in dermatology for immunologically mediated diseases such as psoriasis, the autoimmune blistering diseases, and leukocytoclastic vasculitis. These agents are discussed in detail in Chapters 51 and 52.

Antimetabolites

Methotrexate. The antimetabolite methotrexate is a folic acid analog that competitively inhibits dihydrofolate reductase. Methotrexate has been used for moderate-to-severe psoriasis since 1951. It suppresses immunocompetent cells in the skin, and it also decreases the expression of cutaneous lymphocyte-associated antigen (CLA)–positive T cells and endothelial cell E-selectin, which may account for its efficacy in psoriasis (Sigmundsdottir et al., 2004). It is useful in treating a number of other dermatological conditions, including pityriasis lichenoides et varioliformis, lymphomatoid papulosis, sarcoidosis, pemphigus vulgaris, pityriasis rubra pilaris, lupus erythematosus, dermatomyositis, and cutaneous T-cell lymphoma.

Despite its widespread acceptance for decades as a first-line systemic monotherapy for the treatment of psoriasis, methotrexate (RHEUMATREX, others) was subjected only recently to a randomized, controlled clinical trial comparing its efficacy with that of orally administered cyclosporine for the treatment of moderate to severe chronic plaque psoriasis (Heyndendael et al., 2003). Both medications were equally effective in achieving partial or complete clearing of psoriasis. Methotrexate is used often in combination with phototherapy and photochemotherapy or other systemic agents, and it also may be useful in combination with the biologics (Saporito and Menter, 2004) (see Biological Agents, below).

A usual starting dose for methotrexate therapy is 5 to 7.5 mg/week (maximum of 15 mg/week). This dose may be increased gradually to 20 to 30 mg/week if needed. Widely used regimens include three oral doses given at 12-hour intervals once weekly or weekly intramuscular injections. Doses must be decreased for patients with impaired renal clearance. Methotrexate should never be
coadministered with trimethoprim–sulfamethoxazole, probenecid, salicylates, or other drugs that can compete with it for protein binding and thereby raise plasma concentrations to levels that may result in bone marrow suppression. Fatalities have occurred because of concurrent treatment with methotrexate and nonsteroidal antiinflammatory agents. Methotrexate exerts significant antiproliferative effects on the bone marrow; therefore, complete blood counts should be monitored serially. Physicians administering methotrexate should be familiar with the use of folinic acid (leucovorin) to rescue patients with hematologic crises caused by methotrexate-induced bone marrow suppression. Careful monitoring of liver function tests is necessary but may not be adequate to identify early hepatic fibrosis in patients receiving chronic methotrexate therapy. Some believe that methotrexate-induced hepatic fibrosis occurs more commonly in patients with psoriasis than in those with rheumatoid arthritis. Consequently, liver biopsy is recommended when the cumulative dose reaches 1 to 1.5 g. A baseline liver biopsy is also recommended for patients with increased potential risk for hepatic fibrosis, such as a history of alcohol abuse or infection with hepatitis B or C. Patients with significantly abnormal liver function tests, symptomatic liver disease, or evidence of hepatic fibrosis should not use this drug. Pregnancy and lactation are absolute contraindications to methotrexate use (Roenigk et al., 1998).

Azathioprine (IMURAN) is discussed in detail in Chapters 38 and 52. In dermatologic practice, the drug is used as a steroid-sparing agent for autoimmune and inflammatory dermatoses, including pemphigus vulgaris, bullous pemphigoid, dermatomyositis, atopic dermatitis, chronic actinic dermatitis, lupus erythematosus, psoriasis, pyoderma gangrenosum, and Behçet’s disease (Silvis, 2001). The usual starting dose is 1 to 2 mg/kg per day. Since it often takes 6 to 8 weeks to achieve therapeutic effect, azathioprine is often started early in the course of disease management. Careful laboratory monitoring is important (Silvis, 2001). The enzyme thiopurine S-methyltransferase is critical for the metabolism of azathioprine to nontoxic metabolites. Homozygous deficiency of this enzyme may raise plasma levels of the drug and cause myelosuppression, and some experts advocate measuring this enzyme before initiating azathioprine therapy (see Chapter 38).

Fluorouracil (5-FU) interferes with DNA synthesis by blocking the methylation of deoxyuridylic acid to thymidylic acid (Dinehart, 2000). Topical formulations (CARAC, EFUDEX, FLUOROPLEX) are used in multiple actinic keratoses, actinic cheilitis, Bowen’s disease, and superficial basal cell carcinomas not amenable to other treatments.

Fluorouracil is applied twice daily for 2 to 4 weeks. The treated areas may become severely inflamed during treatment, but the inflammation subsides after the drug is stopped. Intralional injection of 5-FU has been used for keratoacanthomas, warts, and porokeratoses.

Alkylating Agents. Cyclophosphamide (CYTOXAN, NOSAR) is an effective cytotoxic and immunosuppressive agent.

Both oral and intravenous preparations of cyclophosphamide are used in dermatology (Fox and Pandya, 2000). Cyclophosphamide is FDA approved for treatment of advanced cutaneous T-cell lymphoma. Other uses include treatment of pemphigus vulgaris, bullous pemphigoid, cicatricial pemphigoid, paraneoplastic pemphigus, pyoderma gangrenosum, toxic epidermal necrolysis, Wegener’s granulomatosis, polyarteritis nodosa, Churg-Strauss angiitis, Behçet’s disease, scleromyxedema, and cytopathic histiocytic panniculitis (Ho and Zloty, 1993; Silvis, 2001). The usual oral dose is 2 to 3 mg/kg per day in divided doses, and there is often a 4- to 6-week delay in onset of action. Alternatively, intravenous pulse administration of cyclophosphamide may offer advantages, including lower cumulative dose and a decreased risk of bladder cancer (Fox and Pandya, 2000; Silvis, 2001).

Cyclophosphamide has many adverse effects, including the risk of secondary malignancy and myelosuppression, and thus is used only in the most severe, recalcitrant dermatological diseases. The secondary malignancies have included bladder, myeloproliferative, and lymphoproliferative malignancies and have been seen with the use of cyclophosphamide alone or in combination with other antineoplastic drugs.

Mechlorethamine hydrochloride (MUSTARGEN) and carmustine (bischloronitrosourea, BCNU, BCNU) are used topically to treat cutaneous T-cell lymphoma. Both can be applied as a solution or in ointment form. It is important to monitor complete blood counts and liver function tests because systemic absorption can cause bone marrow suppression and hepatitis. Other side effects include allergic contact dermatitis, irritant dermatitis, secondary cutaneous malignancies, and pigmentary changes. Carmustine also can cause erythema and posttreatment telangiectasias (Zackheim et al., 1990).

Calcineurin Inhibitors. Cyclosporine (SANDIMMUNE, NEORAL, SANGCYA) is a potent immunosuppressant isolated from the fungus Tolypocladium inflatum. It inhibits calcineurin, a phosphatase that normally dephosphorylates the cytoplasmic subunit of nuclear factor of activated T cells (NFAT), thus permitting NFAT to translocate to the nucleus and augment transcription of numerous cytokines.
In T-lymphocytes, calcineurin inhibition blocks interleukin 2 (IL-2) gene transcription and release and ultimately results in inhibition of T-cell activation (Cather et al., 2001). The presence of calcineurin in Langerhans’ cells, mast cells, and keratinocytes may further explain the therapeutic efficacy of cyclosporine and the other calcineurin inhibitors (e.g., tacrolimus and pimecrolimus; see below) (Reynolds and Al-Daraji, 2002). Cyclosporine has FDA approval for the treatment of psoriasis. Other cutaneous disorders that typically respond well to cyclosporine are atopic dermatitis (Czech et al., 2000), alopecia areata, epidermolysis bullosa acquisita, pemphigus vulgaris, bullous pemphigoid, lichen planus, and pyoderma gangrenosum. The usual initial oral dose is 3 to 5 mg/kg per day given in divided doses.

Hypertension and renal dysfunction are the major adverse effects associated with the use of cyclosporine. These risks can be minimized by monitoring serum creatinine (which should not rise more than 30% above baseline), calculating creatinine clearance or glomerular filtration rate in patients on long-term therapy or with a rising creatinine, maintaining a daily dose of less than 5 mg/kg, and regular monitoring of blood pressure (Cather et al., 2001). Alternation with other therapeutic modalities may diminish cyclosporine toxicity (Shupack et al., 1997). Laboratory monitoring during therapy is essential. Cyclosporine is not mutagenic. However, as with other immunosuppressive agents, patients with psoriasis treated with cyclosporine are at increased risk of cutaneous, solid organ, and lymphoproliferative malignancies (Flores and Kerdel, 2000). The risk of cutaneous malignancies is compounded if patients have received phototherapy with PUVA.

Tacrolimus (FK506, PROGRAF), a metabolite of Streptomyces tsukubaensis, was discovered in 1984. The structure of tacrolimus is:

![Tacrolimus Structure](image)

It is a potent macrolide immunosuppressant traditionally used to prevent kidney, liver, and heart allograft rejection. Like cyclosporine, tacrolimus works mainly by inhibiting early activation of T-lymphocytes, thereby inhibiting the release of IL-2, suppressing humoral and cell-mediated immune responses, and suppressing mediator release from mast cells and basophils (Anonymous, 2001; Assmann and Ruzicka, 2002). In contrast to cyclosporine, this effect is mediated by binding to the intracellular protein FK506-binding protein 12, generating a complex that inhibits the phosphatase activity of calcineurin.

Tacrolimus is available in oral and topical forms for the treatment of skin disease. Systemic tacrolimus has shown some efficacy in the treatment of inflammatory skin diseases such as psoriasis, pyoderma gangrenosum, and Behçet’s disease (Dé Tran et al., 2001; Assmann and Ruzicka, 2002). When administered systemically, the most common side effects are hypertension, nephrotoxicity, neurotoxicity, gastrointestinal symptoms, hyperglycemia, and hyperlipidemia. Topical formulations of tacrolimus penetrate into the epidermis.

In commercially available topical formulations (0.03% and 0.1%), tacrolimus ointment (PROTOPTIC) is effective in and approved for the treatment of atopic dermatitis in adults (0.03% and 0.1%) and children (0.03%). Other uses in dermatology include intirriginious psoriasis, vitiligo, mucosal lichen planus, graft-versus-host disease, allergic contact dermatitis, and rosacea (Ngheim et al., 2002). It is applied to the affected area twice a day and generally is well tolerated.

A major benefit of topical tacrolimus compared with topical glucocorticoids is that tacrolimus does not cause skin atrophy and therefore can be used safely in locations such as the face and intertriginous areas. Common side effects at the site of application are transient erythema, burning, and pruritus, which tend to improve with continued treatment. Other reported adverse effects include skin tingling, flu-like symptoms, headache, alcohol intolerance, folliculitis, acne, and hyperesthesia (Ngheim et al., 2002). Skin infections have been reported, although whether an increased risk truly exists relative to age-matched controls is uncertain (Anonymous, 2001). Systemic absorption generally is very low and decreases with resolution of the dermatitis. However, topical tacrolimus should be used with extreme caution in patients with Netherton’s syndrome because these patients have been shown to develop elevated blood levels of the drug after topical application (Assmann and Ruzicka, 2002). Mice treated with 0.1% topical tacrolimus had a higher incidence of lymphoma and, after exposure to UV radiation, showed decreased time to skin tumor formation. It therefore is recommended that patients using tacrolimus use...
sunscreen and avoid excessive UV exposure. The risk of lymphoma development in humans is uncertain (Anonymous, 2001).

Pimecrolimus 1% cream (ELIDEL), a macrolide derived from ascomycin, is FDA approved for the treatment of atopic dermatitis in patients older than 2 years of age. The structure of pimecrolimus is:

![](image)

Its mechanism of action and side-effect profile are similar to those of tacrolimus. Burning, while occurring in some patients, appears to be less common with pimecrolimus than with tacrolimus (Ngheim et al., 2002). In addition, pimecrolimus has less systemic absorption. Similar precautions with regard to UV exposure should be taken during treatment with pimecrolimus (Anonymous, 2002b).

### MISCELLANEOUS IMMUNOSUPPRESSANT AND ANTIINFLAMMATORY AGENTS

*Imiquimod (ALDARA)* is a synthetic imidazoquinoline amine believed to exert immunomodulatory effects by acting as a ligand at toll-like receptors in the innate immune system and inducing the cytokines interferon-α (IFN-α), tumor necrosis factor-α (TNF-α), and IL-1, IL-6, IL-8, IL-10, and IL-12. The structure of imiquimod is:

![](image)

Approved for the treatment of genital warts since 1997, imiquimod is applied to genital or perianal lesions three times a week usually for a 16-week period that may be repeated as necessary. Imiquimod also has been approved recently for the treatment of actinic keratoses. In this capacity, imiquimod is applied three times a week for 16 weeks to the face, scalp, and arms (Anonymous, 2004). Phase II trials evaluating imiquimod for the treatment of nodular and superficial basal cell carcinomas (BCC) suggest that imiquimod may prove useful when applied daily over a 6- to 12-week period (Salasche and Shumack, 2003), and the drug is approved for this indication by the FDA. Off-label applications include the treatment of non-genital warts, molluscum contagiosum, extramammary Paget’s disease, and Bowen’s disease. Irritant reactions occur in virtually all patients, and some develop edema, vesicles, erosions, or ulcers. It appears that the degree of inflammation parallels therapeutic efficacy. No systemic effects have been reported.

Systemic vinblastine (VELBAN, others) is approved for use in Kaposi’s sarcoma and advanced cutaneous T-cell lymphoma. Intraleosional vinblastine also is used to treat Kaposi’s sarcoma (Hengge et al., 2002). Intraleosional bleomycin (BLENOXANE, others) is used for recalcitrant warts and has cytotoxic and proinflammatory effects (Templeton et al., 1994). Intraleosional injection of bleomycin into the digits has been associated with a vasospastic response orally. Mycophenolate mofetil is particularly useful as a corticosteroid-sparing agent in the treatment of autoimmune blistering disorders, including pemphigus vulgaris, bullous pemphigoid, cicatricial pemphigoid, and pemphigus foliaceus. It also has been used effectively in the treatment of inflammatory diseases such as psoriasis, atopic dermatitis, and pyoderma gangrenosum.
that mimics Raynaud’s phenomenon, local skin necrosis, and flagellate hyperpigmentation (Abess et al., 2003). Intralesional bleomycin has been used for palliative treatment of squamous cell carcinoma. Systemic bleomycin has been used for Kaposi’s sarcoma (see Chapter 51 for a more complete discussion of these agents). Liposomal anthracyclines [specifically doxorubicin (DOXIL, CAELYX)] may provide first-line monotherapy for advanced Kaposi’s sarcoma (Hengge et al., 2002).

_Dapsone_ (4,4′-diaminodiphenylsulfone) has been in clinical use for almost 50 years. Its structure is:

\[
\text{DAPSONE}
\]

Dapsone is approved for use in dermatitis herpetiformis and leprosy. It is particularly useful in the treatment of linear immunoglobulin A (IgA) dermatosis, bullous systemic lupus erythematosus, erythema elevatum diutinum, and subcorneal pustular dermatosis. In addition, reports indicate efficacy in patients with acne fulminans, pustular psoriasis, lichen planus, Hailey–Hailey disease, pemphigus vulgaris, bullous pemphigoid, cicatricial pemphigoid, leukocytoclastic vasculitis, Sweet’s syndrome, granuloma faciale, relapsing polychondritis, Behçet’s disease, urticarial vasculitis, pyoderma gangrenosum, and granuloma annulare (Paniker and Levine, 2001).

An initial dose of 50 mg/day is prescribed, followed by increases of 25 mg/day at weekly intervals, always with appropriate laboratory testing. Potential side effects of dapsone include methemoglobinemia and hemolysis. The glucose-6-phosphate dehydrogenase (G6PD) level should be checked in all patients before initiating dapsone therapy because dapsone hydroxylamine, the toxic metabolite of dapsone formed by hydroxylation, depletes glutathione within G6PD-deficient cells. The nitroso derivative then causes peroxidation reactions, leading to rapid hemolysis. A maximum dose of 150 to 300 mg/day should be given in divided doses to minimize the risks of methemoglobinemia. The H₂ blocker cimetidine, at a dose of 400 mg three times daily, alters the degree of methemoglobinemia by competing with dapsone for CYPs. Toxicities include agranulocytosis, peripheral neuropathy, and psychosis.

_Thalidomide_ (THALOMID) is an antiinflammatory, immunomodulating, antiangiogenic agent experiencing resurgence in the treatment of dermatologic diseases (see Chapter 52). Its structure is:

\[
\text{THALIDOMIDE}
\]

The mechanisms that underlie the pharmacologic properties of thalidomide are not clear, although modulation of inflammatory cytokines such as TNF-α, IFN-α, IL-10, IL-12, cyclooxygenase 2, and possibly nuclear factor κB (NF-κB) may be involved (Franks et al., 2004). It also can modulate T cells by altering their patterns of cytokine release and can increase keratinocyte migration and proliferation (Wines et al., 2002).

Thalidomide is FDA approved for the treatment of erythema nodosum leprosum. There are reports suggesting its efficacy in actinic prurigo, aphthous stomatitis, Behçet’s disease, Kaposi’s sarcoma, and the cutaneous manifestations of lupus erythematosus, as well as prurigo nodularis and uremic prurigo. Thalidomide has been associated with increased mortality when used to treat toxic epidermal necrolysis. The drug always will be infamous for its association with limb abnormalities (phocomelia), as well as other congenital anomalies. It also may cause an irreversible neuropathy. **Because of its teratogenic effects, thalidomide use is restricted to specially licensed physicians who fully understand the risks. Thalidomide should never be taken by women who are pregnant or who could become pregnant while taking the drug.**
Immunopathogenesis of psoriasis. Psoriasis is a prototypical inflammatory skin disorder in which specific T-cell populations are stimulated by as yet undefined antigen(s) presented by antigen-presenting cells. The T cells release proinflammatory cytokines such as TNF-α and IFN-γ that induce keratinocyte and endothelial cell proliferation.

When evaluating the efficacy of biological agents, it is important to understand the standard measurement of efficacy in psoriasis treatment, the Psoriasis Area Severity Index (PASI). The PASI quantitates the extent and severity of skin involvement in different body regions as a score from 0 (no lesions) to 72 (severe disease). To gain FDA approval for the treatment of psoriasis, a biological agent must decrease the PASI by 75%. While such quantitation is an essential element in controlled clinical trials, many patients in practice may gain clinically significant benefit from biological treatment without achieving this degree of PASI improvement.

Alefacept (AMEVIVE) was the first immunobiological agent approved for the treatment of moderate-to-severe psoriasis in patients who are candidates for systemic therapy. Alefacept consists of a recombinant fully human fusion protein composed of the binding site of the leukocyte function–associated antigen 3 (LFA-3) protein and a human IgG1 Fc domain. The LFA-3 portion of the alefacept molecule binds to CD2 on the surface of T cells, thus blocking a necessary costimulation step in T-cell activation (Figure 62–3). Importantly, since CD2 is expressed preferentially on memory-effector T cells, naive T cells largely are unaffected by alefacept. A second important action of alefacept is its ability to induce apoptosis of memory-effector T cells through simultaneous binding of its IgG1 portion to immunoglobulin receptors on cytotoxic cells and its LFA-3 portion to CD2 on T cells, thus inducing granzyme-mediated apoptosis of memory-effector T cells.

Alefacept is administered by in-office intramuscular injection at a dose of 15 mg/week for 12 weeks. An additional 12-week course can be initiated if required, and a continuous 24-week regimen is under investigation. In an international randomized, double-blind, placebo-controlled phase III trial of intramuscular alefacept (15 mg once weekly for 12 weeks, 10 mg once weekly for 12 weeks, or placebo), 21% of patients receiving the 15-mg dose showed a 75%
Adverse effects generally are mild, and there is no evidence to date of increased risk of malignancy, infection, or end-organ toxicity (Weinberg, 2003).

Etanercept (ENBREL) is FDA approved for the treatment of psoriasis, psoriatic arthritis, rheumatoid arthritis, juvenile rheumatoid arthritis, and ankylosing spondylitis. Etanercept is a soluble, recombinant, fully human TNF receptor fusion protein consisting of two molecules of the ligand-binding portion of the TNF receptor fused to the Fc portion of IgG1. As a dimeric molecule, it can bind two molecules of TNF. Etanercept binds soluble and membrane-bound TNF, thereby inhibiting the action of TNF (Krueger and Callis, 2004).

Etanercept is administered by subcutaneous injection at doses of either 25 or 50 mg twice a week. In a phase III, placebo-controlled, double-blind, parallel-group study, 34% and 44% of patients receiving the 25-mg dose reached PASI reductions of 75% at 12 and 24 weeks, respectively, and 58% and 70% of patients achieved PASI reductions of 50% at 12 and 24 weeks, respectively. At the 50-mg dose, 49% and 59% reached PASI reduction of 75% at 12 and 24 weeks, respectively, and 74% and 77% reached PASI reductions of 50% at 12 and 24 weeks, respectively. Except for injection-site reactions, the drug is well tolerated. Monthly complete blood counts with a differential should be monitored for the first 3 months of treatment. Potential side effects include aplastic anemia, increased risk of infection, and exacerbation of congestive heart failure and demyelinating disorders. The risk of malignancy is unknown but may be increased with the use of etanercept.

Infliximab (REMICADE) is a mouse–human chimeric monoclonal antibody that binds to soluble and membrane-bound TNF-α and inhibits binding with its receptors (Krueger and Callis, 2004). Infliximab is a complement-fixing antibody that induces complement-dependent and cell-mediated lysis when bound to cell-surface-bound TNF-α. It also induces proinflammatory cytokines, such as IL-1 and IL-6, and enhances leukocyte migration. Infliximab is FDA approved for the treatment of Crohn’s disease and rheumatoid arthritis, but it is also in phase III trials for the treatment of psoriasis.

Infliximab is administered by intravenous infusion over 2 hours at doses of 3 or 5 mg/kg, usually at weeks 0, 2, and 6. In a phase II trial, 82% and 72% of patients given the 3 mg/kg dose for 10 weeks achieved PASI reductions of 50% and 75%, respectively, whereas 97% and 75% of those receiving the 5 mg/kg dose achieved PASI reductions of 50% and 75%, respectively (Weinberg, 2003). Complications of therapy include infusion reactions, reactivation of latent tuberculosis infection, exacerbation of congestive heart failure, and multiple sclerosis-like syndromes. Purified protein derivative (PPD) testing is required before initiating therapy. Neutralizing antibodies to
infliximab may develop, and concomitant administration of methotrexate or glucocorticoids may suppress antibody formation.

Denileukin diftitox or DAB389–IL-2, (ONTAK) is a fusion protein composed of diphtheria toxin fragments A and B and the receptor-binding portion of IL-2. DAB389–IL-2 is indicated for advanced cutaneous T-cell lymphoma in patients with more than 20% of T cells expressing the surface marker CD25. The IL-2 portion of the fusion protein binds the CD25 marker on the T cell and promotes destruction of the T cell by the cytocidal action of diphtheria toxin.

In a phase III trial consisting of 9 or 18 μg/kg per day of DAB389–IL-2 given as an intravenous infusion for 5 consecutive days every 3 weeks for up to 6 months or eight courses, the overall response rate was 36% with 18 μg/kg per day and 23% with 9 μg/kg per day. Adverse effects included pain, fevers, chills, nausea, vomiting, and diarrhea. Immediate hypersensitivity manifested by hypotension, back pain, dyspnea, and chest pain occurred in 60% of patients within 24 hours of drug administration; other serious side effects of DAB389–IL-2 are the capillary leak syndrome (i.e., edema, hypoalbuminemia, and/or hypotension), occurring in 20% to 30% of patients, and elevated blood levels of hepatic transaminases (Olsen et al., 2001; Apisarnthanarax et al., 2002).

**INTRAVENOUS IMMUNOGLOBULIN IN DERMATOLOGY**

Intravenous immunoglobulin (IVIG) is prepared from fractionated pooled human sera derived from thousands of donors with various antigenic exposures (see Chapter 52). Commercial preparations of IVIG are composed mainly of IgG with minimal amounts of IgA. There is a risk of anaphylaxis if IgA-deficient patients receive IVIG that is not IgA-poor. Although the mechanism of action of IVIG is not understood fully, proposed mechanisms include anti-idiotype interactions, Fc receptor modulation, cytokine inhibition, neutralization of causative microbes or toxins, superantigen neutralization, and acceleration of IgG catabolism (Colsky, 2000). While mostly anecdotal, reports of successful use of IVIG in the treatment of autoimmune and inflammatory dermatoses are accumulating. IVIG has been used to treat dermatomyositis, chronic recalcitrant urticaria/angioidema, atopic dermatitis, systemic lupus erythematosus, and autoimmune blistering disorders.

A multicenter retrospective analysis of 48 cases of toxic epidermal necrolysis (TEN) treated with IVIG at a dose of 1 g/kg per day for 3 days demonstrated remarkably rapid cessation of cutaneous and mucosal blistering and improved survival (Prins et al., 2003). A subsequent retrospective chart review that compared the outcome of 24 TEN patients treated with IVIG with 21 patients who did not receive IVIG found no improvement in mortality but rather a possible detrimental trend in treated patients (Brown et al., 2004). Clearly, a multicenter, prospective, double-blind, randomized trial is needed to determine the usefulness of IVIG in the treatment of TEN.

**SUNSCREENS**

Photoprotection from the acute and chronic effects of sun exposure is readily available with sunscreens. The major active ingredients of available sunscreens include chemical agents that absorb incident solar radiation in the UVB and/or UVA ranges and physical agents that contain particulate materials that can block or reflect incident energy and reduce its transmission to the skin. Many of the sunscreens available are mixtures of organic chemical absorbers and particulate physical substances. Ideal sunscreens provide a broad spectrum of protection and are formulations that are photostable and remain intact for sustained periods on the skin. They also should be nonirritating, invisible, and nonstaining to clothing. No single sunscreen ingredient possesses all these desirable properties, but many are quite effective nonetheless.

**UVA Sunscreen Agents**

Currently available UVA filters in the United States include (1) avobenzone, also known as Parsol 1789; (2) oxybenzone (2-hydroxy-4-methoxy-benzophenone); (3) titanium dioxide; and (4) zinc oxide. Additional UVA sunscreens, including ecamsule (MEXORYL SX and XL), bisethyhexyloxyphenol methoxyphenyl triazine (TINOSORB S), and methylene bisbenzotriazolyl tetracylbutylphenol (TINOSORB M), are available in Europe and elsewhere but not in the United States.

**UVB Sunscreen Agents**

There are numerous UVB filters, including (1) PABA esters (e.g., padimate O); (2) cinnamates (octinoxate); (3) octocrylene (2-ethylhexyl-2-cyano-3,3 diphenylacrylate); and (4) salicylates (octisalate).

The major measurement of sunscreen photoprotection is the sun protection factor (SPF), which defines a ratio of the minimal dose of incident sunlight that will produce erythema or redness (sunburn) on skin with the sunscreen in place (protected) and the dose that evokes the same reaction on skin without the sunscreen (unprotected). The SPF provides valuable information regarding UVB protection but is useless in documenting UVA efficacy because no standard systems have been developed to measure UVA protection. Such protocols are needed because more than 85% of solar ultraviolet radiation reaching earth’s surface is UVA, which penetrates more deeply into human skin than does UVB and appears to play an important role in photaging and photocarcinogenesis. Despite their universal availability, a major problem with sunscreens is the fact that people do not use them on a regular basis. In a population study evaluating the use of sunscreens in northern England, it was reported that only 35% of females and 8% of males regularly used sunscreens (Ling et al., 2003). Furthermore, 22% of those surveyed used no sunscreen at all, and 34% recalled at least one sunburn reaction in the previous 2 years.
There is evidence that the regular use of sunscreens can reduce the risk of actinic keratoses (Thompson et al., 1993) and squamous cell carcinomas (SCCs) of the skin. One study noted a 46% decrease in the incidence of SCCs in people who used sunscreen regularly for 4.5 years (Green et al., 1999).

Except for total sun avoidance, sunscreens are the best single method of protection from UV-induced damage to the skin. There is a need for more definitive answers to questions related to the efficacy of sunscreens in reducing skin cancer risk. Prospects for more effective photoprotection are excellent as better sunscreen components are developed and as more careful evaluations are performed (Rigel, 2002).

**THE TREATMENT OF PRURITUS**

The term pruritus is derived from the Latin prurire, which means “to itch.” Pruritus is a symptom unique to skin that occurs in a multitude of dermatologic disorders, including dry skin or xerosis, atopic eczema, urticaria, and infestations. Itching also may be a sign of internal disorders, including malignant neoplasms, chronic renal failure, and hepatobiliary disease. The treatment of pruritus varies greatly depending on the underlying disorder.

General measures employing copious application of emollients usually are sufficient for xerosis. Inflammatory disorders such as atopic dermatitis, contact dermatitis, and lichen simplex chronicus may respond better to potent topical glucocorticoids and oral doses of sedating antihistamines. Antihistamines are useful in histamine-induced pruritus and in other pruritic disorders in which the sedating effects of these drugs facilitate sleep and reduce scratching at night, when most pruritic disorders are more symptomatic.

Cholestasis-associated pruritus may respond to cholestyramine (QUESTRAN, others; see Chapter 35), ursodeoxycholic acid (ACTIGALL, others; see Chapter 37), ondansetron (ZOFRAN; see Chapter 37), or rifampin (see Chapter 47). Recently, nalmefene (REVEX) (20 mg twice per day; see Chapter 21) has been shown to be effective in cholestatic pruritus (Bergasa et al., 1999).

The pruritus of uremia is treated most effectively with UVB radiation. Prurigo, a ubiquitous disorder associated with itchy nodules of the skin, is notoriously difficult to treat. In addition to topical and intralesional steroids, prurigo may respond to the opioid antagonist naltrexone (see Chapter 21) at a dose of 50 mg/day (Metze et al., 1999) or to the proton pump inhibitor omeprazole (see Chapter 36).

**MISCELLANEOUS DRUGS**

Azelaic acid (AZELEX, FINACEA) is a naturally occurring dicarboxylic acid used for the treatment of acne and pigmentary disorders such as melasma and postinflammatory hyperpigmentation. Its structure is:

\[
\begin{align*}
\text{CH}_3 & \quad \text{CH} \quad \text{-CH} \quad \text{(CH}_2\text{)}_2 \quad \text{O} \quad \text{-C} \quad \text{(CH}_2\text{)}_7 \quad \text{C} \quad \text{-O} \quad \text{-CH} \quad \text{(CH}_2\text{)}_5 \quad \text{CH} \quad \text{-CH}_3 \\
\text{O} & \quad \text{C} \quad \text{-O} \quad \text{-CH} \quad \text{(CH}_2\text{)}_5 \quad \text{CH} \quad \text{-CH}_3 \\
\end{align*}
\]

In the United States, azelaic acid is available as a 20% cream. Azelaic acid has been used for the treatment of pigmentary disorders because of its inhibition of tyrosinase, the rate-limiting enzyme in the synthesis of melanin (Hsu and Quan, 2001). Azelaic acid also possesses comedolytic and antimicrobial activity and may have additional antiinflammatory properties. Applied topically twice a day, azelaic acid is effective for the treatment of acne. In patients with papulopustular rosacea, 15% azelaic acid gel was superior to metronidazole gel (0.75%) in the treatment of inflammatory lesions and erythema; neither medication improved the telangiectatic blood vessels that frequently accompany rosacea (Elewski et al., 2003).

Calcipotriene (DOVONEX) is a vitamin D analog that is used in the treatment of psoriasis. Its structure is:

\[
\begin{align*}
\text{HO} & \quad \text{OH} \\
\text{H} & \quad \text{H} \\
\end{align*}
\]

It was developed after the fortuitous observation of improved psoriasis in a patient with osteoporosis receiving an oral derivative of 1,25-dihydroxyvitamin D₃ [1,25-(OH)₂D₃], the active form of vitamin D (Morimoto and Kumahara, 1985) (see Chapter 61). 1,25-(OH)₂D₃ plays a major role in calcium homeostasis by activating the vitamin D receptor, which belongs to the steroid/thyroid hormone receptor superfamily. The receptor–vitamin D complex binds to DNA and modulates the transcription of genes related to cell proliferation and differentiation.

Calcipotriene is applied twice daily to plaque psoriasis on the body. Improvement is detectable within 1 to 2 weeks, and maximum clinical response occurs within 6 to 8 weeks. Most patients show some improvement, but
complete resolution occurs in no more than 15%. Maintenance therapy usually is necessary, and tachyphylaxis does not occur (Kragballe, 1992). Reports of hypercalceemia with calcipotriene are rare (Hardman et al., 1993).

**DRUGS FOR HYPERKERATOTIC DISORDERS**

Keratolytic agents—including lactic acid, glycolic acid, salicylic acid, urea, and sulfur—are employed to treat various forms of hyperkeratosis ranging from calluses and verrucae to severe xerosis. Lactic and glycolic acid are α-hydroxy acids that are thought to disrupt ionic bonds and thus diminish corneocyte cohesion (Van Scott and Yu, 1984).

Salicylic acid is a β-hydroxy acid that is thought to function through solubilization of intercellular cement, again reducing corneocyte adhesion. It appears to eliminate the stratum corneum layer by layer from the outermost level downward. This contrasts with the α-hydroxy acids, which preferentially diminish cellular cohesion between the corneocytes at the lowest levels of the stratum corneum.

Urea is an antimicrobial agent that denatures and dissolves proteins and increases skin absorption and retention of water (Hessel et al., 2001). Sulfur is antiseptic, antiparasitic, antiseborrheic, and keratolytic, accounting for its myriad uses in dermatology.

Keratolytics are available in a multitude of formulations for treating skin diseases. Prolonged use of salicylic acid preparations over large areas, especially in children and patients with renal and hepatic impairment, can result in salicylism. Irritation is a common side effect with higher concentrations. Lactic acid (LAC-HYDRIN, others) is an emollient that contains 12% lactic acid that is an effective moisturizer indicated for the treatment of xerosis and ichthyosis vulgaris.

Glycolic acid is marketed in multiple cosmetic preparations (4% to 10%) and is used for the treatment of xerosis, ichthyosis, and photoaging.

**Destructive Agents**

Podophyllin (podophyll resin) is a mixture of chemicals from the plant Podophyllum peltatum (mandrake or May apple). The major constituent of the resin is podophyllotoxin (podofilox). It binds to microtubules and causes mitotic arrest in metaphase. Podophyllin resin (10% to 40%) is applied by a physician and left in place for 2 to 6 hours weekly for the treatment of anogenital warts. Irritation and ulcerative local reactions are the major side effects. It should not be used in the mouth or during pregnancy. Podofilox (CONDYLOX, others) is available as a 0.5% solution for application twice daily for 3 consecutive days. Weekly cycles may be repeated.

---

**DRUGS FOR ANDROGENETIC ALOPECIA**

Androgenetic alopecia, commonly known as male and female pattern baldness, is the most common cause of hair loss in adults older than age 40. Up to 50% of men and women are affected. Androgenetic alopecia is a genetically inherited trait with variable expression. In susceptible hair follicles, dihydrotestosterone binds to the androgen receptor, and the hormone–receptor complex activates the genes responsible for the gradual transformation of large terminal follicles into miniaturized vellus follicles. Treatment of androgenetic areata is aimed at reducing hair loss and maintaining existing hair. The capacity to stimulate substantial regrowth of human hair remains a formidable pharmacological challenge.

Minoxidil (ROGAINE) was first developed as an antihypertensive agent (see Chapter 32) and was noted to be associated with hypertrichosis in some patients. A topical formulation of minoxidil then was developed to exploit this side effect. The structure of minoxidil is:

![Minoxidil](image)

Topical minoxidil is available as a 2% solution (ROGAINE) and a 5% solution (ROGAINE EXTRA STRENGTH FOR MEN). Minoxidil enhances follicular size, resulting in thicker hair shafts, and stimulates and prolongs the anagen phase of the hair cycle, resulting in longer and increased numbers of hairs (Fiedler, 1999). Treatment must be continued, or any drug-induced hair growth will be lost. Allergic and irritant contact dermatitis can occur, and care should be taken in applying the drug because hair growth may emerge in undesirable locations. This is reversible on stopping the drug. Patients should be instructed to wash their hands after applying minoxidil.

Finasteride (PROPECIA) inhibits the type II isozyme of 5α-reductase, the enzyme that converts testosterone to dihydrotestosterone (see Chapter 58). The structure of finasteride is:

![Finasteride](image)
The type II 5α-reductase is found in hair follicles. Balding areas of the scalp are associated with increased dihydrotestosterone levels and smaller hair follicles than nonbalding areas. Orally administered finasteride (1 mg/day) has been shown to variably increase hair growth in men over a 2-year period, increasing hair counts in the vertex and the frontal scalp (Leyden et al., 1999). Finasteride is approved for use only in men. Pregnant women should not be exposed to the drug because of the potential for inducing genital abnormalities in male fetuses. Adverse effects of finasteride include decreased libido, erectile dysfunction, ejaculation disorder, and decreased ejaculate volume. Each of these occurs in less than 2% of patients (Kaufman et al., 1998). Like minoxidil, treatment with finasteride must be continued, or any new hair growth will be lost.

**MISCELLANEOUS AGENTS**

*Capsaicin* is a naturally occurring substance derived from hot chili peppers of the genus *Capsicum*. Its structure is:

![Capsaicin](image)

Capsaicin interacts with the vanilloid receptor (VR1) on sensory afferents. VR1 is a gated cation channel of the TRP family, modulated by a variety of noxious stimuli (Caterina and Julius, 2001). Chronic exposure to capsaicin stimulates and desensitizes this channel. Capsaicin also causes local depletion of substance P, an endogenous neuropeptide involved in sensory perception and pain transmission. Capsaicin is available as a 0.025% cream (*ZOSTRIX*, others) and a 0.075% cream (*ZOSTRIX HP*, others) to be applied three to four times daily. Capsaicin is FDA approved for the treatment of postherpetic neuralgia and painful diabetic neuropathy, although its efficacy in relieving pain is debatable.

**Masoprocol**, a dicatechol compound with an aliphatic spacer, is derived from the plant *Larrea divaricata*; it is a potent 5-lipoxygenase inhibitor with anti-tumor activity. It is effective for the topical therapy of actinic keratoses (Olsen et al., 1991). Masoprocol is available as a cream (*ACTINEX*) and is applied twice daily for approximately 1 month. Common side effects include redness, scaling, and pruritus.

**TREATMENT OF HYPERPIGMENTATION**

Hyperpigmentation is treated with products containing *hydroquinone* that produce reversible depigmentation of the skin by inhibiting the enzymatic oxidation of tyrosine to 3,4-dihydroxyphenyalanine and also inhibiting other melanocyte metabolic processes. It is indicated for the gradual bleaching of hyperpigmented skin in conditions such as melasma, freckles, and solar lentigines. Concomitant application of SPF 15 to 30 sunscreens and meticulous photoprotection are essential to minimize sun-induced exacerbation of hyperpigmentation. Numerous preparations are available (*SOLAQUIN FORTE*, others). The structure of hydroquinone is:

![Hydroquinone](image)

**BIBLIOGRAPHY**

Chapter 62 / Dermatological Pharmacology

**MONOGRAPHS AND REVIEWS**

OVERVIEW OF OCULAR ANATOMY, PHYSIOLOGY, AND BIOCHEMISTRY

The eye is a specialized sensory organ that is relatively secluded from systemic access by the blood–retinal, blood–aqueous, and blood–vitreous barriers; as a consequence, the eye exhibits some unusual pharmacodynamic and pharmacokinetic properties. Because of its anatomical isolation, the eye offers a unique, organ-specific pharmaceutical laboratory to study the autonomic nervous system and effects of inflammation and infectious diseases. No other organ in the body is so readily accessible or as visible for observation; however, the eye also presents some unique opportunities as well as challenges for drug delivery (Robinson, 1993).

Extraocular Structures

The eye is protected by the eyelids and by the orbit, a bony cavity of the skull that has multiple fissures and foramina that conduct nerves, muscles, and vessels (Figure 63–1). In the orbit, connective (i.e., Tenon’s capsule) and adipose tissues and six extraocular muscles support and align the eyes for vision. The retrobulbar region lies immediately behind the eye (or globe). Understanding ocular and orbital anatomy is important for safe periocular drug delivery, including subconjunctival, sub-Tenon’s, and retrobulbar injections.

The eyelids serve several functions. Foremost, their dense sensory innervation and eyelashes protect the eye from mechanical and chemical injuries. Blinking, a coordinated movement of the orbicularis oculi, levator palpebrae, and Müller’s muscles, serves to distribute tears over the cornea and conjunctiva. In humans, the average blink rate is 15 to 20 times per minute. The external surface of the eyelids is covered by a thin layer of skin; the internal surface is lined with the palpebral portion of the conjunctiva, which is a vascularized mucous membrane continuous with the bulbar conjunctiva. At the reflection of the palpebral and bulbar conjunctivae is a space called the fornix, located superiorly and inferiorly behind the upper and lower lids, respectively. Topical medications usually are placed in the inferior fornix, also known as the inferior cul-de-sac.

The lacrimal system consists of secretory glandular and excretory ductal elements (Figure 63–2). The secretory system is composed of the main lacrimal gland, which is located in the temporal outer portion of the orbit, and accessory glands, also known as the glands of Krause and Wolfring (Figure 63–1), located in the conjunctiva. The lacrimal gland is innervated by the autonomic nervous system (Table 63–1 and Chapter 6). The parasympathetic innervation is clinically relevant since a patient may complain of dry eye symptoms while taking medications with anticholinergic side effects, such as tricyclic antidepressants (see Chapter 17), antihistamines (see Chapter 25),...
and drugs used in the management of Parkinson’s disease (see Chapter 20). Located just posterior to the eyelashes are meibomian glands (Figure 63–1), which secrete oils that retard evaporation of the tear film. Abnormalities in gland function, as in acne rosacea and meibomitis, can greatly affect tear film stability.

Conceptually, tears constitute a trilaminar lubrication barrier covering the conjunctiva and cornea. The anterior layer is composed primarily of lipids secreted by the meibomian glands. The middle aqueous layer, produced by the main lacrimal gland and accessory lacrimal glands (i.e., Krause and Wolfring glands), constitutes about 98% of the tear film. Adherent to the corneal epithelium, the posterior layer is a mixture of mucins produced by goblet cells in the conjunctiva. Tears also contain nutrients, enzymes, and immunoglobulins to support and protect the cornea.

The tear drainage system starts through small puncta located on the medial aspects of both the upper and lower eyelids (Figure 63–2). With blinking, tears enter the puncta and continue to drain through the canaliculi, lacrimal sac, nasolacrimal duct, and then into the nose. The nose is

Figure 63–1. Anatomy of the globe in relationship to the orbit and eyelids. Various routes of administration of anesthesia are demonstrated by the blue needle pathways.

Figure 63–2. Anatomy of the lacrimal system.
Ocular Structures

The eye is divided into anterior and posterior segments (Figure 63–3A). Anterior segment structures include the cornea, limbus, anterior and posterior chambers, trabecular meshwork, Schlemm’s canal, iris, lens, zonule, and ciliary body. The posterior segment comprises the vitreous, retina, choroid, sclera, and optic nerve.

Anterior Segment. The cornea is a transparent and avascular tissue organized into five layers: epithelium, Bowman’s membrane, stroma, Descemet’s membrane, and endothelium (Figure 63–3B).

Representing an important barrier to foreign matter, including drugs, the hydrophilic epithelial layer comprises five to six cell layers. The basal epithelial cells lie on a basement membrane that is adjacent to Bowman’s membrane, a layer of collagen fibers. Constituting approximately 90% of the corneal thickness, the stroma, a hydrophilic layer, is uniquely organized with collagen lamellae synthesized by keratocytes. Beneath the stroma lies Descemet’s membrane, the basement membrane of the corneal endothelium. Lying most posteriorly, the endothelium is a monolayer of cells adhering to each other by tight junctions. These cells maintain corneal integrity by active transport processes and serve as a hydrophilic barrier. Hence, drug absorption across the cornea requires penetration of the trilaminar hydrophobic-hydrophilic-hydrophobic domains of the various anatomical layers.

At the periphery of the cornea and adjacent to the sclera lies a transitional zone (1 to 2 mm wide) called the limbus. Limbal structures include the conjunctival epithelium, which contains the stem cells, Tenon’s capsule, episclera, corneoscleral stroma, Schlemm’s canal, and trabecular meshwork (Figure 63–3B). Limbal blood vessels, as well as the tears, provide important nutrients and immunological defense mechanisms for the cornea. The anterior chamber holds approximately 250 μl of aqueous humor. The peripheral anterior chamber angle is formed by the cornea and the iris root. The trabecular meshwork and canal of Schlemm are located just above the apex of this angle. The posterior chamber, which holds approximately 50 μl of aqueous humor, is defined by the boundaries of the ciliary body processes, posterior surface of the iris, and lens surface.

Aqueous Humor Dynamics and Regulation of Intraocular Pressure. Aqueous humor is secreted by the ciliary processes and flows from the posterior chamber, through the pupil, into the anterior chamber, and leaves the eye primarily by the trabecular meshwork and canal of Schlemm. From the canal of Schlemm, aqueous humor drains into an episcleral venous plexus and into the systemic circulation. This conventional pathway accounts for 80% to 95% of aqueous humor outflow and is the main target for cholinergic drugs used in glaucoma therapy. Another outflow pathway is the uveoscleral route (i.e., fluid flows through the ciliary muscles and into the suprachoroidal space), which is the target of selective prostangoids (see Chapter 25 and later in this chapter).

The peripheral anterior chamber angle is an important anatomical structure for differentiating two forms of glaucoma: open-angle glaucoma, which is by far the most common form of glaucoma in the United States, and angle-closure glaucoma. Current medical therapy of open-angle glaucoma is aimed at decreasing aqueous humor production and/or increasing aqueous outflow. The preferred management for angle-closure glaucoma is surgical iridectomy, either by laser or by incision, but short-term medical management

$^7$Although acetylcholine and choline acetyltransferase are abundant in corneal epithelium of most species, the function of this neurotransmitter in this tissue is unknown. $^\ddagger$The ciliary epithelium is also the target of carbonic anhydrase inhibitors. Carbonic anhydrase isoenzyme II is localized to both the pigmented and nonpigmented ciliary epithelium. $^\ddagger$Although $\beta_2$ adrenergic receptors mediate ciliary body smooth muscle relaxation, there is no clinically significant effect on accommodation.
may be necessary to reduce the acute intraocular pressure elevation and to clear the cornea prior to surgery. Long-term intraocular pressure reduction may be necessary, especially if the peripheral iris has permanently covered the trabecular meshwork. Acute angle-closure glaucoma may be induced rarely in anatomically predisposed eyes by anticholinergic, sympathomimetic, and antihistaminic agents. Interestingly, however, individuals with susceptible angles are not aware of a risk of angle-closure glaucoma. Unfortunately, drug warning labels do not always specify the type of glaucoma for which this rare risk exists. Thus, unwarranted concern is raised

Figure 63–3. A. Anatomy of the eye. B. Enlargement of the anterior segment revealing the cornea, angle structures, lens, and ciliary body. (B. Adapted with permission from Riordan-Eva, P., Tabbara, K.F. Anatomy and embryology of the eye. In, General Ophthalmology, 13th ed. (Vaughan, D., Asbury, T., Riordan-Eva, P., eds.) Appleton & Lange, Stamford, CT, 1992.)
among patients who have open-angle glaucoma who need not be concerned about taking these drugs. In any event, in anatomically susceptible eyes, anticholinergic, sympathomimetic, and antihistaminic drugs can lead to partial dilation of the pupil and a change in the vectors of force between the iris and the lens. The aqueous humor then is prevented from passing through the pupil from the posterior chamber to the anterior chamber. The result is known as an acute attack of pupillary-block angle-closure glaucoma. The change in the lens-iris relationship leads to an increase in pressure in the posterior chamber, causing the iris base to be pushed against the angle wall, thereby closing the filtration angle and markedly elevating the intraocular pressure.

**Iris and Pupil.** The iris is the most anterior portion of the uveal tract, which also includes the ciliary body and choroid. The anterior surface of the iris is the stroma, a loosely organized structure containing melanocytes, blood vessels, smooth muscle, and parasympathetic and sympathetic nerves. Differences in iris color reflect individual variation in the number of melanocytes located in the stroma. Individual variation may be an important consideration for ocular drug distribution due to drug-melanin binding (see “Distribution,” below). The posterior surface of the iris is a densely pigmented bilayer of epithelial cells. Anterior to the pigmented epithelium, the dilator smooth muscle is oriented radially and is innervated by the sympathetic nervous system (Figure 63–4) which causes mydriasis (dilation). At the pupillary margin, the sphincter smooth muscle is organized in a circular band with parasympathetic innervation, which when stimulated causes miosis (constriction). The use of pharmacological agents to dilate normal pupils (i.e., for clinical purposes such as examining the ocular fundus) and to evaluate the pharmacological response of the pupil (e.g., unequal pupils, or anisocoria, seen in Horner’s syndrome or Adie’s pupil) is summarized in Table 63–2. Figure 63–5 provides a flowchart for the diagnostic evaluation of anisocoria.

**Ciliary Body.** The ciliary body serves two very specialized roles in the eye: secretion of aqueous humor by the epithelial bilayer and accommodation by the ciliary muscle. The anterior portion of the ciliary body, called the pars plicata, is composed of 70 to 80 ciliary processes with intricate folds. The posterior portion is the pars plana. The ciliary muscle is organized into outer longitudinal, middle radial, and inner circular layers. Coordinated contraction of this smooth muscle apparatus by the parasympathetic nervous system causes the zonule suspending the lens to relax, allowing the lens to become more convex and to shift slightly forward. This process, known as accommodation, permits focusing on near objects and may be pharmacologically blocked by muscarinic cholinergic antagonists, through the process called cycloplegia. Contraction of the ciliary muscle also puts traction on the scleral spur, and hence widens the spaces within the trabecular meshwork. This latter effect accounts for at least some of the intraocular pressure–lowering effect of both directly acting and indirectly acting parasympathomimetic drugs.

**Lens.** The lens, a transparent biconvex structure, is suspended by zonules, specialized fibers emanating from the ciliary body. The lens is approximately 10 mm in diameter and is enclosed in a capsule. The bulk of the lens is composed of fibers derived from proliferating lens epithelial cells located under the anterior portion of the lens capsule. These lens fibers are continuously produced throughout life. Aging, in addition to certain medications, such as corticosteroids, and certain diseases, such as diabetes mellitus, cause the lens to become opacified, which is termed a cataract.

**Posterior Segment.** Because of the anatomical and vascular barriers to both local and systemic access, drug delivery to the eye’s posterior pole is particularly challenging.

**Sclera.** The outermost coat of the eye, the sclera, covers the posterior portion of the globe. The external surface of the scleral shell is covered by an episcleral vascular coat, by Tenon’s capsule, and by the conjunctiva. The ten-
dons of the six extraocular muscles insert into the superficial scleral collagen fibers. Numerous blood vessels pierce the sclera through emissaria to supply as well as drain the choroid, ciliary body, optic nerve, and iris.

Inside the scleral shell, the vascular choroid nourishes the outer retina by a capillary system in the choriocapillaris. Between the outer retina and the choriocapillaris lie Bruch’s membrane and the retinal pigment epithelium, whose tight junctions provide an outer barrier between the retina and the choroid. The retinal pigment epithelium serves many functions, including vitamin A metabolism, phagocytosis of the rod outer segments, and multiple transport processes.

**Retina.** The retina is a thin, transparent, highly organized structure of neurons, glial cells, and blood vessels. Of all structures within the eye, the neurosensory retina has been the most widely studied. The unique organization and biochemistry of the photoreceptors have provided a superb system for investigating signal transduction mechanisms. The wealth of information about rhodopsin has made it an excellent model for the G protein–coupled signal transduction. Such detailed understanding holds promise for targeted therapy for some of the hereditary retinal diseases.

**Vitreous.** Approximately 80% of the eye’s volume is the vitreous, which is a clear medium containing collagen type II, hyaluronic acid, proteoglycans, a variety of macromolecules including glucose, ascorbic acid, amino acids, and a number of inorganic salts. Glutamate in the vitreous has been suspected to have a possible relationship to glaucoma. The ganglion cells appear to die in glaucoma via a process of apoptosis (Quigley et al., 1995; Wax et al., 1998) and glutamate has been shown to induce apoptosis via NMDA-receptor excitotoxicity (Sucher et al., 1997). Elevated glutamate levels have been noted in experimental animal models (Dreyer et al., 1996; Yoles and Schwartz, 1998) and in humans with glaucoma (Dreyer et al., 1996), although this has been questioned (Levkovitch-Verbin et al., 2002). Memantine, an uncompetitive NMDA-receptor antagonist (Vorwerk et al., 1996; Chen and Lipton, 1997), is currently being investigated clinically as a possible treatment for glaucoma.

**Optic Nerve.** The optic nerve is a myelinated nerve conducting the retinal output to the central nervous system. It is composed of (1) an intraocular portion, which is visible as the 1.5-mm optic disk in the retina; (2) an intraorbital portion; (3) an intracanalicular portion; and (4) an intracranial portion. The nerve is ensheathed in meninges continuous with the brain. At present, pharmacological treatment of some optic neuropathies is based on management of the underlying disease. For example, optic neuritis may be treated best with intravenous glucocorticoids (Beck et al., 1992; Beck et al., 1993); glaucomatous optic neuropathy is medically managed by decreasing intraocular pressure.

**PHARMACOKINETICS AND TOXICOLOGY OF OCULAR THERAPEUTIC AGENTS**

**Drug Delivery Strategies**

Properties of varying ocular routes of administration are outlined in Table 63–3. A number of delivery systems have been developed for treating ocular diseases. Most ophthalmic drugs are delivered in solutions, but for compounds with limited solubility, a suspension form facilitates delivery.

Several formulations prolong the time a drug remains on the surface of the eye. These include gels, ointments, solid inserts, soft contact lenses, and collagen shields. *Prolonging the time in the cul-de-sac facilitates drug*
absorption. Ophthalmic gels (e.g., pilocarpine 4% gel) release drugs by diffusion following erosion of soluble polymers. The polymers used include cellulosic ethers, polyvinyl alcohol, carbopol, polyacrylamide, polymethylvinyl ether–maleic anhydride, poloxamer 407, and puronic acid. Ointments usually contain mineral oil and a petrolatum base and are helpful in delivering antibiotics, cycloplegic drugs, or miotic agents. Solid inserts, such as the ganciclovir intravitreal implant, provide a zero-order rate of delivery by steady-state diffusion, whereby drug is released at a more constant rate over a finite period of time rather than as a bolus. This surgical implant has been used to deliver anti-cytomegalovirus medication in proximity to the retinal infection (Marx et al., 1996). The intent is to deliver a sustained dose of medication over several months with reduced spikes in drug delivery (Kunou et al., 2000) independent of patient compliance.

Pharmacokinetics

Classical pharmacokinetic theory based on studies of systemically administered drugs (see Chapter 1) does not fully apply to all ophthalmic drugs (Kaur and Kanwar, 2002). Although similar principles of absorption, distribution, metabolism, and excretion determine the fate of drug disposition in the eye, alternative routes of drug administration, in addition to oral and intravenous routes, introduce other variables in compartmental analysis (Table 63–3 and Figure 63–6). Most ophthalmic medications are formulated to be applied topically. Drugs also may be injected by subconjunctival, sub-Tenon’s, and retrobulbar routes (Figure 63–1 and Table 63–3). For example, anesthetic agents are administered commonly by injection for surgical procedures and antibiotics and glucocorticoids also may be injected to enhance their delivery to local tissues. The antimetabolite 5-fluorouracil and the DNA alkylating agent mitomycin C may be administered subconjunctivally to retard the fibroblast proliferation related to scarring after glaucoma surgery. Mitomycin C also can be applied to the cornea to prevent scarring after corneal surgery. Intraocular (i.e., intravitreal) injections of antibiotics are considered in instances of endophthalmitis, a severe intraocular infection. The sensitivities of the organisms to the antibiotic and the retinal
toxicity threshold may be nearly the same for some anti-
biotics; hence, the antibiotic dose injected intravitreally 
must be carefully titrated. Intraocular inserts are used to 
treat intraocular viral infections. The ganciclovir implant 
is indicated to treat cytomegalovirus retinitis in patients 
with AIDS.

Unlike clinical pharmacokinetic studies on systemic 
drugs, where data are collected relatively easily from 
blood samples, there is significant risk in obtaining tissue 
and fluid samples from the human eye. Consequently, ani-
mal models, frequently rabbits, are studied to provide 
pharmacokinetic data on ophthalmic drugs.

Absorption. After topical instillation of a drug, the rate and extent 
of absorption are determined by the time the drug remains in the 
cul-de-sac and precorneal tear film, elimination by nasolacrimal 
drainage, drug binding to tear proteins, drug metabolism by tear and 
tissue proteins, and diffusion across the cornea and conjunctiva 
(Lee, 1993). A drug’s residence time may be prolonged by changing 
its formulation. Residence time also may be extended by blocking 
the egress of tears from the eye by closing the tear drainage ducts 
with plugs or cautery. Nasolacrimal drainage contributes to systemic 
absorption of topically administered ophthalmic medications. 
Absorption from the nasal mucosa avoids so-called first-pass metab-
olism by the liver (see Chapter 1), and consequently significant sys-
temic side effects may be caused by topical medications, especially 
when used chronically. Possible absorption pathways of an oph-
thalmic drug following topical application to the eye are shown 
schematically in Figure 63–6.

Transcorneal and transconjunctival/scleral absorption are the 
desired routes for localized ocular drug effects. The time period

![Table 63–3](https://example.com/table63-3.png)

*See text for more complete discussion of individual routes.

![Figure 63–6](https://example.com/figure63-6.png)

*Possible absorption pathways of an ophthalmic drug following topical application to the eye. Solid black arrows 
represent the corneal route; dashed blue arrows represent the 
conjunctival/scleral route; the black dashed line represents the 
nasolacrimal absorption pathway. (Adapted with permission 
from Chien et al., 1990.)*
between drug instillation and its appearance in the aqueous humor is defined as the lag time. The drug concentration gradient between the tear film and the cornea and conjunctival epithelium provides the driving force for passive diffusion across these tissues. Other factors that affect a drug’s diffusion capacity are the size of the molecule, chemical structure, and steric configuration. Transcorneal drug penetration is conceptualized as a differential solubility process; the cornea may be thought of as a trilamellar “fat-water-fat” structure corresponding to the epithelial, stromal, and endothelial layers. The epithelium and endothelium represent barriers for hydrophilic substances; the stroma is a barrier for hydrophobic compounds. Hence, a drug with both hydrophilic and lipophilic properties is best suited for transcorneal absorption.

Drug penetration into the eye is approximately linearly related to its concentration in the tear film. Certain disease states, such as corneal ulcers and other corneal epithelial defects, may alter drug penetration. Medication absorption usually is increased when an anatomic barrier is compromised or removed. Experimentally, drugs may be screened for their potential clinical utility by assessing their corneal permeability coefficients. These pharmacokinetic data combined with the drug’s octanol/water partition coefficient (for lipophilic drugs) or distribution coefficient (for ionizable drugs) yield a parabolic relationship that is a useful parameter for predicting ocular absorption. Of course, such in vitro studies do not account for other factors that affect corneal absorption, such as epithelial integrity, blink rate, dilution by tear flow, nasolacrimal drainage, drug binding to proteins and tissue, and transconjunctival absorption; hence, these studies have limitations in predicting ocular drug absorption in vivo.

**Distribution.** Topically administered drugs may undergo systemic distribution primarily by nasal mucosal absorption and possibly by local ocular distribution by transcorneal/transconjunctival absorption. Following transcorneal absorption, the aqueous humor accumulates the drug, which then is distributed to intraocular structures as well as potentially to the systemic circulation via the trabecular meshwork pathway (Figure 63–3B). Melanin binding of certain drugs is an important factor in some ocular compartments. For example, the mydriatic effect of α adrenergic receptor agonists is slower in onset in human volunteers with darkly pigmented irides compared to those with lightly pigmented irides. In rabbits, radiolabeled atropine binds significantly to melanin granules in irides of nonalbino animals. This finding correlates with the fact that atropine’s mydriatic effect lasts longer in nonalbino rabbits than in albino rabbits, and suggests that drug–melanin binding is a potential reservoir for sustained drug release. Another clinically important consideration for drug–melanin binding involves the retinal pigment epithelium. In the retinal pigment epithelium, accumulation of chloroquine (see Chapter 39) causes a toxic retinal lesion known as a “bull’s-eye” maculopathy, which is associated with a decrease in visual acuity.

**Metabolism.** Enzymatic biotransformation of ocular drugs may be significant since a variety of enzymes, including esterases, oxidoreductases, lyosomal enzymes, peptidases, glucuronide and sulfate transferases, glutathione-conjugating enzymes, catechol-O-methyltransferase, monoamine oxidase, and 11β-hydroxysteroid dehydrogenase are found in the eye. The esterases have been of particular interest because of the development of produgs for enhanced corneal permeability; for example, dipivefrin hydrochloride is a prodrug for epinephrine, and latanoprost is a prodrug for prostaglandin F₂α, both drugs are used for glaucoma management. Topically applied ocular drugs are eliminated by the liver and kidney after systemic absorption, but enzymatic transformation of systemically administered drugs also is important in ophthalmology.

**Toxicology.** All ophthalmic medications are potentially absorbed into the systemic circulation (Figure 63–6), so undesirable systemic side effects may occur. Most ophthalmic drugs are delivered locally to the eye, and the potential local toxic effects are due to hypersensitivity reactions or to direct toxic effects on the cornea, conjunctiva, periorcular skin, and nasal mucosa. Eyedrops and contact lens solutions commonly contain preservatives such as benzalkonium chloride, chlorobutanol, chelating agents, and thimerosal for their antimicrobial effectiveness. In particular, benzalkonium chloride may cause a punctate keratopathy or toxic ulcerative keratopathy (Grant and Schuman, 1993). Thimerosal currently is used rarely due to a high incidence of hypersensitivity reactions.

**THERAPEUTIC AND DIAGNOSTIC APPLICATIONS OF DRUGS IN OPHTHALMOLOGY**

**Chemotherapy of Microbial Diseases in the Eye**

**Antibacterial Agents.** **General Considerations.** A number of antibiotics have been formulated for topical ocular use (Table 63–4). The pharmacology, structures, and kinetics of individual drugs have been presented in detail in Section VIII. Appropriate selection of antibiotic and route of administration is dependent on the patient’s symptoms, the clinical examination, and the culture/sensitivity results. Specifically formulated antibiotics also may be extemporaneously prepared by qualified pharmacists for serious eye infections such as corneal infiltrates or ulcers and endophthalmitis.

**Therapeutic Uses.** Infectious diseases of the skin, eyelids, conjunctivae, and lacrimal excretory system are encountered regularly in clinical practice. Periorcular skin infections are divided into preseptal and postseptal or orbital cellulitis. Depending on the clinical setting (i.e., preceding trauma, sinusitis, age of patient, relative immunocompromised state), oral or parenteral antibiotics are administered. The microbiological spectrum for orbital cellulitis is changing; for example, there has been a sharp decline in *Haemophilus influenzae* after the introduction in 1985 of the *H. influenzae* vaccine (Ambati et al., 2000).

**Dacryoadenitis,** an infection of the lacrimal gland, is most common in children and young adults. It may be bacterial (typically *Staphylococcus aureus*, *Streptococcus* species) or viral (most commonly seen in mumps, infectious mononucleosis, influenza, and herpes zoster). When bacterial infection is suspected, systemic antibiotics usually are indicated.
Dacryocystitis is an infection of the lacrimal sac. In infants and children, the disease usually is unilateral and secondary to an obstruction of the nasolacrimal duct. In adults, dacryocystitis and canalicular infections may be caused by *Staphylococcus aureus*, *Streptococcus* species, *Diptheroids*, *Candida* species, and *Actinomyces israelii*. Any discharge from the lacrimal sac should be sent for smears and cultures. Systemic antibiotics typically are indicated.

*For specific information on dosing, formulation, and trade names, refer to the *Physician’s Desk Reference for Ophthalmology*, which is published annually. †Abbreviations: H, hypersensitivity; BD, blood dyscrasia; D-RCD, drug-related corneal deposits. ‡Polymyxin B is formulated for delivery in combination with bacitracin, neomycin, gramicidin, oxytetracycline, or trimethoprim. See Chapters 43 through 46 for further discussion of these antibacterial agents.

**Dacryocystitis** is an infection of the lacrimal sac. In infants and children, the disease usually is unilateral and secondary to an obstruction of the nasolacrimal duct. In adults, dacyrocystitis and canalicular infections may be caused by *Staphylococcus aureus*, *Streptococcus* species, *Diptheroids*, *Candida* species, and *Actinomyces israelii*. Any discharge from the lacrimal sac should be sent for smears and cultures. Systemic antibiotics typically are indicated.

Infectious processes of the lids include *hordeolum* and *blepharitis*. A hordeolum, or stye, is an infection of the meibomian, Zeis, or Moll glands at the lid margins. The typical offending bacterium is *S. aureus*, and the usual treatment consists of warm compresses and topical antibiotic ointment. Blepharitis is a common bilateral inflammatory process of the eyelids characterized by irritation and burning, and it also is usually associated with a *Staphylococcus* species. Local hygiene is the mainstay of therapy; topical antibiotics frequently are used, usually in ointment form, particularly when the disease is accompanied by conjunctivitis and keratitis. Systemic *tetracycline*, *doxycycline*, *minocycline*, and *erythromycin* often are effective in reducing severe eyelid inflammation, but must be used for weeks to months.

**Conjunctivitis** is an inflammatory process of the conjunctiva that varies in severity from mild hyperemia to severe purulent discharge. The more common causes of conjunctivitis include viruses, allergies, environmental irritants, contact lenses, and chemicals. The less common causes include other infectious pathogens, immune-mediated reactions, associated systemic diseases, and tumors of the conjunctiva or eyelid. The more commonly reported infectious agents are adenovirus and herpes simplex virus, followed by other viral (e.g., enterovirus, coxsackievirus, measles virus, varicella zoster virus, and vaccinia-viara virus) and bacterial sources (e.g., *Neisseria* species, *Streptococcus pneumoniae*, *Haemophilus* species, *S. aureus*, *Moraxella lacunata*, and chlamydial species). *Rickettsia*, fungi, and parasites, in both cyst and trophozoite form, are rare causes of conjunctivitis. Effective man-
agement is based on selection of an appropriate antibiotic for suspected bacterial pathogens. Unless an unusual causative organism is suspected, bacterial conjunctivitis is treated empirically with a broad-spectrum topical antibiotic without obtaining a culture.

*Keratitis*, or corneal inflammation, can occur at any level of the cornea (e.g., epithelium, subepithelium, stroma, and endothelium). It can be due to noninfectious or infectious causes. Numerous microbial agents have been identified as causes of infectious keratitis, including bacteria, viruses, fungi, spirochetes, and cysts and trophozoites. Severe infections, with tissue loss (corneal ulcers), generally are treated more aggressively than infections without tissue loss (corneal infiltrates). The mild, small, more peripheral infections usually are not cultured and the eyes are treated with broad-spectrum topical antibiotics. In more severe, central, or larger infections, corneal scrapings for smears, cultures, and sensitivities are performed and the patient is immediately started on intensive hourly, around-the-clock topical antibiotic therapy. The goal of treatment is to eradicate the infection and reduce the amount of corneal scarring and the chance of corneal perforation and severe decreased vision or blindness. The initial medication selection and dosage are adjusted according to the clinical response and culture and sensitivity results.

*Endophthalmitis* is a potentially severe and devastating inflammatory, and usually infectious, process involving the intraocular tissues. When the inflammatory process encompasses the entire globe, it is called *panophthalmitis*. Endophthalmitis is usually caused by bacteria or fungi, or rarely by spirochetes. The typical case occurs during the early postoperative course (e.g., after cataract, glaucoma, cornea, or retinal surgery), following trauma, or by endogenous seeding in the immunocompromised host or intravenous drug user. Acute postoperative endophthalmitis requires a prompt vitreous tap for smears and cultures and empirical injection of intravitreal antibiotics. Immediate vitrectomy (i.e., specialized surgical removal of the vitreous) is beneficial for patients who have light perception–only vision (Endophthalmitis Vitrectomy Study Group, 1995). Vitrectomy for other causes of endophthalmitis (e.g., glaucoma bleb-related, posttraumatic, or endogenous) may be beneficial. In cases of endogenous seeding, parenteral antibiotics have a role in eliminating the infectious source, but the efficacy of systemic antibiotics with trauma is not well established.

**Antiviral Agents.** *General Considerations.* The various antiviral drugs currently used in ophthalmology are summarized in Table 63–5 (see Chapter 49 for additional details about these agents).

*For additional details, see Chapter 49. †Abbreviations: PK, punctate keratopathy; H, hypersensitivity.*
**Therapeutic Uses.** The primary indications for the use of antiviral drugs in ophthalmology are viral keratitis, herpes zoster ophthalmicus (Liesegang, 1999; Chern and Margolis, 1998), and retinitis. There currently are no antiviral agents for the treatment of viral conjunctivitis caused by adenoviruses, which usually has a self-limited course and typically is treated by symptomatic relief of irritation.

**Viral keratitis,** an infection of the cornea that may involve either the epithelium or stroma, is most commonly caused by herpes simplex type I and varicella zoster viruses. Less common viral etiologies include herpes simplex type II, Epstein-Barr virus, and cytomegalovirus. Topical antiviral agents are indicated for the treatment of epithelial disease due to herpes simplex infection. When treating viral keratitis topically, there is a very narrow margin between the therapeutic topical antiviral activity and the toxic effect on the cornea; hence, patients must be followed very closely. The role of oral acyclovir and glucocorticoids in herpetic corneal and external eye disease has been examined in the Herpetic Eye Disease Study (Herpetic Eye Disease Study Group, 1997a; Herpetic Eye Disease Study Group, 1998). Topical glucocorticoids are contraindicated in herpetic epithelial keratitis due to active viral replication. In contrast, for herpetic disciform keratitis, which predominantly is presumed to involve a cell-mediated immune reaction, topical glucocorticoids accelerate recovery (Wilhelmus et al., 1994). For recurrent herpetic stromal keratitis, there is clear benefit from treatment with oral acyclovir in reducing the risk of recurrence (Herpetic Eye Disease Study Group, 1998).

**Herpes zoster ophthalmicus** is a latent reactivation of a varicella zoster infection in the first division of the trigeminal cranial nerve. Systemic acyclovir, valacyclovir, and famciclovir are effective in reducing the severity and complications of herpes zoster ophthalmicus (Colin et al., 2000). Currently, there are no ophthalmic preparations of acyclovir approved by the FDA, although an ophthalmic ointment is available for investigational use.

**Viral retinitis** may be caused by herpes simplex virus, cytomegalovirus (CMV), adenovirus, and varicella zoster virus. With the highly active antiretroviral therapy (HAART; see Chapter 50), CMV retinitis does not appear to progress when specific anti-CMV therapy is discontinued, but some patients develop an immune recovery uveitis (Jacobson et al., 2000; Whitcup, 2000). Treatment usually involves long-term parenteral administration of antiviral drugs. Intravitreal administration of ganciclovir has been found to be an effective alternative to the systemic route (Sanborn et al., 1992). Acute retinal necrosis and progressive outer retinal necrosis, most often caused by varicella zoster virus, can be treated by various combinations of oral, intravenous, intravitreal injection, and intravitreal implantation of antiviral medications (Roig-Melo et al., 2001).

**Antifungal Agents.** **General Considerations.** The only currently available topical ophthalmic antifungal preparation is a polyene, natamycin (NATACYN), which has the following structure:

![NATAMYCIN](image)

Other antifungal agents may be extemporaneously compounded for topical, subconjunctival, or intravitreal routes of administration (Table 63–6). The pharmacology and structures of available antifungal agents are given in Chapter 48.

**Therapeutic Uses.** As with systemic fungal infections, the incidence of ophthalmic fungal infections has risen with the growing number of immunocompromised hosts. Ophthalmic indications for antifungal medications include fungal keratitis, scleritis, endophthalmitis, mucormycosis, and canaliculitis. Risk factors for fungal keratitis include trauma, chronic ocular surface disease, and immunosuppression (including topical steroid use). When fungal infection is suspected, samples of the affected tissues are obtained for smears, cultures, and sensitivities, and this information is used for drug selection.

**Antiprotozoal Agents.** **General Considerations.** Parasitic infections involving the eye usually manifest themselves as a form of uveitis, an inflammatory process of either the anterior or posterior segments, and less commonly as conjunctivitis, keratitis, and retinitis.

**Therapeutic Uses.** In the United States, the most commonly encountered protozoal infections include Acanthamoeba and Toxoplasma gondii. In contact-lens wearers who develop keratitis, physicians should be highly suspicious of the presence of Acanthamoeba (McCulley et al., 2000). Additional risk factors for Acanthamoeba keratitis include poor contact lens hygiene, wearing contact lenses in a pool or hot tub, and ocular trauma. Treatment usually consists of a combination topical antibiotic, such as poly-
myxin B sulfate, bacitracin zinc, and neomycin sulfate (e.g., NEOSPORIN), and sometimes an imidazole (e.g., clotrimazole, miconazole, or ketoconazole). In the United Kingdom, the aromatic diamidines (i.e., propamidine isethionate in both topical aqueous and ointment forms, BROLENE) have been used successfully to treat this relatively resistant infectious keratitis (Hargrave et al., 1999). The cationic antiseptic agent polyhexamethylene biguanide (PHMB) also is typically used in drop form for acanthamoeba keratitis, although this is not an FDA-approved antiprotozoal agent. Topical chlorhexidine can be used as an alternative to PHMB. Oral itraconazole or ketoconazole often are used in addition to the topical medications. Resolution of Acanthamoeba keratitis may require many months of treatment.

*Only natamycin (NATACYN) is commercially available for ophthalmic use. The other antifungal drugs must be formulated for the given method of administration. For further dosing information, refer to the Physicians’ Desk Reference for Ophthalmology. For additional discussion of these antifungal agents, see Chapter 48.

myxin B sulfate, bacitracin zinc, and neomycin sulfate (e.g., NEOSPORIN), and sometimes an imidazole (e.g., clotrimazole, miconazole, or ketoconazole). In the United Kingdom, the aromatic diamidines (i.e., propamidine isethionate in both topical aqueous and ointment forms, BROLENE) have been used successfully to treat this relatively resistant infectious keratitis (Hargrave et al., 1999). The cationic antiseptic agent polyhexamethylene biguanide (PHMB) also is typically used in drop form for acanthamoeba keratitis, although this is not an FDA-approved antiprotozoal agent. Topical chlorhexidine can be used as an alternative to PHMB. Oral itraconazole or ketoconazole often are used in addition to the topical medications. Resolution of Acanthamoeba keratitis may require many months of treatment.

Toxoplasmosis may present as a posterior (e.g., focal retinochoroiditis, papillitis, vitritis, or retinitis) or occasionally as an anterior uveitis. Treatment is indicated when inflammatory lesions encroach upon the macula and threaten central visual acuity. Several regimens have been recommended with concurrent use of systemic steroids: (1) pyrimethamine, sulfadiazine, and folic acid (leucovorin); (2) pyrimethamine, sulfadiazine, clindamycin, and folic acid; (3) sulfadiazine and clindamycin; (4) clindamycin; and (5) trimethoprim-sulfamethoxazole with or without clindamycin.

Other protozoal infections (e.g., giardiasis, leishmaniasis, and malaria) and helminths are less common eye pathogens in the United States. Systemic pharmacological management as well as vitrectomy may be indicated for selected parasitic infections.

In the eye, infections can occur in a variety of locations, such as the cornea, sclera, vitreous and retina, and can be due to bacteria, viruses, fungi, and parasites. Treatment is based on severity of infection, location, and the class of infectious agent. Within each group of microbial cause, different organisms are treated with different medications. Gram-positive bacteria respond to certain antibiotics and gram-negative bacteria to others. Some organisms are quite susceptible to many antimicrobial agents, while others are not. Still others may have been susceptible in the past but have become resistant. The task of staying ahead of the rapidly developing resistances is becoming increasingly difficult. In ophthalmology, fortunately, newer-generation topical fluoroquinolones recently were brought to market, which have at least temporarily helped stem the tide of resistant infections. Additional topical fluoroquinolones are in development.

While the selection of topical antiviral agents is rather limited, two new systemic antiviral agents have become available in the past decade. Similarly, there is only one commercially available topical antifungal medication, but there are numerous systemic agents, several of them new in the past few years. Potentially, some of these systemic medications could be modified for topical use or even formulat-
ed as intraocular implants, greatly expanding our options in the treatment of many ophthalmic infectious diseases.

**Use of Autonomic Agents in the Eye**

**General Considerations.** General autonomic pharmacology has been discussed extensively in Chapters 6 through 10. The autonomic agents used in ophthalmology as well as the responses (i.e., mydriasis and cycloplegia) to muscarinic cholinergic antagonists are summarized in Table 63–7.

**Therapeutic Uses.** Autonomic drugs are used extensively for diagnostic and surgical purposes and for the treatment of glaucoma, uveitis, and strabismus.

*Refer to Physicians’ Desk Reference for Ophthalmology for specific indications and dosing information. †Mydriasis and cycloplegia, or paralysis of accommodation, of the human eye occurs after one drop of atropine 1%, scopolamine 0.5%, homatropine 1%, cyclopentolate 0.5% or 1%, and tropicamide 0.5% or 1%. Recovery of mydriasis is defined by return to baseline pupil size to within 1 mm. Recovery of cycloplegia is defined by return to within two diopters of baseline accommodative power. The maximal mydriatic effect of homatropine is achieved with a 5% solution, but cycloplegia may be incomplete. Maximal cycloplegia with tropicamide may be achieved with a 1% solution. Times to development of maximal mydriasis and to recovery, respectively, are: for atropine, 30 to 40 minutes and 7 to 10 days; for scopolamine, 20 to 130 minutes and 3 to 7 days; for homatropine, 40 to 60 minutes and 1 to 3 days; for cyclopentolate, 30 to 60 minutes and 1 day; for tropicamide, 20 to 40 minutes and 6 hours. Times to development of maximal cycloplegia and to recovery, respectively, are: for atropine, 60 to 180 minutes and 6 to 12 days; for scopolamine, 30 to 60 minutes and 3 to 7 days; for homatropine, 30 to 60 minutes and 1 to 3 days; for cyclopentolate, 25 to 75 minutes and 6 hours to 1 day; for tropicamide, 30 minutes and 6 hours.*
**Glaucoma.** In the United States, glaucoma is the second leading cause of blindness in African-Americans, the third leading cause in Caucasians, and the leading cause in Hispanic-Americans (Congdon et al., 2004). African-Americans have three times the age-adjusted prevalence of glaucoma compared to Caucasians (Friedman et al., 2004). Characterized by progressive optic nerve cupping and visual field loss, glaucoma is responsible for the bilateral blindness of 90,000 Americans (half of whom are African-American) (Congdon et al., 2004), and about 2.2 million have the disease (1.86% of the population over age 40). This number is expected to increase by 50% by the year 2020 (Friedman et al., 2004). Risk factors associated with glaucomatous nerve damage include increased intraocular pressure (IOP), positive family history of glaucoma, African-American heritage, and possibly myopia and hypertension. The production and regulation of aqueous humor have been discussed in an earlier section of this chapter. Previously an intraocular pressure of greater than 21 was considered abnormal. This, however, is incorrect, as intraocular pressure is not an accurate indicator of disease. Nonetheless, elevated intraocular pressure is a risk factor for glaucoma. Several randomized, controlled trials have determined that reducing intraocular pressure can delay glaucomatous nerve or field damage (Flurouracil Filtering Surgery Study Group, 1996; AGIS Investigators, 2000; Heijl et al., 2002). Although markedly elevated intraocular pressures (e.g., greater than 30 mm Hg) usually will lead to optic nerve damage, the optic nerves in certain patients apparently can tolerate intraocular pressures in the mid-to-high twenties. These patients are referred to as *ocular hypertensives*. A recent prospective multicenter trial found that prophylactic medical reduction of intraocular pressure reduced the risk of progression to glaucoma from about 10% to about 5% (Kass et al., 2002). Other patients have progressive glaucomatous optic nerve damage despite having intraocular pressures in the normal range, and this form of the disease sometimes is called *normal- or low-tension glaucoma*. A reduction of intraocular pressure by 30% reduces disease progression from about 35% to about 10%, even for normal-tension glaucoma patients (Collaborative Normal-Tension Glaucoma Study Group, 1998a; Collaborative Normal-Tension Glaucoma Study Group, 1999b). Despite overwhelming evidence that intraocular pressure reduction is a helpful treatment, at present the pathophysiological processes involved in glaucomatous optic nerve damage and the relationship to aqueous humor dynamics are not understood.

Current pharmacotherapies are targeted to decrease the production of aqueous humor at the ciliary body and to increase outflow through the trabecular meshwork and uveoscleral pathways. There is no consensus on the best intraocular pressure–lowering technique for glaucoma therapy. Currently, a National Eye Institute–sponsored clinical trial, the Collaborative Initial Glaucoma Treatment Study (CIGTS), aims to determine whether it is best, in terms of preservation of visual function and quality of life, to treat patients newly diagnosed with open-angle glaucoma with filtering surgery or with medication. Initial results show no difference in disease progression rates between the two treatment groups at 5 years (Lichter et al., 2001), but the study is ongoing.

The CIGTS study aside, a stepped medical approach depends on the patient’s health, age, and ocular status. Some general principles prevail in patient management: (1) asthma and chronic obstructive pulmonary disease with a bronchospastic component are relative contraindications to the use of topical β adrenergic receptor antagonists because of the risk of significant side effects from systemic absorption *via* the nasolacrimal system; (2) some cardiac dysrhythmias (*i.e.*, bradycardia and heart block) also are relative contraindications to β adrenergic antagonists for similar reasons; (3) history of nephrolithiasis, or kidney stones, sometimes is a contraindication for carbonic anhydrase inhibitors; (4) young patients usually are intolerant of miotic therapy secondary to visual blurring from induced myopia; (5) direct miotic agents are preferred over cholinesterase inhibitors in “phakic” patients (*i.e.*, those patients who have their own crystalline lens), since the latter drugs can promote cataract formation; and (6) in patients who have an increased risk of retinal detachment, miotics should be used with caution, since they have been implicated in promoting retinal tears in susceptible individuals; such tears are thought to be due to altered forces at the vitreous base produced by ciliary body contraction induced by the drug.

The goal is to prevent progressive glaucomatous optic-nerve damage with minimum risk and side effects from either topical or systemic therapy. With these general principles in mind, a stepped medical approach may begin with a topical prostaglandin analog. Due to their once-daily dosing, low incidence of systemic side effects, and potent intraocular pressure lowering effect, prostaglandin analogs have largely replaced β adrenergic receptor antagonists as first-line medical therapy for glaucoma. The prostaglandin analogs consist of latanoprost (XALATAN), travoprost (TRAVATAN), bimatoprost (LUMIGAN), and unoprostone (RESCULA). The chemical structure of latanoprost is shown below.
from altered ciliary muscle tension to effects on trabecular meshwork cells to release of matrix metalloproteases and digestion of extracellular matrix materials that may impede outflow tracts. There also is less myocilin protein noted in monkey smooth muscle after PGF<sub>2α</sub> treatment (Lindsey et al., 2001).

The β-receptor antagonists now are the next most common topical medical treatment. There are two classes of topical β blockers. The nonselective ones bind to both β<sub>1</sub> and β<sub>2</sub> receptors and include timolol maleate and hemihydrate, levobunolol, metipranolol, and carteolol. There is one β<sub>1</sub>-selective antagonist, betaxolol, available for ophthalmic use, but it is less efficacious than the nonselective β blockers since the β receptors of the eye are largely of the β<sub>2</sub> subtype. However, because the β<sub>1</sub> receptors are found preferentially in the heart while the β<sub>2</sub> receptors are found in the lung, betaxolol is less likely to cause breathing difficulty. In the eye, the targeted tissues are the ciliary body epithelium and blood vessels, where β<sub>2</sub> receptors account for 75% to 90% of the total population. How β blockade leads to decreased aqueous production and reduced IOP is uncertain. Production of aqueous humor seems to be activated by a β-receptor-mediated cyclic AMP–PKA pathway; β blockade blunts adrenergic activation of this pathway by preventing catecholamine stimulation of the β receptor, thereby decreasing intracellular cAMP. Another hypothesis is that β blockers decrease ocular blood flow, which decreases the ultrafiltration responsible for aqueous production (Juzycz and Zimmerman, 1997).

When there are medical contraindications to the use of prostaglandin analogs or β-receptor antagonists, other agents, such as an α<sub>2</sub> adrenergic agonist or topical carbonic anhydrase inhibitor may be used as first-line therapy. The α<sub>2</sub> adrenergic agonists improve the pharmacologic profile of the nonselective sympathomimetic agent epinephrine and its derivative, dipivefrin (PROPINE). Epinephrine stimulates both α and β adrenergic receptors. The drug appears to decrease IOP by enhancing both conventional (via a β-receptor mechanism) and uveoscleral outflow (perhaps via prostaglandin production) from the eye. Although effective, epinephrine is poorly tolerated, principally due to localized irritation and hyperemia. Dipivefrin is an epinephrine prodrug that is converted into epinephrine by esterases in the cornea. It is much better tolerated, but still is prone to cause epinephrine-like side effects (Fang and Kass, 1997). The α<sub>2</sub> adrenergic agonist clonidine is effective at reducing IOP, but also readily crosses the blood–brain barrier and causes systemic hypotension; as a result it no longer is used for glaucoma. In contrast, apraclonidine (IOPIDINE) is a relatively selective α<sub>2</sub> adrenergic agonist that is highly ionized at physiologic pH and therefore does not cross the blood–brain barrier. Brimonidine (ALPHAGAN, others) is also a selective α<sub>2</sub> adrenergic agonist, but is lipophilic, enabling easy corneal penetration. Both apraclonidine and brimonidine reduce aqueous production and may enhance some uveoscleral outflow. Both appear to bind to pre- and postsynaptic α<sub>2</sub> receptors. By binding to the presynaptic receptors, the drugs reduce the amount of neurotransmitter release from sympathetic nerve stimulation and thereby lower IOP. By binding to postsynaptic α<sub>2</sub> receptors, these drugs stimulate the G<sub>i</sub> pathway, reducing cellular cyclic AMP production, thereby reducing aqueous humor production (Juzycz et al., 1997).

The development of a topical carbonic anhydrase inhibitor took many years but was an important event because of the poor side-effect profile of oral carbonic anhydrase inhibitors (CAIs). Dorzolamide (TRUSOPT) and brinzolamide (AZOPT) both work by inhibiting carbonic anhydrase (isoenzyme II), which is found in the ciliary body epithelium. This reduces the formation of bicarbonate ions, which reduces fluid transport and thus IOP (Sharir, 1997). Any of these four drug classes can be used as additive second- or third-line therapy. In fact, the β-receptor antagonist timolol has been combined with the carbonic anhydrase inhibitor dorzolamide (see structure below) in a single medication (COSOPT).

![Structure of Dorzolamide](image1)

![Structure of Brinzolamide](image2)

Such combinations reduce the number of drops needed and may improve compliance. Other combination products involving prostaglandin analogs and β blockers are in development.

Topical miotic agents are historically important glaucoma medications but are less commonly used today. Miotics lower IOP by causing muscarinic-induced contraction of the ciliary muscle, which facilitates aqueous outflow. They do not affect aqueous production. Multiple miotic agents have been developed. Pilocarpine and carbacol are cholinomimetics that stimulate muscarinic receptors. Echathiophate (PHOSPHOLINE IODIDE) is an organophosphate inhibitor of acetylcholinesterase; it is relatively stable in aqueous solution, and by virtue of its quaternary ammonium structure, is positively charged and poorly absorbed. The usefulness of these medicines is lessened by their numerous side effects and the need to use them three to four times a day (Kaufman and Gabelt, 1997).

If combined topical therapy fails to achieve the target intraocular pressure or fails to halt glaucomatous optic nerve damage, then systemic therapy with carbonic anhydrase inhibitors is a final medication option before resorting to laser or incisional surgical treatment. The best-tolerated oral preparation is acetazolamide in sustained-release capsules (see Chapter 28), followed by methazolamide. The least well-tolerated are acetazolamide tablets.

**Toxicity of Agents in Treatment of Glaucoma.** Ciliary body spasm is a muscarinic cholinergic effect that can lead to induced myopia and a changing refraction due to iris and ciliary body contraction. Epinephrine-related compounds, effective in intraocular pressure reduction, can cause a vasoconstrictive–vasodilation rebound phenomenon leading to a red eye. Ocular and skin allergies from topical epinephrine, related prodrug formulations, apraclonidine, and brimonidine are common. Brimonidine is less likely to cause ocular allergy and is therefore more commonly used. These agents can cause CNS depression and apnea in neonates and are contraindicated in children under the age of 2.

Systemic absorption of epinephrine-related drugs and β adrenergic antagonists can induce all the side effects found with direct systemic administration. The use of carbonic anhydrase inhibitors systematically may give some patients significant problems with
malaise, fatigue, depression, paresthesias, and nephrolithiasis; the topical CAIs may minimize these relatively common side effects. These medical strategies for managing glaucoma do help to slow the progression of this disease, yet there are potential risks from treatment-related side effects, and treatment effects on quality of life must be recognized.

**Uveitis.** Inflammation of the uvea, or uveitis, has both infectious and noninfectious causes, and medical treatment of the underlying cause (if known) is essential in addition to the use of topical therapy. Cyclopentolate, or sometimes even longer-acting antimuscarinic agents such as atropine, scopolamine, and homatropine frequently are used to prevent posterior synechiae formation between the lens and iris margin and to relieve ciliary muscle spasm that is responsible for much of the pain associated with anterior uveitis. If posterior synechiae already have formed, an α adrenergic agonist may be used to break the synechiae by enhancing pupillary dilation. A solution containing scopolamine 0.3% in combination with 10% phenylephrine is available for this purpose. Topical steroids usually are adequate to decrease inflammation, but sometimes they must be supplemented by systemic steroids.

**Strabismus.** Strabismus, or ocular misalignment, has numerous causes and may occur at any age. Besides causing diplopia (double vision), in children, strabismus may lead to amblyopia (reduced vision). Nonsurgical efforts to treat amblyopia include occlusion therapy, orthoptics, optical devices, and pharmacological agents. An eye with hyperopia, or farsightedness, must accommodate to focus distant images. In some hyperopic children, the synkinetic accommodative-convergence response leads to excessive convergence and a manifest esotropia (turned-in eye). The brain rejects diplopia and suppresses the image from the deviated eye. If proper vision is not restored by about the age of 7, the brain never learns to process visual information from that eye. The result is that the eye appears structurally normal but does not develop normal visual acuity and is therefore amblyopic. Unfortunately this is a fairly common cause of visual disability. In this setting, atropine (1%) instilled in the preferred seeing eye produces cycloplegia and the inability of this eye to accommodate, thus forcing the child to use the amblyopic eye (Pediatric Eye Disease Investigator Group, 2002; Pediatric Eye Disease Investigator Group, 2003). Echotoxiphate iodide also has been used in the setting of accommodative strabismus. Accommodation drives the near reflex, the triad of miosis, accommodation, and convergence. An irreversible cholinesterase inhibitor such as echotoxiphate causes miosis and an accommodative change in the shape of the lens; hence, the accommodative drive to initiate the near reflex is reduced, and less convergence will occur.

**Surgery and Diagnostic Purposes.** For certain surgical procedures and for clinical funduscopic examination, it is desirable to maximize the view of the retina and lens. Muscarinic cholinergic antagonists and α₂ adrenergic agonists frequently are used singly or in combination for this purpose (Table 63–7).

Intraoperatively, there are circumstances when miosis is preferred, and two cholinergic agonists are available for intraocular use, acetylcholine and carbachol. Patients with myasthenia gravis may first present to an ophthalmologist with complaints of double vision (diplopia) or lid droop (ptosis); the edrophonium test is helpful in diagnosing these patients (see Chapter 8).

**Use of Immunomodulatory Drugs for Ophthalmic Therapy**

**Glucocorticoids.** Glucocorticoids have an important role in managing ocular inflammatory diseases; their chemistry and pharmacology are described in Chapter 59.

**Therapeutic Uses.** Currently the glucocorticoids formulated for topical administration to the eye are dexamethasone (DECADRON, others), prednisolone (PRED FORTE, others), fluorometholone (FML, others), loteprednol (ALREX, LOTEMAX), medrysone (HMS), and rimexolone (VEXOL). Because of their antiinflammatory effects, topical corticosteroids are used in managing significant ocular allergy, anterior uveitis, external eye inflammatory diseases associated with some infections and ocular cicatricial pemphigoid, and postoperative inflammation following refractive, corneal, and intraocular surgery. After glaucoma filtering surgery, topical steroids can delay the wound-healing process by decreasing fibroblast infiltration, thereby reducing potential scarring of the surgical site (Araujo et al., 1995). Steroids are commonly given systemically and by sub-Tenon’s capsule injection to manage posterior uveitis. Intravitreal injection of steroids now is being used to treat a variety of retinal conditions including age-related macular degeneration, diabetic retinopathy, and cystoid macular edema. Parenteral steroids followed by tapering oral doses are the preferred treatment for optic neuritis (Kaufman et al., 2000; Trobe et al., 1999).

**Toxicity of Steroids.** Steroid drops, pills, and creams are associated with ocular problems, as are intravitreal and intravenous steroids. Ocular complications include the development of posterior subcapsular cataracts, secondary infections (see Chapter 59), and secondary open-angle glaucoma (Becker and Mills, 1963). There is a significant increase in risk for developing secondary glaucoma when there is a positive family history of glaucoma. In the absence of a family history of open-angle glauco-
ma, only about 5% of normal individuals respond to topical or long-term systemic steroids with a marked increase in intraocular pressure. With a positive family history, however, moderate to marked steroid-induced intraocular pressure elevations may occur in up to 90% of patients. The pathophysiology of steroid-induced glaucoma is not fully understood, but there is evidence that the GLCIA gene may be involved (Stone et al., 1997). Typically, steroid-induced elevation of intraocular pressure is reversible once administration of the steroid ceases. However, intraocular or sub-Tenon’s steroid-related pressure elevation may persist for months and may require treatment with glaucoma medication or even filtering surgery. Newer topical steroids, so called “soft steroids” (e.g., loteprednol), have been developed that reduce, but do not eliminate, the risk of elevated intraocular pressure.

**Nonsteroidal Antiinflammatory Agents. General Considerations.** Nonsteroidal drug therapy for inflammation is discussed in Chapter 26. Nonsteroidal antiinflammatory drugs (NSAIDs) now are being applied to the treatment of ocular disease.

**Therapeutic Uses.** Currently, there are three topical NSAIDs approved for ocular use: diclofenac (VOLTAREN), flurbiprofen (OCUFEN), and ketorolac (ACULAR). Diclofenac and flurbiprofen are discussed in Chapter 26; the chemical structure of ketorolac, a pyrrolo-pyrolle derivative, is shown below:

![Chemical structure of ketorolac](image)

Flurbiprofen is used to counter unwanted intraoperative miosis during cataract surgery. Ketorolac is given for seasonal allergic conjunctivitis. Diclofenac is used for postoperative inflammation. Both ketorolac (Weisz et al., 1999) and diclofenac have been found to be effective in treating cystoid macular edema occurring after cataract surgery. In patients treated with prostaglandin analogs such as latanoprost or bimatoprost, ketorolac and diclofenac may help decrease postoperative inflammation. They also are useful in decreasing pain after corneal refractive surgery. Topical NSAIDs occasionally have been associated with sterile corneal melts and perforations, especially in older patients with ocular surface disease, such as dry eye syndrome.

**Antihistamines and Mast-Cell Stabilizers.** Pheniramine (see Chapter 24) and antazoline, both H₁-receptor antagonists, are formulated in combination with naphazoline, a vasoconstrictor, for relief of allergic conjunctivitis. The chemical structure of antazoline is:

![Chemical structure of antazoline](image)

Topical antihistamines include emedastine difumarate (EMADINE) and levocabastine hydrochloride (LIVOSTIN).

Cromolyn sodium (CROLOM), which prevents the release of histamine and other autacoids from mast cells (see Chapter 27), has found limited use in treating conjunctivitis that is thought to be allergen-mediated, such as vernal conjunctivitis. Lodoxamide tromethamine (ALOMIDE) and pemirolast (ALAMAST), mast-cell stabilizers, also are available for ophthalmic use. Nedocromil (ALOCRIL) also is primarily a mast-cell stabilizer with some antihistamine properties. Olopatadine hydrochloride (PATANOL), ketotifen fumarate (ZADITOR), and azelastine (OPTIVAR) are H₁ antagonists with mast cell–stabilizing properties. Epinastine (ELESTAT) antagonizes H₁ and H₂ receptors and exhibits mast cell–stabilizing activity.

**Immunosuppressive and Antimitotic Agents. General Considerations.** The principal application of immunosuppressive and antimitotic agents to ophthalmology relates to the use of 5-fluorouracil and mitomycin C in corneal and glaucoma surgeries. Interferon alpha-2b also has occasionally been used. Certain systemic diseases with serious vision-threatening ocular manifestations—such as Behçet’s disease, Wegener’s granulomatosis, rheumatoid arthritis, and Reiter’s syndrome—require systemic immunosuppression (see Chapter 52).

**Therapeutic Uses.** In glaucoma surgery, both fluorouracil and mitomycin (MUTAMYCIN), which also are antineoplastic agents (see Chapter 51), improve the success of filtration surgery by limiting the postoperative wound-healing process. Mitomycin is used intraoperatively as a single subconjunctival application at the trabeculectomy site. Meticulous care is used to avoid intraocular penetration, since mitomycin is extremely toxic to intraocular structures. Fluorouracil may be used intraoperatively at the trabeculectomy site and/or subconjunctivally during the postoperative course (Fluorouracil Filtering Surgery Study Group, 1989). Although both agents work by limiting the healing process, sometimes this can result in thin,
ischemic, avascular tissue that is prone to breakdown. The resultant leaks can cause hypotony (low intraocular pressure) and increase the risk of infection.

In cornea surgery, mitomycin has been used topically after excision of pterygium, a fibrovascular membrane that can grow onto the cornea. Mitomycin can be used to reduce the risk of scarring after certain procedures to remove corneal opacities and also prophylactically to prevent corneal scarring after excimer laser surface ablation (photorefractive and phototherapeutic keratectomy). Mitomycin also is used to treat certain conjunctival and corneal tumors. Interferon alpha-2b has been used in the treatment of conjunctival papilloma and certain conjunctival tumors. Although the use of mitomycin for both corneal surgery and glaucoma filtration surgeries augments the success of these surgical procedures, caution is advocated in light of the potentially serious delayed ocular complications (Rubinfeld et al., 1992; Hardten and Samuelson, 1999).

**Immunomodulatory Agent.** Topical cyclosporine (RESTASIS) is approved for the treatment of chronic dry eye associated with inflammation. Cyclosporine is an immunomodulatory agent that inhibits activation of T cells. Use of cyclosporine is associated with decreased inflammatory markers in the lacrimal gland, increased tear production, and improved vision and comfort (Sall et al., 2000).

**Drugs and Biological Agents Used in Ophthalmic Surgery**

**Adjuncts in Anterior Segment Surgery.** Viscoelastic substances assist in ocular surgery by maintaining spaces, moving tissue, and protecting surfaces. These substances are prepared from hyaluronate, chondroitin sulfate, or hydroxypropylmethylcellulose and share the following important physical characteristics: viscosity, shear flow, elasticity, cohesiveness, and coatability. Various viscoelastic agents emphasize certain features that are broadly characterized as dispersive or cohesive. They are used almost exclusively in anterior segment surgery. Complications associated with viscoelastic substances are related to transient elevation of intraocular pressure after the surgical procedure.

**Ophthalmic Glue.** Cyanoacrylate tissue adhesive (ISO-DENT, DERMABOND, HISTOACRYL), while not FDA approved for the eye, is widely used in the management of corneal ulcerations and perforations. It is applied in liquid form and polymerized into a solid plug.

Fibrinogen glue (TISSEEL) is increasingly being used on the ocular surface to secure tissue such as conjunctiva, amniotic membrane, and lamellar corneal grafts. It is FDA approved for use in cardiac and gastrointestinal surgery, but not for the eye.

**Corneal Band Keratopathy.** Edetate disodium (disodium EDTA; ENDRATE) is a chelating agent that can be used to remove a band keratopathy (i.e., a calcium deposit at the level of Bowman’s membrane on the cornea). After the overlying corneal epithelium is removed, it is applied topically to chelate the calcium deposits from the cornea.

**Anterior Segment Gases.** Sulfur hexafluoride (SF6) and perfluoropropane gases have long been used as vitreous substitutes during retinal surgery. In the anterior segment they are used in nonexpansile concentrations to treat Descemet’s detachments, typically after cataract surgery. These detachments can cause mild to severe corneal edema. The gas is injected into the anterior chamber to push Descemet’s membrane up against the stroma, where ideally it reattaches and clears the corneal edema.

**Vitreous Substitutes.** The primary use of vitreous substitutes is reattachment of the retina following vitrectomy and membrane-peeling procedures for complicated proliferative vitreoretinopathy and traction retinal detachments. Several compounds are available, including gases, perfluorocarbon liquids, and silicone oil (Table 63–8). With the exception of air, the gases expand because of interaction with systemic oxygen, carbon dioxide, and nitrogen, and this property makes them desirable to temporarily tamponade areas of the retina. However, use of these expansile gases carries the risk of complications from elevated intraocular pressure, subretinal gas, corneal edema, and cataract formation. The gases are absorbed over a time period of days (for air) to 2 months (for perfluoropropane).

The liquid perfluorocarbons, with specific gravities between 1.76 and 1.94, are denser than vitreous and are helpful in flattening the retina when vitreous is present. If a lens becomes dislocated into the vitreous, a perfluorocarbon liquid injection posteriorly will float the lens anteriorly, leading to easier surgical retrieval. This liquid can be an important tool for flattening and unrolling severely detached and contorted retinas such those found in giant retinal tears and proliferative vitreoretinopathy. This liquid is potentially toxic if it remains in chronic contact with the retina.

Silicone oil has had extensive use both in Europe and in the United States for long-term tamponade of the retina. Complications from silicone oil use include glaucoma,

Surgical Hemostasis and Thrombolytic Agents. Hemostasis has an important role in most surgical procedures and usually is achieved by temperature-mediated coagulation. In some intraocular surgeries, thrombin has a valuable role in hemostasis. Intravitreal administration of thrombin can assist in controlling intraocular hemorrhage during vitrectomy. When used intraocularly, a potentially significant inflammatory response may occur, but this reaction can be minimized by thorough irrigation after hemostasis is achieved. This coagulation factor also may be applied topically via soaked sponges to exposed conjunctiva and sclera, where hemostasis may be a challenge due to the rich vascular supply.

Topical aminocaproic acid (CAPROGEL) has been advocated to prevent rebleeding after traumatic hyphema (blood in the anterior chamber), but recent clinical trials report mixed success (Karkhaneh et al., 2003; Pieramici et al., 2003).

Depending on the intraocular location of a clot, there may be significant problems relating to intraocular pressure, retinal degeneration, and persistent poor vision. Tissue plasminogen activator (t-PA) (see Chapter 54) has been used during intraocular surgeries to assist evacuation of a hyphema, subretinal clot, or nonclearing vitreous hemorrhage. t-PA also has been administered subconjunctivally and intracameral (i.e., controlled intraocular administration into the anterior segment) to lyse blood clots obstructing a glaucoma filtration site. The main complication related to the use of t-PA is bleeding.

Botulinum Toxin Type A in the Treatment of Strabismus, Blepharospasm, and Related Disorders. Botulinum toxin type A (BOTOX) has been used to treat strabismus, blepharospasm, Meige’s syndrome, spasmodic torticollis hemifacial spasm, facial wrinkles, and certain migraine headaches (Tsui, 1996; Price et al., 1997) (see also Chapter 9). By preventing acetylcholine release at the neuromuscular junction, botulinum toxin A usually causes a temporary paralysis of the locally injected muscles. The variability in duration of paralysis may be related to the rate of developing antibodies to the toxin, upregulation of nicotinic cholinergic postsynaptic receptors, and aberrant regeneration of motor nerve fibers at the neuromuscular junction. Complications related to this toxin include double vision (diplopia) and lid droop (ptosis).

Blind and Painful Eye. Retrobulbar injection of either absolute or 95% ethanol may provide relief from chronic pain associated with a blind and painful eye. Retrobulbar chlorpromazine also has been used. This treatment is preceded by administration of local anesthesia. Local infiltration of the ciliary nerves provides symptomatic relief from pain, but other nerve fibers may be damaged, causing paralysis of the extraocular muscles, including those in the eyelids, or neuroparalytic keratitis. The sensory fibers of the ciliary nerves may regenerate, and repeated injections sometimes are needed to control pain.

Systemic Agents with Ocular Side Effects. Just as certain systemic diseases have ocular manifestations, certain systemic drugs have ocular side effects. These can range from mild and inconsequential to severe and vision threatening.

Retina. Numerous drugs have toxic side effects on the retina. The antiarthritics and antimalarial medicines hydroxychloroquine (PLAQUEMIL) and chloroquine can cause a central retinal toxicity by an unknown mechanism. With normal dosages, toxicity does not appear until about 6 years after the drug is started. Stopping the drug will not reverse the damage, but will prevent further toxicity. Sildenafil (VIAGRA) inhibits PDE5 in the corpus cavernosum for the purpose of helping to achieve and maintain penile erection. The drug also mildly inhibits PDE6, which controls the levels of cyclic GMP in the retina. Visually, this can result in seeing a blueish haze or experiencing light sensitivity. Although no retinal damage has been reported, no long-term studies have been reported (Marmor and Kessler, 1999). Two new phosphodiesterase inhibitors, vardenafil and tadalafil, also are associated with similar visual disturbances.

Optic Nerve. Multiple medications can cause a toxic optic neuropathy characterized by gradually progressive bilateral central scotomas and vision loss. There can be accompanying optic nerve pallor. These medicines include ethambutol, chloramphenicol, and rifampin. Systemic or ocular steroids can cause elevated IOP and glaucoma. If the steroids cannot be stopped, glaucoma medications, and even filtering surgery, often are required.

Anterior Segment. Steroids also have been implicated in cataract formation. If vision is reduced, cataract surgery may be necessary. Rifabutin, if used in conjunction with clarithromycin or fluconazole for treatment of Mycobacterium avium complex (MAC) opportunistic infections in HIV-positive persons, is associated with an iridocyclitis and even hypopyon. This will resolve with steroids or by stopping the medication.

Ocular Surface. Isotretinoin (ACCUTANE) has a drying effect on mucous membranes and is associated with dry eye.
Corneal Side Effects of Systemic Medications. The cornea, conjunctiva, and even eyelids can be affected by systemic medications. One of the most common drug deposits found in the cornea is from the cardiac medication amiodarone. It deposits in the inferior and central cornea in a whorl-like pattern termed cornea verticillata. It appears as fine tan or brown pigment in the epithelium. Fortunately, the deposits seldom affect vision and, therefore, this is rarely a cause to discontinue the medication. The deposits disappear slowly if the medication is stopped. Other medications can cause a similar pattern, including indomethacin, atovaquone, chloroquine, and hydroxychloroquine.

The phenothiazines, including chlorpromazine and thioridazine, can cause brown pigmented deposits in the cornea, conjunctiva, and eyelids. The deposits generally are found in Descemet’s membrane and the posterior cornea. They typically do not affect vision. The ocular deposits generally persist after discontinuation of the medication and can even worsen, perhaps because the medication deposits in the skin are slowly released and accumulate in the eye.

Gold treatments for arthritis (now rarely used) can lead to gold deposition in the cornea and conjunctiva, which are termed chrysiasis and are gold to violet in color. With lower cumulative doses (1 to 2 g) the deposits are found primarily in the epithelium and anterior stroma. These deposits usually disappear with discontinuation of the medication. With higher doses, the gold is deposited in Descemet’s membrane and posterior stroma and can involve the entire stroma. These changes can be permanent. The deposits generally do not affect vision and are not a reason to stop gold therapy.

Tetracyclines can cause a yellow discoloration of the light-exposed conjunctiva. Systemic minocycline can induce a blue-gray scleral pigmentation that is most prominent in the interpalpebral zone (Morrow and Abbott, 1998).

Agents Used to Assist in Ocular Diagnosis

A number of agents are used in an ocular examination (e.g., mydriatic agents and topical anesthetics, and dyes to evaluate corneal surface integrity), to facilitate intraocular surgery (e.g., mydriatic and miotic agents, topical and local anesthetics), and to help in making a diagnosis in cases of anisocoria (Figure 63–5) and retinal abnormalities (e.g., intravenous contrast agents). The autonomic agents have been discussed earlier. The diagnostic and therapeutic uses of topical and intravenous dyes and of topical anesthetics are discussed below.

Anterior Segment and External Diagnostic Uses. Epiphora (excessive tearing) and surface problems of the cornea and conjunctiva are commonly encountered external ocular disorders. The dyes fluorescein, rose bengal, and lissamine green are used in evaluating these problems. Available both as a 2% alkaline solution and as an impregnated paper strip, fluorescein reveals epithelial defects of the cornea and conjunctiva and aqueous humor leakage that may occur after trauma or ocular surgery. In the setting of epiphora, fluorescein is used to help determine the patency of the nasolacrimal system. In addition, this dye is used as part of the procedure of applanation tonometry (intraocular pressure measurement) and to assist in determining the proper fit of rigid and semiflexible contact lenses. Fluorescein in combination with proparacaine or benoxinate is available for procedures in which a disclosing agent is needed in conjunction with a topical anesthetic. Fluorexon (FLUORESOFT), a high-molecular-weight fluorescent solution, is used when fluorescein is contraindicated (as when soft contact lenses are in place).

Rose bengal and lissamine green, which also are available as a 1% solution and as saturated paper strips, stain devitalized tissue on the cornea and conjunctiva.

Posterior Segment Diagnostic and Therapeutic Uses. The integrity of the blood–retinal and retinal pigment epithelial barriers may be examined directly by retinal angiography using intravenous administration of either fluorescein sodium or indocyanine green (structures shown below). These agents commonly cause nausea and may precipitate serious allergic reactions in susceptible individuals.

Verteporfin (VISUDYNE) is approved for photodynamic therapy of the exudative form of age-related macular degeneration with predominantly classic choroidal neovas-
cular membranes (Fine et al., 2000). Verteporfin also is used in the treatment of predominantly classic choroidal neovascularization caused by conditions such as pathological myopia and presumed ocular histoplasmosis syndrome. The chemical structure of verteporfin, which is a mixture of two regioisomers (I and II), is shown below:

Verteporfin is administered intravenously, and once it reaches the choroidal circulation, the drug is light-activated by a nonthermal laser source. Depending on the size of the neovascular membrane and concerns of occult membranes and recurrence, multiple photodynamic treatments may be necessary. Activation of the drug in the presence of oxygen generates free radicals, which cause vessel damage and subsequent platelet activation, thrombosis, and occlusion of choroidal neovascularization. The halflife of the drug is 5 to 6 hours. It is eliminated predominantly in the feces. The potential side effects include headache, injection site reactions, and visual disturbances. The drug causes temporary photosensitization, and patients must avoid exposure of skin or eyes to direct sunlight or bright indoor lights for 5 days after receiving it.

Other Agents for Ophthalmic Therapy

Vitamins and Trace Elements. General Considerations. Table 63–9 summarizes the current understanding of vitamins related to eye function and disease, especially the biochemistry of vitamin A.

Although vitamin A must be supplied from the environment, most actions of vitamin A, like those of vitamin D, are exerted through hormone-like receptors. Vitamin A has diverse actions in cellular regulation and differentiation that go far beyond its classically defined function in vision. Analogs of vitamin A, because of their prominent effects on epithelial differentiation, have found important therapeutic applications in the treatment of a variety of dermatological conditions and are being evaluated in cancer chemoprevention.

History. The relationship of night blindness to nutritional deficiency was definitively recognized in the 1800s. Ophthalmia brasiliana (keratomalacia), a disease of the eyes that afflicted primarily poorly nourished slaves, was first described in 1865. Later it was observed that the nurslings of mothers who fasted were prone to develop spontaneous sloughing of the cornea. Other reports of nutritional keratomalacia soon followed from all parts of the world.

Experimental rather than clinical observations, however, led to the discovery of vitamin A. In 1913, McCollum and Davis, and Osborne and Mendel independently reported that animals fed artificial diets with lard as the sole source of fat developed a nutritional deficiency that could be corrected by the addition to the diet of a factor contained in butter, egg yolk, and cod liver oil. An outstanding symptom of this experimental nutritional deficiency was xerophthalmia (dryness and thickening of the conjunctiva). Clinical and experimental vitamin A deficiencies were recognized to be related during World War I, when it became apparent that xerophthalmia in human beings was a result of a decrease in the amount of butterfat in the diet.

Chemistry and Terminology. Retinoid refers to the chemical entity retinol and other closely related naturally occurring derivatives. Retinoids, which exert most of their effects by binding to specific nuclear receptors and modulating gene expression, also include structurally related synthetic analogs that need not have retinol-like (vitamin A) activity (Evans and Kaye, 1999).
The purified plant pigment carotene (provitamin A) is a remarkably potent source of vitamin A. β-Carotene, the most active carotenoid found in plants, has the structural formula shown in Figure 63–7A. The structural formulas for the vitamin A family of retinoids are shown in Figure 63–7B.

Retinol, a primary alcohol, is present in esterified form in the tissues of animals and saltwater fish, mainly in the liver. A number of cis-trans isomers exist because of the unsaturated carbons in the retinol side chain. Fish liver oils contain mixtures of the stereoisomers; synthetic retinol is the all-trans isomer. Interconversion between isomers readily takes place in the body. In the visual cycle, the reaction between retinal (vitamin A aldehyde) and opsin to form rhodopsin occurs only with the 11-cis isomer. Ethers and esters derived from the alcohol also show activity in vivo. The ring structure of retinol (β-ionone), or the more unsaturated ring in 3-dehydroretinol (dehydro-β-ionone), is essential for activity; hydrogenation destroys biological activity. Of all known derivatives, all-trans-retinol and its aldehyde, retinal, exhibit the greatest biological potency in vivo; 3-dehydroretinol has about 40% of the potency of all-trans-retinol.

Retinoic acid, in which the alcohol moiety has been oxidized, shares some but not all of the actions of retinol. Retinoic acid is ineffective in restoring visual or reproductive function in certain species where retinol is effective. However, retinoic acid is very potent in promoting growth and controlling differentiation and maintenance of epithelial tissue in vitamin A–deficient animals. Indeed, all-trans-retinoic acid (tretinoin) appears to be the active form of vitamin A in all tissues except the retina, and is ten- to one hundredfold more potent than retinol in various systems in vitro. Isomerization of this compound in the body yields 13-cis-retinoic acid (isotretinoin), which is nearly as potent as tretinoin in many of its actions on epithelial tissues, but may be only one-fifth as potent in producing the toxic symptoms of hypervitaminosis A.

Many retinoic acid analogs have been synthesized, including the prodrug etretinate, which is the ethyl ester of the active compound acitretin. These compounds are representative of the “second-generation” retinoids, in which the β-ionone ring is aromatized; they are more active than tretinoin in some systems but are less active in others. The highly potent “third-generation” retinoids feature two aromatic rings that serve to restrict the flexibility of the polyenoic side chain. This class of aromatic retinoids has been called arotinoids, and includes the carboxylic acid Ro 13-7410, and the ethyl sulfone Ro 15-1570.

**Physiological Functions and Pharmacological Actions.** Vitamin A plays an essential role in the function of the retina, is necessary for growth and differentiation of epithelial tissue, and is required for growth of bone, reproduction, and embryonic development. Together with certain carotenoids, vitamin A enhances immune function, reduces the consequences of some infectious diseases, and may protect against the development of certain malignancies. As a result, there is considerable interest in the pharmacological use of retinoids for cancer prophylaxis and for treating various premalignant conditions. Because of the effects of vitamin A on epithelial tissues, retinoids and their analogs are used to treat a number of skin diseases, including some of the consequences of aging and prolonged exposure to the sun (see Chapter 62).

The functions of vitamin A are mediated by different forms of the molecule. In vision, the functional vitamin is retinal. Retinoic acid appears to be the active form in functions associated with growth, differentiation, and transformation.

Retinal and the Visual Cycle. Vitamin A deficiency interferes with vision in dim light, a condition known as night blindness (nyctalopia).

Photoreception is accomplished by two types of specialized retinal cells, termed rods and cones. Rods are especially sensitive to light of low intensity; cones act as receptors of high-intensity light and are responsible for color vision. The initial step is the absorption of light by a chromophore attached to the receptor protein. The chromophore of both rods and cones is 11-cis-retinal. The holoreceptor in rods is termed rhodopsin—a combination of the protein opsin and 11-cis-retinal attached as a prosthetic group. The three different types of cone cells (red, green, and blue) contain individual, related photoreceptor proteins and respond optimally to light of different wavelengths.

In the synthesis of rhodopsin, 11-cis-retinol is converted to 11-cis-retinal in a reversible reaction that requires pyridine nucleotides. 11-cis-Retinal then combines with the ε-amino group of a specific lysine residue in opsin to form rhodopsin. Most rhodopsin is located in the membranes of the discs situated in the outer segments of the rods. The polypeptide chain of the protein spans the membrane seven times, a characteristic shared by all receptors whose functions are transduced via G proteins.

The visual cycle, depicted in Figure 63–8, is initiated by the absorption of a photon of light, followed by the photodecomposition, or bleaching, of rhodopsin through a cascade of unstable conformational states, leading ultimately to the isomerization of 11-cis-retinal to the all-trans form and dissociation of the opsin moiety. Activated rhodopsin interacts rapidly with another protein of the retinal rod outer segment, a G protein termed transducin or Gt. Transducin stimulates a cyclic GMP–specific phosphodiesterase (Figure 63–9). The resultant decline in cyclic GMP concentration causes a decreased conductance of cyclic GMP–gated Na⁺ channels in the plasma membrane and an increased transmembrane potential (Figure 63–10). After processing within the retinal circuitry, this primary receptor potential ultimately leads to the generation of action potentials that travel to the brain via the optic nerve (Stryer, 1991). All-trans-retinal can isomerize to 11-cis-retinal, which then may

Figure 63–7. A. Structural formula for β-Carotene. B. Structural formulas for the vitamin A family of retinoids.
recombine with opsin to form rhodopsin. Alternatively, all-trans-retinal can cycle through all-trans-retinol and 11-cis-retinol to 11-cis-retinal, which combines with opsin to regenerate rhodopsin (Figure 63–8).

Humans deficient in vitamin A lose their ability for dark adaptation. Rod vision is affected more than cone vision. Upon depletion of retinol from liver and blood, usually at plasma concentrations of retinol of less than 0.2 mg/liter (0.70 μM), the concentrations of retinol and rhodopsin in the retina fall. Unless the deficiency is overcome, opsin, lacking the stabilizing effect of retinal, decays and anatomical deterioration of the rods’ outer segments takes place. In rats maintained on a vitamin A–deficient diet, irreversible ultrastructural changes leading to blindness then supervene, a process that takes approximately 10 months.

Following short-term deprivation of vitamin A, dark adaptation can be restored to normal by the addition of retinol to the diet. However, vision does not return to normal for several weeks after adequate amounts of retinol have been supplied. The reason for this delay is unknown.

**Vitamin A and Epithelial Structures.** The functional and structural integrity of epithelial cells throughout the body is dependent upon an adequate supply of vitamin A. The vitamin plays a major role in the induction and control of epithelial differentiation in mucus-secreting or keratinizing tissues. In the presence of retinol or retinoic acid, basal epithelial cells are stimulated to produce mucus. Excessive concentrations of the retinoids lead to the production of a thick layer of mucin, the inhibition of keratinization, and the display of goblet cells.

In the absence of vitamin A, goblet mucous cells disappear and are replaced by basal cells that have been stimulated to proliferate. These undermine and replace the original epithelium with a stratified, keratinizing epithelium. The suppression of normal secretions leads to irritation and infection. Reversal of these changes is achieved by the administration of retinol, retinoic acid, or other retinoids. When this process happens in the cornea, severe hyperkeratization (xerophthalmia) may lead to permanent blindness. Worldwide, xerophthalmia remains one of the most common causes of blindness.

**Mechanism of Action.** In isolated fibroblasts or epithelial tissue, retinoids enhance the synthesis of some proteins (e.g., fibronectin) and reduce the synthesis of others (e.g., collagenase, certain species of keratin), and molecular evidence suggests that these actions can be entirely accounted for by changes in nuclear transcription (Mangelsdorf et al., 1994). Retinoic acid appears to
be considerably more potent than retinol in mediating these effects.

Retinoic acid influences gene expression by combining with nuclear receptors. Multiple retinoid receptors have been described. These are grouped into two families. One family, the retinoic acid receptors (RARs), designated α, β, and γ are derived from genes localized to human chromosomes 17, 3, and 12, respectively. The second family, the retinoid X receptors (RXRs), also is composed of α, β, and γ receptor isoforms (Chambon, 1995). The retinoid receptors show extensive sequence homology to each other in both their DNA and hormone-binding domains and belong to a receptor superfamily that includes receptors for steroid and thyroid hormones and calcitriol (Mangelsdorf et al., 1994). Cellular responses to thyroid hormones, calcitriol, and retinoic acid are enhanced by the presence of RXR. Gene activation involves binding of the hormone-receptor complex to promoter elements in target genes, followed by dimerization with an RXR-ligand complex. The endogenous RXR ligand is 9-cis-retinoic acid (Heyman et al., 1992; Levin et al., 1992). No comparable receptor for retinol has been identified; retinol may need to be oxidized to retinoic acid to produce its effects within target cells.

Retinoids can influence the expression of receptors for certain hormones and growth factors, and thus can influence the growth, differentiation, and function of target cells by both direct and indirect actions (Love and Gudas, 1994).

**Therapeutic Uses.** Nutritional vitamin A deficiency causes xerophthalmia, a progressive disease characterized by nyctalopia (night blindness), xerosis (dryness), and keratomalacia (corneal thinning) which may lead to perforation; xerophthalmia may be reversed with vitamin A therapy (WHO/UNICEF/IVAGG Task Force, 1988). However, rapid, irreversible blindness ensues once the cornea perforates. Vitamin A also is involved in epithelial differentiation and may have some role in corneal epithelial wound healing. Currently, there is no evidence to support using topical vitamin A for keratoconjunctivitis sicca in the absence of a nutritional deficiency. The current recommendation for retinitis pigmentosa is to administer 15,000 IU of vitamin A palmitate daily under the supervision of an ophthalmologist and to avoid high-dose vitamin E.

The recent Age-Related Eye Disease Study (AREDS) found a reduction in the risk of progression of some types of age-related macular degeneration for those randomized to receive high-doses of vitamins C (500 mg), E (400 IU), β-carotene (15 mg), cupric oxide (2 mg), and zinc (80 mg) (Age-Related Eye Disease Study Research Group, 2001b). Interestingly, zinc has been found to be neuroprotective in a rat model of glaucoma. The mechanism appears to be mediated by heat shock proteins and may represent a novel treatment strategy for glaucoma (Park et al., 2001).

**Wetting Agents and Tear Substitutes.** **General Considerations.** The current management of dry eyes usually includes instilling artificial tears and ophthalmic lubricants. In general, tear substitutes are hypotonic or isotonic solutions composed of electrolytes, surfactants, preservatives, and some viscosity-increasing agent that prolongs the residence time in the cul-de-sac and precorneal tear film. Common viscosity agents include cellulose polymers (e.g., carboxymethylcellulose, hydroxyethyl cellulose, hydroxypropyl cellulose, hydroxypropyl methylcellulose, and methylcellulose), polyvinyl alcohol, polyethylene glycol, polysorbate, mineral oil, glycerin, and dextran. The tear substitutes are available as preservative-containing or preservative-free preparations. The viscosity of the tear substitute depends on its exact formulation and can range from watery to gel-like. Some tear formulations also are combined with a vasoconstrictor, such as naphazoline, phenylephrine, or tetrahydrozoline. In other countries, hyaluronic acid sometimes is used as a viscous agent; hyaluronate has not been approved for use in the United States.

The lubricating ointments are composed of a mixture of white petrolatum, mineral oil, liquid or alcohol lanolin, and sometimes a preservative. These highly viscous formulations cause considerable blurring of vision, and consequently they are used primarily at bedtime, in critically ill patients, or in very severe dry eye conditions.

Such aqueous and ointment formulations are only fair substitutes for the precorneal tear film, which is truly a poorly understood lipid, aqueous, and mucin trilaminar barrier (see above).

**Therapeutic Uses.** Many local eye conditions and systemic diseases may affect the precorneal tear film. Local eye disease, such as blepharitis, ocular rosacea, ocular pemphigoid, chemical burns, or corneal dystrophies, may alter the ocular surface and change the tear

---

**Figure 63–10. Ion movements across the surface membrane of a rod.** In the dark there is a circulating current as cations, mainly Na ions, cross the outer segment membrane while K ions exit from the inner segment. Rhodopsin is embedded in stacks of disc membranes that are separated from each other and from the surface membrane. Light, absorbed by rhodopsin, leads to a change in the concentration of a diffusible substance and the closure of ion channels in the outer segment surface membrane, and this reduces the circulating current. (Reproduced with permission from Lamb, T.D. Transduction in vertebrate photoreceptors: the roles of cyclic GMP and calcium. Trends Neurosci., 1986, 9:224–228.)
composition. Appropriate treatment of the symptomatic dry eye includes treating the accompanying disease and possibly the addition of tear substitutes. There are also a number of systemic conditions that may manifest themselves with symptomatic dry eyes, including Sjögren’s syndrome, rheumatoid arthritis, vitamin A deficiency, Stevens-Johnson syndrome, and trachoma. Treating the systemic disease may not eliminate the symptomatic dry eye complaints; chronic therapy with tear substitutes or surgical occlusion of the lacrimal drainage system may be indicated.

**Osmotic Agents and Drugs Affecting Carbonic Anhydrase. General Considerations.** The main osmotic drugs for ocular use include glycerin, mannitol (see Chapter 28), and hypertonic saline. With the availability of these agents, the use of urea for management of acutely elevated intraocular pressure is nearly obsolete.

**Therapeutic Uses.** Ophthalmologists occasionally use glycerin and mannitol for short-term management of acute rises in intraocular pressure. Sporadically, these agents are used intraoperatively to dehydrate the vitreous prior to anterior segment surgical procedures. Many patients with acute glaucoma do not tolerate oral medications because of nausea; therefore, intravenous administration of mannitol and/or acetazolamide may be preferred over oral administration of glycerin. These agents should be used with caution in patients with congestive heart failure or renal failure.

Corneal edema is a clinical sign of corneal endothelial dysfunction, and topical osmotic agents may effectively dehydrate the cornea. Identifying the cause of corneal edema will guide therapy, and topical osmotic agents, such as hypertonic saline, may temporize the need for surgical intervention in the form of a corneal transplant. Sodium chloride is available in either aqueous or ointment formulations. Topical glycerin is also available; however, because it causes pain upon contact with the cornea and conjunctiva, its use is limited to urgent evaluation of filtration-angle structures. In general, when corneal edema occurs secondary to acute glaucoma, the use of an oral osmotic agent to help reduce intraocular pressure is preferred to topical glycerin, which simply clears the cornea temporarily. Reducing the intraocular pressure will help clear the cornea more permanently to allow both a view of the filtration angle by gonioscopy and a clear view of the iris as required to perform laser iridotomy.

Toxicology is the science of the adverse effects of chemicals, including drugs, on living organisms. The discipline often is divided into several major areas. The descriptive toxicologist performs toxicity tests (see below) to obtain information that can be used to evaluate the risk that exposure to a chemical poses to humans and to the environment. The mechanistic toxicologist attempts to determine how chemicals exert deleterious effects on living organisms. Such studies are essential for the development of tests for the prediction of risks, for facilitating the search for safer chemicals, and for rational treatment of the manifestations of toxicity. The regulatory toxicologist judges whether a drug or other chemical has a low enough risk to justify making it available for its intended purpose. Two specialized areas of toxicology are particularly important for medicine. Forensic toxicology, which combines analytical chemistry and fundamental toxicology, is concerned with the medicolegal aspects of chemicals. Forensic toxicologists assist in postmortem investigations to establish the cause or circumstances of death. Clinical toxicology focuses on diseases that are caused by or are uniquely associated with toxic substances. Clinical toxicologists treat patients who are poisoned by drugs and other chemicals and develop new techniques for the diagnosis and treatment of such intoxications.

The clinician must evaluate the possibility that a patient’s signs and symptoms may be caused by toxic chemicals present in the environment or administered as therapeutic agents. Many of the adverse effects of drugs mimic symptoms of disease. Appreciation of the principles of toxicology is necessary for the recognition and management of such clinical problems.

DOSE–RESPONSE RELATIONSHIP

Evaluation of the dose–response or the dose–effect relationship is crucially important to toxicologists. There is a graded dose–response relationship in an individual and a quantal dose–response relationship in the population (see Chapters 1 and 5). Graded doses of a drug given to an individual usually result in a greater magnitude of response as the dose is increased. In a quantal dose–response relationship, the percentage of the population affected increases as the dose is raised; the relationship is quantal in that the effect is specified to be either present or absent in a given individual (see Figure 5–4). This quantal dose–response phenomenon is extremely important in toxicology and is used to determine the median lethal dose (LD₅₀) of drugs and other chemicals.
The LD$_{50}$ of a compound is determined experimentally, usually by administration of the chemical to mice or rats (orally or intraperitoneally) at several doses (usually four or five) in the lethal range (Figure 64–1A). To linearize such data, the response (death) can be converted to units of deviation from the mean, or probits (probability units). The probit designates the deviation from the median; a probit of 5 corresponds to a 50% response, and because each probit equals one standard deviation, a probit of 4 equals 16% and a probit of 6 equals 84%. A plot of the percentage of the population responding, in probit units, against log dose yields a straight line (Figure 64–1B). The LD$_{50}$ is determined by drawing a vertical line from the point on the line where the probit unit equals 5 (50% mortality). The slope of the dose–effect curve also is important. The LD$_{50}$ for both compounds depicted in Figure 64–1 is the same (10 mg/kg). However, the slopes of the dose–response curves are quite different. At a dose equal to one-half the LD$_{50}$ (5 mg/kg), less than 5% of the animals exposed to compound B would die, but 30% of the animals given compound A would die.

The quantal, or “all-or-none,” response is not limited to lethality. As described in Chapters 1 and 5, similar dose–effect curves can be constructed for any effect produced by chemicals.

**RISK AND ITS ASSESSMENT**

There are marked differences in the LD$_{50}$ values of various chemicals. Some result in death at doses of a fraction of a microgram (LD$_{50}$ for botulinum toxin equals 10 pg/kg); others may be relatively harmless in doses of several grams or more. While categories of toxicity that are of some practicality have been devised based on the amount required to produce death, often it is not easy to distinguish between toxic and nontoxic chemicals. Paracelsus (1493–1541) noted: “All substances are poisons; there is none which is not a poison. The right dose differentiates a poison and a remedy.” It is simply not possible to categorize all chemicals as either safe or toxic. The real concern is the risk associated with use of the chemical. In the assessment of risk, one must consider concentration or dose as well as the harmful effects of the chemical accrued directly or indirectly through adverse effects on the environment when used in the quantity and in the manner proposed. Depending on the use and disposition of a chemical, a very toxic compound ultimately may be less harmful than a relatively nontoxic one.

At present, there is much concern about the risk from exposure to chemicals that have produced cancer in laboratory animals. For most of these chemicals, it is not known if they also produce cancer in humans. Regulatory agencies take one of three approaches to potential chemical carcinogens. For food additives, the U.S. Food and Drug Administration (FDA) is very cautious because large numbers of people are likely to be exposed to the chemicals, and they are not likely to have beneficial effects to individuals. For drugs, the FDA weighs the relative risks and benefits of the drugs for patients. Thus it is unlikely that the FDA will approve the use of a drug that produces tumors in laboratory animals for a mild ailment, but it may approve its use for a serious disease. In fact, most cancer chemotherapeutic drugs also are chemical carcinogens.

In the regulation of environmental carcinogens, government agencies, such as the U.S. Environmental Protection Agency (EPA), attempt to limit lifetime exposure such that the incidence of cancer due to the chemical would be no more than one in a million people. To determine the daily allowable exposure for humans, mathematical models are used to extrapolate doses of chemicals that produce a particular incidence of tumors in laboratory animals (often in the range of 10% to 20%) to those that should produce cancer in no more than one person in a million. The models used are conservative and are thought to provide adequate protection from undue risks from exposure to potential carcinogens. As discussed in Chapter 3, variations in drug metabolism often result in substantial differences between the biological responses of humans and rodents.

**Acute versus Chronic Exposure.** Effects of acute exposure to a chemical often differ from those that follow chronic exposure. Acute exposure occurs when a dose is delivered as a single event. Chronic exposure is likely to be to small quantities of a substance over a long period of
time, which often results in slow accumulation of the compound in the body. Evaluation of cumulative toxic effects is receiving increased attention because of chronic exposure to low concentrations of various natural and synthetic chemical substances in the environment.

**Chemical Forms of Drugs That Produce Toxicity.** The “parent” drug administered to the patient often is the chemical form producing the desired therapeutic effect; the parent drug also may produce the toxic effects of drug. However, both therapeutic and toxic effects also can be due to metabolites of the drug produced by enzymes, light, or reactive oxygen species. In considering the toxicity of drugs and chemicals, it is important to understand their metabolism, activation, or decomposition.

**Toxic Metabolites.** The metabolites of many chemicals are responsible for their toxicities. Most organophosphate insecticides are biotransformed by cytochrome P450 enzymes (CYPs) to produce the active toxin. For example, parathion is biotransformed to paraoxon (Figure 64–2). Paraoxon is a stable metabolite that binds to and inactivates cholinesterase. Some drug metabolites are not chemically stable and are referred to as reactive intermediates. An example of a toxic reactive intermediate is the metabolite of acetaminophen (Figure 64–3), which is very reactive and binds to nucleophiles such as glutathione; when cellular glutathione is depleted, the metabolite binds to cellular macromolecules, the mechanism by which acetaminophen kills liver cells (see Chapter 26). Both parathion and acetaminophen are more toxic under conditions in which CYPs are increased, such as following ethanol or phenobarbital exposure, because CYPs produce the toxic metabolites (see Chapter 3).

**Phototoxic and Photoallergic Reactions.** Many chemicals are activated to toxic metabolites by hepatic enzymatic biotransformation. However, some chemicals can be activated in the skin by ultraviolet and/or visible radiation. In photoallergy, radiation absorbed by a drug, such as a sulfonamide, results in its conversion to a product that is a more potent allergen than the parent compound. Phototoxic reactions to drugs, in contrast to photoallergic ones, do not have an immunological component. Drugs that are either absorbed locally into the skin or have reached the skin through the systemic circulation may be the object of photochemical reactions within the skin; this can lead directly either to chemically induced photosensitivity reactions or to enhancement of the usual effects of sunlight. Tetracyclines, sulfonamides, chlorpro-

**SPECTRUM OF UNDESIRED EFFECTS**

The spectrum of undesired effects of chemicals may be broad and ill defined (Figure 64–5). In therapeutics, a
drug typically produces numerous effects, but usually only one is sought as the primary goal of treatment; most of the other effects are referred to as undesirable effects of that drug for that therapeutic indication. Side effects of drugs usually are nondeleterious; they include effects such as dry mouth occurring with tricyclic antidepressant therapy. Some side effects may be adverse or toxic. Mechanistic categorization of toxic effects is a necessary prelude to their avoidance or, if they occur, to effect their rational and successful management.

Types of Toxic Reactions. Toxic effects of drugs may be classified as pharmacological, pathological, or genotoxic (alterations of DNA), and their incidence and seriousness are related, at least over some range, to the concentration of the toxic chemical in the body. An example of a pharmacological toxicity is excessive depression of the central nervous system (CNS) by barbiturates; of a pathological effect, hepatic injury produced by acetaminophen; of a genotoxic effect, a neoplasm produced by a nitrogen mustard. If the concentration of chemical in the tissues does not exceed a critical level, the effects usually will be reversible. The pharmacological effects usually disappear when the concentration of drug or chemical in the tissues is decreased by biotransformation or excretion from the body. Pathological and genotoxic effects may be repaired. If these effects are severe, death may ensue within a short time; if more subtle damage to DNA is not repaired, cancer may appear in a few months or years in laboratory animals or in a decade or more in humans.

Local versus Systemic Toxicity. Local toxicity occurs at the site of first contact between the biological system and the toxicant. Local effects can be caused by ingestion of caustic substances or inhalation of irritant materials. Systemic toxicity requires absorption and distribution of the toxicant; most substances, with the exception of highly reactive chemical species, produce systemic toxic effects. The two categories are not mutually exclusive. Tetraethyl lead, for example, injures skin at the site of contact and deleteriously affects the CNS after it is absorbed into the circulation (see Chapter 65).

Most systemic toxicants predominantly affect one or a few organs. The target organ of toxicity is not necessarily the site of accumulation of the chemical. For example, lead is concentrated in bone, but its primary toxic action is on soft tissues; DDT (chlorophenothane) is concentrated in adipose tissue but produces no known toxic effects there.

The CNS is involved in systemic toxicity most frequently because many compounds with prominent effects elsewhere also affect the brain. Next in order of frequency of involvement in systemic toxicity are the circulatory system; the blood and hematopoietic system; visceral organs such as liver, kidney, and lung; and the skin. Muscle and bone are least often affected. With substances that have a predominantly local effect, the frequency of tissue reaction depends largely on the portal of entry (skin, gastrointestinal tract, or respiratory tract).

Reversible and Irreversible Toxic Effects. The effects of drugs on humans, whenever possible, must be reversible; otherwise, the drugs would be prohibitively toxic. If a chemical produces injury to a tissue, the capacity of the tissue to regenerate or recover largely will determine the reversibility of the effect. Injuries to a tissue such as liver, which has a high capacity to regenerate, usually are reversible; injury to the CNS is largely irreversible because the highly differentiated neurons of the brain have a more limited capacity to divide and regenerate.

Delayed Toxicity. Most toxic effects of drugs occur at a predictable (usually short) time after administration. However, such is not always the case. For example, aplastic anemia caused by chloramphenicol may appear weeks after the drug has been discontinued. Carcinogenic effects of chemicals usually have a long latency period: 20 to 30 years may pass before tumors are observed. Because such delayed effects cannot be assessed during any reasonable period of initial evaluation of a chemical, there is an urgent need for reliably predictive short-term tests for such toxicity, as well as for systematic surveillance of the long-term effects of marketed drugs and other chemicals (see Chapter 5).

Chemical Carcinogens. Chemical carcinogens are classified into two major groups, genotoxic and nongenotoxic. Genotoxic carcinogens interact with DNA, whereas nongenotoxic carcinogens do not. Chemical carcinogenesis is a multistep process. Most genotoxic carcinogens are themselves unreactive (procarcinogens or proximate carcinogens) but are converted to primary or ultimate carcinogens in the body. The drug-metabolizing enzymes often convert the proximate carcinogens to reactive electron-deficient intermediates (electrophiles). These reactive intermediates can interact with electron-rich (nucleophilic) centers in DNA to produce a mutation. Such interaction of the ultimate carcinogen with DNA in a cell is thought to be the initial step in chemical carcinogenesis. The DNA may revert to nor-
nical if DNA repair mechanisms operate successfully; if not, the transformed cell may grow into a tumor that becomes apparent clinically.

Nongenotoxic carcinogens, also referred to as promoters, do not produce tumors alone but do potentiate the effects of genotoxic carcinogens. Promotion involves facilitation of the growth and development of so-called dormant or latent tumor cells. The time from initiation to the development of a tumor probably depends on the presence of such promoters; for many human tumors, the latent period is 15 to 45 years.

To determine whether a chemical is potentially carcinogenic to humans, two main types of laboratory tests are conducted. One type of study is performed to determine whether the chemical is mutagenic because many carcinogens are also mutagens. These studies often use assays such as the Ames test (see below), which can be completed within a few days and can detect genotoxic carcinogens but not promoters. The second type of study to detect chemical carcinogens consists of feeding laboratory animals (mice and rats) the chemical at high dosages for their entire life span, after which autopsies and histopathological examinations are performed on each animal. The incidence of tumors in control animals and animals fed the chemical are compared to determine whether the chemical produces an increased incidence of tumors. This latter study can detect both promoters and genotoxic carcinogens.

**Allergic Reactions.** Chemical allergy is an adverse reaction that results from previous sensitization to a particular chemical or to one that is structurally similar. Such reactions are mediated by the immune system. The terms hypersensitivity and drug allergy often are used to describe the allergic state.

For a low-molecular-weight chemical to cause an allergic reaction, it or its metabolic product usually acts as a hapten, combining with an endogenous protein to form an antigenic complex. Such antigens induce the synthesis of antibodies, usually after a latent period of at least 1 or 2 weeks. Subsequent exposure of the organism to the chemical results in an antigen–antibody interaction that provokes the typical manifestations of allergy. Dose–response relationships usually are not apparent for the provocation of allergic reactions.

Allergic responses have been divided into four general categories based on the mechanism of immunological involvement (Coombs and Gell, 1975). Type I, or anaphylactic, reactions, are mediated by IgE antibodies. The Fc portion of IgE can bind to receptors on mast cells and basophils (see Chapter 27). If the Fab portion of the antibody molecule then binds antigen, various mediators (e.g., histamine, leukotrienes, and prostaglandins) are released and cause vasodilation, edema, and an inflammatory response. The main targets of this type of reaction are the gastrointestinal tract (food allergies), the skin (urticaria and atopic dermatitis), the respiratory system (rhinitis and asthma), and the vasculature (anaphylactic shock). These responses tend to occur quickly after challenge with an antigen to which the individual has been sensitized and are termed immediate hypersensitivity reactions.

Type II, or cytolytic, reactions are mediated by both IgG and IgM antibodies and usually are attributed to their ability to activate the complement system. The major target tissues for cytolytic reactions are the cells in the circulatory system. Examples of type II allergic responses include penicillin-induced hemolytic anemia, methyl dopa–induced autoimmune hemolytic anemia, quinidine–induced thrombocytopenic purpura, and sulfonamide–induced granulocytopenia. Fortunately, these autoimmune reactions to drugs usually subside within several months after removal of the offending agent.

Type III, or Arthus, reactions are mediated predominantly by IgG; the mechanism involves the generation of antigen–antibody complexes that subsequently fix complement. The complexes are deposited in the vascular endothelium, where a destructive inflammatory response called serum sickness occurs. This phenomenon contrasts with the type II reaction, in which the inflammatory response is induced by antibodies directed against tissue antigens. The clinical symptoms of serum sickness include urticarial skin eruptions, arthralgia or arthritis, lymphadenopathy, and fever. These reactions usually last for 6 to 12 days and then subside after the offending agent is eliminated. Several drugs (e.g., sulfonamides, penicillins, certain anticonvulsants, and iodides) can induce serum sickness. Stevens-Johnson syndrome, such as that caused by sulfonamides, is a more severe form of immune vasculitis. Manifestations of this reaction include erythema multiforme, arthritis, nephritis, CNS abnormalities, and myocarditis.

Type IV, or delayed-hypersensitivity, reactions are mediated by sensitized T-lymphocytes and macrophages. When sensitized cells come in contact with antigen, an inflammatory reaction is generated by the production of lymphokines and the subsequent influx of neutrophils and macrophages. An example of type IV or delayed hypersensitivity is the contact dermatitis caused by poison ivy.

**Idiosyncratic Reactions.** Idiosyncrasy is an abnormal reactivity to a chemical that is peculiar to a given individual. The idiosyncratic response may take the form of extreme sensitivity to low doses or extreme insensitivity to high doses of chemicals. We now know that certain idiosyncratic reactions can result from genetic polymorphisms that cause individual differences in drug pharmacokinetics; for example, an increased incidence of peripheral neuropathy is seen in patients with inherited deficiencies in acetylation when isoniazid is used to treat tuberculosis. The polymorphisms also can be due to pharmacodynamic factors such as drug-receptor interactions (Evans and Relling, 1999). For example, many black males (about 10%) develop a serious hemolytic anemia when they receive primaquine as an antimalarial therapy. Such individuals have a deficiency of erythrocyte glucose-6-phosphate dehydrogenase (see Chapter 39). Genetically determined resistance to the anticoagulant action of warfarin is due to an alteration in the vitamin K epoxide reductase (see Chapter 54). The use of genetic information to explain interindividual differences in drug responses or to individualize dosages of drugs for patients with known genetic polymorphisms is referred to as pharmacogenomics (see Chapters 3 and 4).

**Interactions between Chemicals.** The existence of numerous toxicants requires consideration of their potential interactions (Figure 64–6). Concurrent exposures may alter the pharmacokinetics of drugs by changing rates of absorption, the degree of protein binding, or the rates of biotransformation or excretion of one or both interacting compounds. The pharmacodynamics of chemicals can be altered by competition at the receptor; for example, atropine is used
to treat organophosphate insecticide toxicity because it blocks muscarinic cholinergic receptors and prevents their stimulation by the excess acetylcholine accruing from inhibition of acetylcholinesterase by the insecticide. Nonreceptor pharmacodynamic drug interactions also can occur when two drugs have different mechanisms of action: Aspirin and heparin given together can cause unexpected bleeding. The response to combined toxicants thus may be equal to, greater than, or less than the sum of the effects of the individual agents.

Numerous terms describe pharmacological and toxicological interactions (Figure 64–6B). An additive effect describes the combined effect of two chemicals that equals the sum of the effect of each agent given alone; the additive effect is the most common. A synergistic effect is one in which the combined effect of two chemicals exceeds the sum of the effects of each agent given alone. For example, both carbon tetrachloride and ethanol are hepatotoxins, but together they produce much more injury to the liver than expected from the sum of their individual effects. Potentiation is the increased effect of a toxic agent acting simultaneously with a nontoxic one. Iso-propanol alone, for example, is not hepatotoxic; however, it greatly increases the hepatotoxicity of carbon tetrachloride. Antagonism is the interference of one chemical with the action of another. An antagonistic agent is often desirable as an antidote. Functional or physiological antagonism occurs when two chemicals produce opposite effects on the same physiological function. For example, this principle is applied to the use of intravenous infusion of dopamine to maintain perfusion of vital organs during certain severe intoxications characterized by marked hypotension. Chemical antagonism or inactivation is a reaction between two chemicals to neutralize their effects. For example, dimercaprol chelates various metals to decrease their toxicity (see Chapter 65). Dispositional antagonism is the alteration of the disposition of a substance (its absorption, biotransformation, distribution, or excretion) so that less of the agent reaches the target organ or its persistence there is reduced (see below). Antagonism at the receptor for the chemical entails the blockade of the effect of an agonist with an appropriate antagonist that competes for the same site. For example, the antagonist naloxone is used to treat respiratory depression produced by opioids (see Chapter 21).

### DESCRIPTIVE TOXICITY TESTS IN ANIMALS

Two main principles underlie all descriptive toxicity tests performed in animals. First, effects of chemicals produced in laboratory animals, when properly qualified, apply to human toxicity. When calculated on the basis of dose per unit of body surface, toxic effects in human beings usually are encountered in the same range of concentrations as those in experimental animals. On the basis of body weight, human beings generally are more vulnerable than experimental animals. Such information is used to select dosages for clinical trials of candidate therapeutic agents and to attempt to set limits on permissible exposure to environmental toxicants.

Second, exposure of experimental animals to toxic agents in high doses is a necessary and valid method to discover possible hazards to human beings who are exposed to much lower doses. This principle is based on the quantal dose–response concept. As a matter of practicality, the number of animals used in experiments on toxic materials usually will be small compared with the size of human populations potentially at risk. For example, 0.01% incidence of a serious toxic effect (such as cancer) represents 25,000 people in a population of 250 million. Such an incidence is unacceptably high. Yet, detecting an incidence of 0.01% experimentally probably would require a minimum of 30,000 animals. To estimate risk at low dosage, large doses must be given to relatively small groups. The validity of the necessary extrapolation is clearly a crucial question.

Chemicals are first tested for toxicity by estimation of the LD$_{50}$ in two animal species by two routes of administration; one of these is the expected route of exposure of human beings to the chemical being tested. The number of animals that die in a 14-day period after a single dose is recorded. The animals also are examined for signs of intoxication, lethargy, behavioral modification, and morbidity. The chemical is next tested for toxicity by repeat exposure, usually for 90 days. This study is performed most often in two species by the route of intended use or exposure with at least three doses. A number of parameters are monitored during this period, and at the end of the study, organs and tissues are examined by a pathologist.

Long-term or chronic studies are carried out in animals at the same time that clinical trials are undertaken. For drugs, the length of...
exposure depends somewhat on the intended clinical use. If the drug normally would be used for short periods under medical supervision, as would an antimicrobial agent, a chronic exposure of animals for 6 months might suffice. If the drug would be used in human beings for longer periods, a study of chronic use for 2 years may be required.

Studies of chronic exposure often are used to determine the carcinogenic potential of chemicals. These studies usually are performed in rats and mice for the average lifetime of the species. Other tests are designed to evaluate teratogenicity (congenital malformations), perinatal and postnatal toxicity, and effects on fertility. Teratogenicity studies usually are performed by administering drugs to pregnant rats and rabbits during the period of organogenesis.

In addition to chronic studies for evaluation of carcinogenic potential or teratogenicity, drugs often are tested for mutagenic potential. The most popular such test currently available, the reverse mutation test developed by Ames and colleagues (Ames et al., 1975), uses a strain of *S. typhimurium* that has a mutant gene for the enzyme phosphoribosyl adenosine triphosphate (ATP) synthetase. This enzyme is required for histidine synthesis, and the bacterial strain is unable to grow in a histidine-deficient medium unless a reverse mutation is induced. Because many chemicals are not mutagenic or carcinogenic unless activated by enzymes on the endoplasmic reticulum, rat hepatic microsomes usually are added to the medium containing the mutant bacteria and the drug. The Ames test is rapid and sensitive. Its usefulness for the prediction of genotoxic carcinogens is widely accepted, but it does not detect nongenotoxic carcinogens (promoters).

### INCIDENCE OF ACUTE POISONING

The true incidence of poisoning in the United States is not known, but in 2003, nearly 2.4 million cases were voluntarily reported to the American Association of Poison Control Centers. The number of actual poisonings almost certainly exceeds by far the number reported.

Deaths in the United States owing to poisoning number more than 1100 per year. The incidence of poisoning in children younger than 5 years of age has decreased dramatically over the past four decades. For example, there were no reported childhood deaths owing to aspirin in 2003, compared with about 140 deaths per year in the early 1960s. This favorable trend probably is due to safety packaging of drugs, drain cleaners, turpentine, and other household chemicals; improved medical training and care; and increased public awareness of potential poisons.

The substances involved most frequently in human poison exposures are shown in Table 64–1. Analgesic drugs lead the list, followed by two nondrug entries, cleaning agents and cosmetics. However, the top five categories of substances that produce deaths are drugs (Table 64–2). The categories most commonly associated with fatalities are analgesics (e.g., acetaminophen and salicylates), sedative-hypnotics/antipsychotics, antidepressants, stimulants and street drugs (including *opiates* and *cocaine*), and cardiovascular drugs (including *digoxin* and Ca$^{2+}$ channel blockers). The most common categories of nonpharmaceutical poisons were alcohols (particularly methanol) and fumes (principally carbon monoxide). Most of the people who die from poisoning are adults, and the deaths often result from intentional rather than accidental exposure. Children younger than 6 years of age account for 52% of the poisoning incidents reported but only 3% of the deaths. Children between 1 and 2 years of age have the highest incidence of accidental poisoning. Fortunately, most of the substances available to these young children are not highly toxic. Iron and pesticides are the leading cause of pediatric accidental poisoning fatalities.

The incidence of serious and fatal adverse drug reactions in U.S. hospitals is extremely high (Lazarou et al., 1998; Institute of Medicine, 1999). It is estimated that about 2 million hospitalized patients have serious adverse drug reactions each year, and about 100,000 have fatal adverse drug reactions. If this estimate is correct, then more people die annually from medication errors than from highway

accidents, breast cancer, or the acquired immune deficiency syndrome (AIDS).

### MAJOR SOURCES OF INFORMATION ON POISONING

Pharmacology textbooks are a good source of information on the treatment of poisoning by drugs, but they usually say little about other chemicals. Additional information on drugs and other chemicals can be found in books on poisoning (Ellenhorn, 1997; Goldfrank et al., 2002; Haddad et al., 1998; Klaassen, 2001). A popular computerized system for information on toxic substances is POISINDEX (Micromedex, Inc., Denver, CO).

The Web site of the American Association of Poison Control Centers (http://www.aapcc.org/) lists 78 members, including 11 regional centers. Valuable information can be obtained from these centers by telephone (800-222-1222). The National Library of Medicine maintains a very informative Web site on toxicology and environmental health (http://sis.nlm.nih.gov/Tox/ToxMain.html), including a link to ToxNet (http://toxnet.nlm.nih.gov/), a cluster of databases on toxicology, hazardous chemicals, and related areas.

### PREVENTION AND TREATMENT OF POISONING

Many acute poisonings from drugs could be prevented if physicians provided common-sense instructions about the storage of drugs and other chemicals and if patients or parents of patients accepted this advice. These instructions are so widely publicized that they need not be repeated here.

For clinical purposes, all toxic agents can be divided into two classes: those for which a specific treatment or antidote exists and those for which there is no specific treatment. For the vast majority of drugs and other chemicals, there is no specific treatment; symptomatic medical care that supports vital functions is the only strategy.

As in other medical emergencies, supportive therapy is the mainstay of the treatment of drug poisoning. The adage, “Treat the patient, not the poison,” remains the most basic and important principle of clinical toxicology. Maintenance of respiration and circulation takes precedence. Serial measurement and charting of vital signs and important reflexes help to judge the progress of intoxication, response to therapy, and need for additional treatment. This monitoring usually requires hospitalization. The classification in Table 64–3 often is used to indicate the severity of CNS intoxication. Treatment with large doses of stimulants and sedatives often causes more harm than the poison. Chemical antidotes should be used judiciously; heroic measures seldom are necessary.

Treatment of acute poisoning must be prompt. The first goal is to maintain the vital functions if their impairment is imminent. The second goal is to keep the concentration of poison in the crucial tissues as low as possible by preventing absorption and enhancing elimination. The third goal is to combat the pharmacological and toxicological effects at the effector sites.

### Prevention of Further Absorption of Poison

**Emesis.** Historically, emesis was one of the major tools of gastric decontamination in the management of acute poi-
soning. However, its routine use in the emergency room is declining. According to the annual report of the Toxic Exposure Surveillance System (TESS) (Watson et al., 2004), emesis accounted for only 0.7% of the therapy provided in human exposure cases in 2003 compared with 7.5% in 1993 (Litovitz et al., 1994) and 13.8% in 1983 (Veltri et al., 1984). Although emesis still may be indicated for immediate intervention after poisoning by oral ingestion of chemicals, it is contraindicated in certain situations: (1) If the patient has ingested a corrosive poison, such as a strong acid or alkali (e.g., drain cleaners), emesis increases the likelihood of gastric perforation and further necrosis of the esophagus; (2) if the patient is comatose or in a state of stupor or delirium, emesis may cause aspiration of the gastric contents; (3) if the patient has ingested a CNS stimulant, further stimulation associated with vomiting may precipitate convulsions; and (4) if the patient has ingested a petroleum distillate (e.g., kerosene, gasoline, or petroleum-based liquid furniture polish), regurgitated hydrocarbons can be aspirated readily and cause chemical pneumonitis (Ervin, 1983). In contrast, emesis should be considered if the ingested solution contains potentially dangerous compounds, such as pesticides.

There are marked differences in the capabilities of various petroleum distillates to produce hydrocarbon pneumonia, which is an acute hemorrhagic necrotizing process. In general, the ability of various hydrocarbons to produce pneumonitis is inversely proportional to their viscosity: If the viscosity is high, as with oils and greases, the risk is limited; if the viscosity is low, as with mineral seal oil found in liquid furniture polishes, the risk of aspiration is high.

Vomiting can be induced mechanically by stroking the posterior pharynx. However, this technique is not as effective as the administration of ipecac or apomorphine.

**Ipecac.** The most common household emetic is syrup of ipecac (not ipecac fluid extract, which is 14 times more potent and may cause fatalities). Syrup of ipecac is available in 0.5- and 1-fluid ounce containers (approximately 15 and 30 ml), which may be purchased without prescription. The drug can be given orally, but it takes 15 to 30 minutes to produce emesis; this compares favorably with the time usually required for adequate gastric lavage. The oral dose is 15 ml in children from 6 months to 12 years of age and 30 ml in older children and adults. Because emesis may not occur when the stomach is empty, administration of ipecac should be followed by a drink of water.

In 2004, the American Academy of Clinical Toxicology and the European Association of Poisons Control Centers and Clinical Toxicologists issued position papers on the use of ipecac syrup in poisonings (Anonymous, 2004). After careful review of the medical literature, these groups concluded that syrup of ipecac should not be administered routinely in the management of poisoned patients. In studies with various marker substances, the beneficial effects of ipecac-induced emesis were highly variable and diminished rapidly with time. Another concern was that initial use of ipecac in fact may be counterproductive by reducing the efficacy of other, later, and presumably more effective treatments such as use of activated charcoal, oral antidotes, and whole-bowel irrigation. Ipecac may be indicated when it can be administered to conscious, alert patients within 60 minutes of poisoning.

Ipecac acts as an emetic because of its local irritant effect on the enteric tract and its effect on the chemoreceptor trigger zone (CTZ) in the area postrema of the medulla. Syrup of ipecac may be effective even when antiemetic drugs (such as phenothiazines) have been

</table>
ingested. Ipecac can produce toxic effects on the heart because of its content of emetine, but this usually is not a problem with the dose used for emesis. If emesis does not occur, ipecac should be removed by gastric lavage. Chronic abuse of ipecac for weight reduction can result in cardiomyopathy, ventricular fibrillation, and death.

**Apomorphine.** Apomorphine stimulates the CTZ and causes emesis. The drug is unstable in solution and must be prepared just prior to use and thus is not often readily available. Apomorphine is not effective orally and must be given parenterally, usually by the subcutaneous route, 6 mg for adults and 0.06 mg/kg for children (Goldfrank et al., 2002). However, this can be an advantage over ipecac in that it can be administered to an uncooperative patient and produces vomiting in 3 to 5 minutes. Because apomorphine is a respiratory depressant, it should not be used if the patient has been poisoned by a CNS depressant or if the patient’s respiration is slow and labored. At present, apomorphine is used rarely as an emetic.

**Gastric Lavage.** Gastric lavage is accomplished by inserting a tube into the stomach and washing the stomach with water, normal saline, or one-half normal saline to remove the unabsorbed poison. The procedure should be performed as soon as possible, but only if vital functions are adequate or supportive procedures have been implemented. The contraindications to this procedure generally are the same as for emesis, and there is the additional potential complication of mechanical injury to the throat, esophagus, and stomach. A position statement on the use of gastric lavage by American and European clinical toxicologists (Anonymous, 1997) concluded that gastric lavage should not be used routinely in the management of the poisoned patient but should be reserved for patients who have ingested a potentially life-threatening amount of poison and when the procedure can be undertaken within 60 minutes of ingestion.

The only equipment needed for gastric lavage is a tube and a large syringe. The tube should be as large as possible so that the wash solution, food, and poison (whether in the form of a capsule, pill, or liquid) will flow freely, and lavage can be accomplished quickly. A 36-French tube or larger should be used in adults and a 24-French tube or larger in children. Orogastric lavage is preferred over nasogastric lavage because a larger tube can be employed. To prevent aspiration, an endotracheal tube with an inflatable cuff should be positioned before lavage is initiated if the patient is comatose, having seizures, or has lost the gag reflex. During gastric lavage, the patient should be placed on his or her left side because of the anatomical asymmetry of the stomach, with the head hanging face down over the edge of the examining table. If possible, the foot of the table should be elevated. This technique minimizes chances of aspiration.

The contents of the stomach should be aspirated with an irrigating syringe and saved for chemical analysis. The stomach then may be washed with saline solution. Saline solution is safer than water in young children because of the risk of water intoxication, manifested by tonic-clonic seizures and coma. Only small volumes (120 to 300 ml) of lavage solution should be instilled into the stomach at one time so that the poison is not pushed into the intestine. Lavage is repeated until the returns are clear, which usually requires 10 to 12 washings and a total of 1.5 to 4 L of lavage fluid. When the lavage is complete, the stomach may be left empty, or an antidote may be instilled through the tube. If no specific antidote for the poison is known, an aqueous suspension of activated charcoal and a cathartic often is given.

**Chemical Adsorption.** Activated charcoal avidly absorbs drugs and chemicals on the surfaces of the charcoal particles, thereby preventing absorption and toxicity. Many, but not all, chemicals are adsorbed by charcoal. For example, alcohols, hydrocarbons, metals, and corrosives are not well adsorbed by activated charcoal, and charcoal therefore is of little value in treating these poisonings. The effectiveness of charcoal also depends on the time since the ingestion and on the dose of charcoal; one should attempt to achieve a charcoal–drug ratio of at least 10:1. Activated charcoal also can interrupt the enterohepatic circulation of drugs and enhance the net rate of diffusion of the chemical from the body into the gastrointestinal tract. For example, serial doses of activated charcoal have been shown to enhance the elimination of theophylline and phenobarbital.

During the last two decades, there has been an increase in the use of activated charcoal and a corresponding decrease in the use of ipecac-induced emesis and gastric lavage in the treatment of poisoning. Studies in patients with drug overdoses and in normal subjects fail to show a benefit of treatment with ipecac or lavage plus activated charcoal as compared with charcoal alone. Based on these findings, American and European clinical toxicologists issued a position paper in 1999 on the use of multidose activated charcoal in treatment of acute poisoning (Anonymous, 1999). They concluded that while experimental and clinical trials demonstrate that elimination of some drugs can be enhanced by treatment with activated charcoal in volunteer studies, rarely has it been demonstrated to reduce morbidity or mortality in a controlled study. The position paper recommends consideration of activated charcoal treatment only if a patient has ingested a life-threatening amount of carbamazepine, dapsone, phenobarbital, quinine, or theophylline. Even then, there are certain contraindications, such as an unprotected airway, the presence of intestinal obstruction, or if the gastrointestinal tract is not intact or there is decreased peristalsis. There is a need for ongoing study of the efficacy of this treatment for other drugs and to establish optimal dosage regimens.

Activated charcoal usually is prepared as a mixture of at least 50 g (about 10 heaping tablespoons) in a glass of water. The mixture is then administered either orally or via a gastric tube. Because most poisons do not appear to desorb from the charcoal if charcoal is
present in excess, the adsorbed poison need not be removed from the gastrointestinal tract. Activated charcoal should not be used simultaneously with ipecac because charcoal can adsorb the emetic agent in ipecac and thus reduce the drug’s emetic effect. Charcoal also may adsorb and decrease the effectiveness of specific antidotes.

Activated charcoal must be distinguished from the so-called universal antidote, which consists of two parts burned toast (not activated charcoal), one part tannic acid (strong tea), and one part magnesium oxide. In practice, the universal antidote is ineffective.

As mentioned earlier, the presence of an adsorbent in the intestine may interrupt enterohepatic circulation of a toxicant, thus enhancing its excretion. Activated charcoal is useful in interrupting the enterohepatic circulation of drugs such as tricyclic antidepressants and glutethimide. A nonabsorbable polythiol resin has been used to treat poisoning by methylmercury owing to its capacity to bind mercury excreted into the bile (see Chapter 65). Cholestyramine hastens the elimination of cardiac glycosides by a similar mechanism.

Chemical Inactivation. Antidotes can change the chemical nature of a poison by rendering it less toxic or preventing its absorption. Formaldehyde poisoning can be treated with ammonia to form hexamethylenetetramine; sodium formaldehyde sulfoxylate can convert mercuric ion to the less soluble metallic mercury; and sodium bicarbonate converts ferrous iron to ferrous carbonate, which is poorly absorbed. Chemical inactivation techniques seldom are used today, however, because valuable time may be lost, whereas emetics, activated charcoal, and gastric lavage are rapid and effective.

In the past, neutralization was the usual treatment of poisoning with acids or bases. Vinegar, orange juice, or lemon juice has been used often for the patient who has ingested alkali, and various antacids often have been advocated for treatment of acid burns. The use of neutralizing agents is controversial because they may produce excessive heat. Carbon dioxide gas produced from bicarbonates used to treat oral poisoning with acids can cause gastric distension and even perforation. The treatment of choice for ingestion of either acids or alkalis is dilution with water or milk. Similarly, burns produced by acid or alkali on the skin should be treated with copious amounts of water.

Purgation. The rationale for using an osmotic cathartic is to minimize absorption by hastening the passage of the toxicant through the gastrointestinal tract. Few, if any, controlled clinical data are available on the effectiveness of cathartics in the treatment of poisoning. Cathartics generally are considered harmless unless the poison has injured the gastrointestinal tract. Cathartics are indicated after the ingestion of enteric-coated tablets, when the time after ingestion is greater than 1 hour, and for poisoning by volatile hydrocarbons. Sorbitol is the most effective, but sodium sulfate and magnesium sulfate also are used; all act promptly and usually have minimal toxicity. However, magnesium sulfate should be used cautiously in patients with renal failure or in those likely to develop renal dysfunction, and Na+-containing cathartics should be avoided in patients with congestive heart failure.

Whole-bowel irrigation (WBI) is a technique that not only promotes defecation but also eliminates the entire contents of the intestines. This technique uses a high-molecular-weight polyethylene glycol and isosmolar electrolyte solution (PEG-E S) that does not alter serum electrolytes. It is available commercially as GOLYTELY and COlyte. A position statement on WBI issued by the American Academy of Clinical Toxicology and the European Association of Poisons Centres and Clinical Toxicologists, indicates that WBI should not be used routinely in the management of the poisoned patient. Even though volunteer studies have shown substantial decreases in the bioavailability of certain ingested drugs, evidence from controlled clinical trials is lacking. WBI may be considered in cases of acute poisoning by sustained-release or enteric-coated drugs and possibly toxic ingestions of iron, lead, zinc, or packets of illicit drugs.

Inhalation and Dermal Exposure to Poisons. When a poison has been inhaled, the first priority is to remove the patient from the source of exposure. Similarly, if the skin has had contact with a poison, it should be washed thoroughly with water. Contaminated clothing should be removed. Initial treatment of all types of chemical injuries to the eye must be rapid; thorough irrigation of the eye with water for 15 minutes should be performed immediately.

Enhanced Elimination of the Poison

Biotransformation. Once a chemical has been absorbed, procedures sometimes can be employed to enhance its rate of elimination. Many drugs are metabolized by hepatic CYPs, and components of this system can be induced by a number of compounds (see Chapter 3). However, induction of these oxidative enzymes is too slow (days) to be valuable in the treatment of acute poisoning by most chemical agents.

Many chemicals are toxic because they are biotransformed into more toxic chemicals. Thus inhibition of biotransformation should decrease the toxicity of such drugs. For example, ethanol is used to inhibit the conversion of methanol to its highly toxic metabolite, formaldehyde, by alcohol dehydrogenase (see Chapter 22). Acetaminophen is converted by the CYP system to an electrophilic metabolite that is detoxified by glutathione, a cellular nucleophile (Figure 64–3). Acetaminophen does not cause hepatotoxicity until glutathione is depleted, whereupon the reactive metabolite binds to essential macromolecular constituents of the hepatocyte, resulting in cell death. The liver can be protected by maintenance of the concentration of glutathione, and this can be accomplished by the administration of N-acetylcysteine (see Chapter 26).

Some drugs are detoxified by conjugation with glucuronic acid or sulfate before elimination from the body, and the availability of the endogenous cosubstrates for conjugation may limit the rate of elimination; such is the case in the detoxification of acetaminophen. Methods to replete these compounds will provide an additional mechanism to treat poisoning. Similarly, detoxication of cyanide by conversion to thiocyanate can be accelerated by the administration of thiosulfate.

Biliary Excretion. The liver excretes many drugs and other foreign chemicals into bile, but little is known about efficient ways to enhance biliary excretion of xenobiotics for the treatment of acute poisoning. Inducers of microsomal enzyme activity enhance biliary excretion of some xenobiotics, but the effect is slow in onset.

Urinary Excretion. Drugs and poisons are excreted into the urine by glomerular filtration and active tubular secretion (see...
Chapter 28); they can be reabsorbed into the blood if they are in a lipid-soluble form that will penetrate the tubule or if there is an active mechanism for their transport.

There are no methods known to accelerate the active transport of poisons into urine, and enhancement of glomerular filtration is not a practical means to facilitate elimination of toxicants. However, passive reabsorption from the tubular lumen can be altered. Diuretics inhibit reabsorption by decreasing the concentration gradient of the drug from the lumen to the tubular cell and by increasing flow through the tubule. Furosemide is used most often, but osmotic diuretics also are employed (see Chapter 28). Forced diuresis should be used with caution, especially in patients with renal, cardiac, or pulmonary complications.

Nonionized compounds are reabsorbed far more rapidly than ionized polar molecules; therefore, a shift from the nonionized to the ionized species of the toxicant by alteration of the pH of the tubular fluid may hasten elimination (see Chapter 1). Acidic compounds such as phenobarbital and salicylates are cleared much more rapidly in alkaline than in acidic urine. In 2004, American and European clinical toxicologists issued a position paper on the use of urine alkalinization in treatment of acute poisoning (Proudfoot et al., 2004). Urine alkalinization increases the urine elimination of chlorpropamide, 2,4-dichlorophenoxyacetic acid, diflunisal, fluoride, mecoprop, methotrexate, phenobarbital, and salicylate. However, urine alkalinization is recommended as first-line treatment only for patients with moderately severe salicylate poisoning who do not meet the criteria for hemodialysis. Urine alkalinization and high urine flow (approximately 600 ml/h) should also be considered in patients with severe 2,4-dichlorophenoxyacetic acid and mecoprop poisoning. Even though it has been shown to be effective in enhancing elimination of phenobarbital (Figure 64–7), urine alkalinization is not recommended as first-line treatment in cases of phenobarbital poisoning because multiple-dose activated charcoal has been shown to be superior. Urine alkalinization is contraindicated in the case of compromised renal function or failure. Hypokalemia is the most common complication but can be corrected by giving potassium supplements.

Intravenous sodium bicarbonate is used to alkalinize the urine. Renal excretion of basic drugs such as amphetamine theoretically can be enhanced by acidification of the urine. Acidification can be accomplished by the administration of ammonium chloride or ascorbic acid. Urinary excretion of an acidic compound is particularly sensitive to changes in urinary pH if its pKₐ is within the range of 3.0 to 7.5; for bases, the corresponding range is 7.5 to 10.5.

**Dialysis.** Hemodialysis or hemoperfusion usually has limited use in the treatment of intoxication with chemicals. However, under certain circumstances, such procedures can be lifesaving. The utility of dialysis depends on the amount of poison in the blood relative to the total-body burden. Thus, if a poison has a large volume of distribution, as is the case for the tricyclic antidepressants, the plasma will contain too little of the compound for effective removal by dialysis. Extensive binding of the compound to plasma proteins impairs dialysis greatly. The elimination of a toxicant by dialysis also depends on dissociation of the compound from binding sites in tissues; for some chemicals, this rate may be slow and limiting.

Although peritoneal dialysis requires a minimum of personnel and can be started as soon as the patient is admitted to the hospital, it is too inefficient to be of value for the treatment of acute intoxications. Hemodialysis (extracorporeal dialysis) is much more effective than peritoneal dialysis and may be essential in a few life-threatening intoxications, such as with methanol, ethylene glycol, and salicylates.

Passage of blood through a column of charcoal or adsorbent resin (hemoperfusion) is a technique for the extracorporeal removal of a poison (Winchester, 1983). Because of the high adsorptive capacity and affinity of the material in the column, some chemicals that are bound to plasma proteins can be removed. The principal side effect of hemoperfusion is depletion of platelets.

**Antagonism or Chemical Inactivation of an Absorbed Poison.** The functional and pharmacological antagonism of the effects of absorbed toxicants was discussed earlier. If a patient is poisoned with a compound that acts as an agonist at a receptor for which a specific blocking agent is available, administration of the receptor antagonist may be highly effective. Functional antagonism also can
be valuable for support of the patient’s vital functions. For example, anticonvulsant drugs are used to treat chemically induced convulsions. However, drugs that stimulate antagonistic physiological mechanisms are not always of clinical value and may even decrease survival because it often is difficult to titrate the effect of one drug against another when the two act on opposing systems. An example of such a complication is the use of CNS stimulants to attempt to reverse respiratory depression. Convulsions are a typical complication of such therapy, and mechanical support of respiration is preferred. In addition, the duration of action of the poison and the antidote may differ, sometimes leading to poisoning with the antidote.

Specific chemical antagonists of a toxicant, such as opioid antagonists (see Chapter 21) and atropine as an antagonist of pesticide-induced acetylcholine excess (see Chapter 7), are valuable but unfortunately rare. A recently approved antagonist is fomepizole, an inhibitor of alcohol dehydrogenase, approved for treatment for poisoning by ethylene glycol and methanol (Barceloux et al., 1999; Myck and Leikin, 2003). Chelating agents with high selectivity for certain metal ions are used more commonly (see Chapter 65). Antibodies offer the potential for the production of specific antidotes for a host of common poisons and for drugs that frequently are abused or misused. A notable example of such success is the use of purified digoxin-specific Fab fragments of antibodies in the treatment of potentially fatal cases of poisoning with digoxin (see Chapter 33). The development of human monoclonal antibodies directed against specific toxins has significant potential therapeutic value.

### BIBLIOGRAPHY

### MONOGRAPHS AND REVIEWS

Ellenhorn, M.J. Ellenhorns Medical Toxicology. 2d ed. Williams & Wilkins, Baltimore, 1997.

People continue to be exposed to heavy metals in the environment. Metals contaminate water and food in some areas. Metals also leach from eating utensils and cookware. The emergence of the industrial age and large-scale mining brought occupational diseases caused by various toxic metals. Metallic constituents of pesticides and even therapeutic agents (e.g., antimicrobials) have been additional sources of hazardous exposure. The burning of fossil fuels containing heavy metals, the addition of tetraethyl lead to gasoline, and the increase in industrial applications of metals have made environmental pollution the major source of heavy-metal poisoning. The first part of this chapter covers the toxic properties of lead, mercury, arsenic, and cadmium, as well as radioactive heavy metals, and treatment of the consequences of toxic exposure to these metals. The second part of the chapter covers the chemical properties and therapeutic uses of several heavy-metal antagonists.

Heavy metals exert their toxic effects by combining with one or more reactive groups (ligands) essential for normal physiological functions. Heavy-metal antagonists (chelating agents) are designed specifically to compete with these groups for the metals and thereby prevent or reverse toxic effects and enhance the excretion of metals. Heavy metals, particularly those in the transition series, may react in the body with ligands containing oxygen (—OH, —COO−, —PO₄H₂, >C==O), sulfur (—SH, —S—S—), and nitrogen (—NH₂ and >NH). The resulting metal complex (or coordination compound) is formed by a coordinate bond in which both electrons are contributed by the ligand.

### THE IDEAL CHELATOR

The heavy-metal antagonists discussed in this chapter share the capacity to form complexes with heavy metals and thereby prevent or reverse the binding of metallic cations to body ligands. These drugs are referred to as chelating agents. A chelate is a complex formed between a metal and a compound that contains two or more potential ligands. The product of such a reaction is a heterocyclic ring. Five- and six-membered chelate rings are the most stable, and a polydentate (multiligand) chelator typically is designed to form such a highly stable complex, far more stable than when a metal is combined with only one ligand atom.

The stability of chelates varies with the metal and the ligand atoms. For example, lead and mercury have greater affinities for sulfur and nitrogen than for oxygen ligands; calcium, however, has a greater affinity for oxygen than for sulfur and nitrogen. These differences in affinity serve as the basis of selectivity of action of a chelating agent in the body.

The effectiveness of a chelating agent for the treatment of poisoning by a heavy metal depends on several factors, including the relative affinity of the chelator for the heavy metal as compared with essential body metals, the distribution of the chelator in the body as compared with the distribution of the metal, and the capacity of the chelator to mobilize the metal from the body once chelated.

An ideal chelating agent would have the following properties: high solubility in water, resistance to biotransformation, ability to reach sites of metal storage, capacity...
to form nontoxic complexes with toxic metals, ability to retain chelating activity at the pH of body fluids, and ready excretion of the chelate. A low affinity for Ca\(^{2+}\) also is desirable because Ca\(^{2+}\) in plasma is readily available for chelation, and a drug might produce hypocalcemia despite high affinity for heavy metals. The most important property of a therapeutic chelating agent is greater affinity for the metal than that of the endogenous ligands. The large number of ligands in the body is a formidable barrier to the effectiveness of a chelating agent. Observations in vitro on chelator–metal interactions provide only a rough guide to the treatment of heavy-metal poisoning. Empirical observations in vivo are necessary to determine the clinical utility of a chelating agent.

Lead

Through natural occurrence and its industrial use, lead is ubiquitous in the environment. The decreased addition of tetraethyl lead to gasoline over the past two decades has resulted in decreased concentrations of lead in blood in humans. The primary sources of environmental exposure to lead are leaded paint and drinking water; most of the overt toxicity from lead results from environmental and industrial exposures.

Acidic foods and beverages—including tomato juice, fruit juice, carbonated beverages, cider, and pickles—can dissolve the lead when packaged or stored in improperly glazed containers. Foods and beverages thus contaminated have caused fatal human lead poisoning. Lead poisoning in children is a common result of their ingestion of paint chips from old buildings. Paints applied to dwellings before World War II, when lead carbonate (white) and lead oxide (red) were common constituents of interior and exterior house paints, are primarily responsible. In such paint, lead may constitute 5% to 40% of dried solids. Young children are poisoned most often by nibbling sweet-tasting paint chips and dust from lead-painted window sills and do or frames. The American Standards Association specified in 1955 that paints for toys, furniture, and the interior of dwellings should not contain more than 1% lead in the final dried solids of fresh paint, and in 1978, the Consumer Product Safety Commission (CPSC) banned paint containing more than 0.06% lead for use in and around households. Renovation or demolition of older homes, using a physical process that would cause an airborne dispersion of lead dust or fumes, may cause substantial contamination and lead poisoning. Lead poisoning from the use of discarded automobile-battery casings made of wood and vulcanite and used as fuel during times of economic distress, such as during World Wars I and II, has been reported. Sporadic cases of lead poisoning have been traced to miscellaneous sources such as lead toys, retained bullets, drinking water that is conveyed through lead pipes, artists’ paint pigments, ashes and fumes of painted wood, jewelers’ wastes, home battery manufacture, and lead type. Finally, lead also is a common contaminant of illicitly distilled whiskey (“moonshine”) because automobile radiators frequently are used as condensers and other components of the still are connected by lead solder.

Occupational exposure to lead has decreased markedly because of appropriate regulations and programs of medical surveillance. Workers in lead smelters have the highest potential for exposure because fumes are generated, and dust containing lead oxide is deposited in their environment. Workers in storage-battery factories face similar risks.

Dietary intake of lead also has decreased since the 1940s, when the estimate of intake was about 500 μg/day in the U.S. population, to less than 20 μg/day in 2000. This decrease has been due largely to (1) a decrease in the use of lead-soldered cans for food and beverages; (2) a decrease in the use of lead pipes and lead-soldered joints in water distribution systems; (3) the introduction of lead-free gasoline; and (4) public awareness of the hazards of indoor leaded paint (NRC, 1993). A decline in blood levels from 13 μg/dl in the 1980s to less than 5 μg/dl has been observed in the general U.S. population (Pirkle et al., 1998). However, many children living in central portions of large cities still have blood lead concentrations over 10 μg/dl.

Absorption, Distribution, and Excretion. The major routes of absorption of lead are from the gastrointestinal (GI) tract and the respiratory system. GI absorption of lead varies with age; adults absorb approximately 10% of ingested lead, whereas children absorb up to 40%. Little is known about lead transport across the GI mucosa; lead and Ca\(^{2+}\) may compete for a common transport mechanism because there is a reciprocal relationship between the dietary content of Ca\(^{2+}\) and lead absorption. Iron deficiency also enhances intestinal absorption of lead apparently because in the absence of iron, the divalent metal transporter (DMT) can readily transport lead in place of iron. Absorption of inhaled lead varies with the form (vapor versus particle) as well as with concentration. Approximately 90% of inhaled lead particles from ambient air are absorbed (Goyer and Clarkson, 2001).

After absorption, about 99% of lead in the bloodstream binds to hemoglobin in erythrocytes. Only 1% to 3% of the circulating blood lead is in the serum available to the tissues. Inorganic lead initially distributes in the soft tissues, particularly the tubular epithelium of the kidney and in the liver. In time, lead is redistributed and deposited in bone, teeth, and hair. About 95% of the body burden of lead eventually is found in bone. Only small quantities of inorganic lead accumulate in the brain, mostly in gray matter and the basal ganglia.

The deposition of Pb\(^{2+}\) in bone closely resembles that of Ca\(^{2+}\), but Pb\(^{2+}\) is deposited as tertiary lead phosphate, which does not contribute to toxicity. After a recent exposure, the concentration of lead often is higher in the flat bones than in the long bones, although, as a general rule, the long bones contain more lead. In the early period of deposition, the concentration of lead is highest in the epiphyseal portion of the long bones. This is especially true in growing bones, where deposits may be detected by radiography as rings of increased density in the ossification centers of the epiphyseal cartilage and as a series of transverse lines in the diaphyses, so-called lead lines. Such findings are of diagnostic significance in children.

Factors that affect the distribution of calcium similarly affect that of lead. Thus a high intake of phosphate favors skeletal storage of lead and a lower concentration in soft tissues. Conversely, a low phosphate intake mobilizes lead in bone and elevates its content in soft tissues. High intake of calcium in the absence of elevated intake of phosphate has a similar effect owing to competition with lead for available phosphate. Vitamin D tends to promote lead deposition in bone if sufficient phosphate is available; otherwise, Ca\(^{2+}\) deposition preempts that of Pb\(^{2+}\). Parathyroid hormone mobilizes lead from the
Chapter 65  /  Heavy Metals and Heavy-Metal Antagonists  1755

skeleton and augments the concentration of lead in blood and the rate of its excretion in urine.

In experimental animals, lead is excreted in bile, and much more lead is excreted in feces than in urine, whereas urinary excretion is a more important route of excretion in humans (Kehoe, 1987). The concentration of lead in urine is directly proportional to that in plasma, but because most lead in blood is in the erythrocytes, only a small quantity of lead is filtered. Lead also is excreted in milk and sweat and is deposited in hair and nails. Placental transfer of lead also occurs.

The half-life of lead in blood is 1 to 2 months, and a steady state thus is achieved in about 6 months. After establishment of a steady state early in human life, the daily intake of lead normally approximates the output, and concentrations of lead in soft tissues are relatively constant. However, the concentration of lead in bone apparently increases, and its half-life in bone is estimated to be 20 to 30 years. Because the capacity for lead excretion is limited, even a slight increase in daily intake may produce a positive lead balance. The average daily intake of lead is approximately 0.2 mg; positive lead balance begins at a daily intake of about 0.6 mg, an amount that ordinarily will not produce overt toxicity within a lifetime. However, the time to accumulate toxic amounts disproportionately as the amount ingested increases. For example, a daily intake of 2.5 mg lead requires nearly 4 years for the accumulation of a toxic burden, whereas a daily intake of 3.5 mg requires but a few months because deposition in bone is too slow to protect the soft tissues during rapid accumulation.

Acute Lead Poisoning. Acute lead poisoning is relatively infrequent and follows ingestion of acid-soluble lead compounds or inhalation of lead vapors. Local actions in the mouth produce marked astrin-gency, thirst, and a metallic taste. Nausea, abdominal pain, and vomiting ensue. The vomitus may be milky from the presence of lead chloride. Although the abdominal pain is severe, it is unlike that of chronic poisoning. Stools may be black from lead sulfide, and there may be diarrhea or constipation. If large amounts of lead are absorbed rapidly, a shock syndrome may develop as the result of massive GI loss of fluid. Acute central nervous system (CNS) symp-toms include paresthesias, pain, and muscle weakness. An acute hemolytic crisis sometimes causes severe anemia and hemoglobin-uria. The kidneys are damaged, and oliguria and urinary changes are evident. Death may occur in 1 or 2 days. If the patient survives the acute episode, characteristic signs and symptoms of chronic lead poisoning are likely to appear.

Chronic Lead Poisoning. The medical term for lead poisoning is plumbism, after the Latin word for lead, plumbum. The chemical symbol for lead, Pb, also is derived from this Latin root, as is the modern word plumber, which reflects the significant prior use of metallic lead in pipes, fixtures, and gutters. Signs and symptoms of plumbism can be divided into six categories: GI, neuromuscular, CNS, hematological, renal, and other. They may occur separately or in combination. The neuromuscular and CNS syndromes usually result from intense exposure, whereas the GI syndrome more commonly reflects a very slowly and insidiously developing intoxication. The CNS syndrome is more common among children, whereas the GI syndrome is more prevalent in adults.

Gastrointestinal Effects. Lead affects the smooth muscle of the gut, producing intestinal symptoms that are an important early sign of exposure to the metal. The abdominal syndrome often begins with vague symptoms, such as anorexia, muscle discomfort, malaise, and headache. Constipation usually is an early sign, especially in adults, but diarrhea occurs occasionally. A persistent metallic taste appears early in the course of the syndrome. As intoxication advances, anorexia and constipation become more marked. Intestinal spasm, which causes severe abdominal pain (lead colic), is the most distressing feature of the advanced abdominal syndrome. The attacks are paroxysmal and generally excruciating. The abdominal muscles become rigid, and tenderness is especially manifested in the region of the umbilicus. In cases where colic is not severe, removal of the patient from the environment of exposure may be sufficient for relief of symptoms. Calcium gluconate administered intrave-nously is recommended for relief of pain and usually is more effective than morphine.

Neuromuscular Effects. The neuromuscular syndrome (lead palsy) occurs with repeated lead exposure, as characterized by the house painter and other workers with excessive occupational exposure to lead more than a half century ago; it now is rare in the United States. Muscle weakness and easy fatigue occur long before actual paralysis and may be the only symptoms. Weakness or palsy may not become evident until after extended muscle activity. The muscle groups involved usually are the most active ones (extensors of the forearm, wrist, and fingers and extraocular muscles). Wrist drop and, to a lesser extent, foot drop with the appropriate history of exposure are almost pathognomonic for lead poisoning. There usually is no sensory involvement. Degenerative changes in the moto-neurons and their axons have been described.

CNS Effects. The CNS syndrome, or lead encephalopathy, is the most serious manifestation of lead poisoning and is much more common in children than in adults. The early signs of the syndrome include clumsiness, vertigo, ataxia, falling, headache, insomnia, restlessness, and irritability. As the encephalopathy develops, the patient may first become excited and confused; delirium with repetitive tonic-clonic convulsions or lethargy and coma follow. Vomiting, a common sign, usually is projectile. Visual disturbances also are present. Although the signs and symptoms are characteristic of increased intracranial pressure, craniotomy to relieve intracranial pressure is not beneficial. However, treatment for cerebral edema may become necessary. There may be a proliferative meningitis, intense edema, punctate hemorrhages, gliosis, and areas of focal necrosis. Demyelination has been observed in nonhuman primates. The mortality rate among patients who develop cerebral involvement is about 25%. When chelation therapy is begun after the symp-toms of acute encephalopathy appear, approximately 40% of survivors have neurological sequelae such as mental retardation, electroencephalographic abnormalities or frank seizures, cerebral palsy, optic atrophy, or dystonia musculorum deformans (Chisolm and Barltrop, 1979).

Exposure to lead occasionally produces clear-cut progressive mental deterioration in children. The history of these children indicates normal development during the first 12 to 18 months of life or longer, followed by a steady loss of motor skills and speech. They may have severe hyperkinetic and aggressive behavior disorders and a poorly controllable convulsive disorder. The lack of
sensory perception severely impairs learning. Concentrations of lead in whole blood exceed 60 μg/dl (2.9 μM), and X-rays may show multiple heavy bands of increased density in the growing long bones. It once was thought that such exposure to lead was restricted largely to children in inner-city slums. However, all children are exposed chronically to low levels of lead in their diets, in the air they breathe, and in the dirt and dust in their play areas. This is reflected in elevated concentrations of lead in the blood of many children and may be a cause of subtle CNS toxicity, including learning disabilities, lowered IQ, and behavioral abnormalities. An increased incidence of hyperkinetic behavior and a statistically significant, although modest, decrease in IQ have been shown in children with higher blood lead concentrations (Needleman et al., 1990; Baghurst et al., 1992; Banks et al., 1997; Bellinger et al., 1992). Increased blood lead levels in infancy and early childhood later may be manifested as decreased attention span, reading disabilities, and failure to graduate from high school. Most studies report a 2- to 4-point IQ deficit for each microgram per deciliter increase in blood lead within the range of 5 to 35 μg/dl. As a result, the Centers for Disease Control and Prevention (CDC) considers a blood lead concentration of 10 μg/dl or greater to indicate excessive absorption of lead in children and to constitute grounds for environmental assessment, cleanup, and/or intervention. Chelation therapy should be considered when blood lead concentrations exceed 25 μg/dl. The CDC recommends universal screening of children beginning at 6 months of age.

**Hematological Effects.** When the blood lead concentration is near 80 μg/dl or greater, basophilic stippling occurs in erythrocytes; this is not pathognomonic of lead poisoning.

A more common hematological manifestation of chronic lead intoxication is a hypochromic microcytic anemia, which is observed more frequently in children and is morphologically similar to that resulting from iron deficiency. The anemia is thought to result from two factors: a decreased life span of the erythrocytes and an inhibition of heme synthesis.

Very low concentrations of lead influence the synthesis of heme. The enzymes necessary for heme synthesis are distributed widely in mammalian tissues, and each cell probably synthesizes its own heme for incorporation into such proteins as hemoglobin, myoglobin, cytochromes, and catalases. Lead inhibits heme formation at several points, as shown in Figure 65–1. Inhibition of δ-aminolevulinate (δ-ALA) dehydratase and ferrochelatase, which are sulfhydryl-dependent enzymes, is well documented. Ferrochelatase is the enzyme responsible for incorporating the ferrous ion into protoporphyrin to form heme. When ferrochelatase is inhibited by lead, excess protoporphyrin takes the place of heme in the hemoglobin molecule. Zinc is incorporated into the protoporphyrin molecule, resulting in the formation of zinc-protoporphyrin, which is intensely fluorescent and may be used to diagnose lead toxicity. Lead poisoning in both humans and experimental animals is characterized by accumulation of protoporphyrin IX and nonheme iron in red blood cells, by accumulation of δ-ALA in plasma, and by increased urinary excretion of δ-ALA. There also is increased urinary excretion of coproporphyrin III (the oxidation product of coproporphyrinogen III), but it is not clear whether this is due to inhibition of enzymatic activity or to other factors. Increased excretion of porphobilinogen and uroporphyrin has been reported only in severe cases. The pattern of excretion of pyrroles in lead poisoning differs from that characteristic of symptomatic episodes of acute intermittent porphyria and other hepatocellular disorders (Table 65–1). The increase in δ-ALA synthase activity is due to reduction of the cellular concentra-

---

**Figure 65–1.** Lead interferes with the biosynthesis of heme at several enzymatic steps. Steps that definitely are inhibited by lead are indicated by blue blocks. Steps at which lead is thought to act but where evidence for this is inconclusive are indicated by gray blocks.

tion of heme, which regulates the synthesis of δ-ALA synthase by feedback inhibition.

Measurement of heme precursors provides a sensitive index of recent absorption of inorganic lead salts. δ-ALA dehydratase activity in hemolysates and δ-ALA in urine are sensitive indicators of exposure to lead but are not as sensitive as quantification of blood lead concentrations.

**Renal Effects.** Although less dramatic than those in the CNS and GI tract, renal effects do occur. Renal toxicity occurs in two forms: a reversible tubular disorder (usually seen after acute exposure of children to lead) and an irreversible interstitial nephropathy (observed more commonly in long-term industrial lead exposure) (Goyer and Clarkson, 2001). Clinically, a Fanconi-like syndrome is seen with proteinuria, hematuria, and casts in the urine (Craswell, 1987; Bernard and Becker, 1988). Hyperuricemia with gout occurs more frequently in the presence of chronic lead nephropathy than in any other type of chronic renal disease. Histologically, lead nephropathy is revealed by characteristic nuclear inclusion bodies composed of a lead–protein complex; they appear early and resolve after chelation therapy. Such inclusion bodies have been reported in the urine sediment of workers exposed to lead in an industrial setting (Schumann et al., 1980).

**Other Effects.** Other signs and symptoms of lead poisoning are an ashen color of the face and pallor of the lips; retinal stippling; appearance of “premature aging,” with stooped posture, poor muscle tone, and emaciation; and a black, grayish, or blue-black “lead line” along the gingival margin. The lead line, a result of periodontal deposition of lead sulfide, may be removed by good dental hygiene. Similar pigmentation may result from the absorption of mercury, bismuth, silver, thallium, or iron. There is a relationship between the concentration of lead in blood and blood pressure, and it has been suggested that this may be due to subtle changes in calcium metabolism or renal function (Staessen, 1995). Lead also interferes with vitamin D metabolism (Rosen et al., 1980; Mahaffey et al., 1982). A decreased sperm count in lead-exposed males has been described (Lerda, 1992). The human carcinogenicity of lead is not well established but has been suggested (Cooper and Gaffey, 1975), and case reports of renal adenocarcinoma in lead workers have been published.

**Diagnosis of Lead Poisoning.** In the absence of a positive history of abnormal exposure to lead, the diagnosis of lead poisoning is missed easily because the signs and symptoms of lead poisoning are shared by other diseases. For example, the signs of encephalopathy may resemble those of various degenerative conditions. Physical examination does not easily distinguish lead colic from other abdominal disorders. Clinical suspicion should be confirmed by determinations of the concentration of lead in blood and protoporphyrin in erythrocytes. As noted earlier, lead at low concentrations decreases heme synthesis at several enzymatic steps. This leads to buildup of the diagnostically important substrates δ-ALA, coproporphyrin (both measured in urine), and zinc protoporphyrin (measured in the red cell as erythrocyte protoporphyrin). For children, the erythrocyte protoporphyrin level is insufficiently sensitive to identify children with elevated blood lead levels below about 25 μg/dl, and the screening test of choice is blood lead measurement.

Since lead has been removed from paints and gasoline, the mean blood levels of lead in children in the United States have decreased from 17 μg/dl in the 1970s to 6 μg/dl in the 1990s (Schoen, 1993). The concentration of lead in blood is an indication of recent absorption of the metal (Figure 65–2). Children with concentrations of lead in blood above 10 μg/dl are at risk of developmental disabilities. Adults with concentrations below 30 μg/dl exhibit no known functional injury or symptoms; however, they will have a definite decrease in δ-ALA dehydratase activity, a slight increase in urinary excretion of δ-ALA, and an increase in erythrocyte protoporphyrin. Patients with a blood lead concentration of 30 to 75 μg/dl have all

**Figure 65–2.** Manifestations of lead toxicity associated with varying concentrations of lead in blood of children and adults. δ-ALA = δ-aminolevulinate.
the preceding laboratory abnormalities and, usually, nonspecific, mild symptoms of lead poisoning. Clear symptoms of lead poisoning are associated with concentrations that exceed 75 μg/dl of whole blood, and lead encephalopathy usually is apparent when lead concentrations are greater than 100 μg/dl. In persons with moderate-to-severe anemia, interpretation of the significance of concentrations of lead in blood is improved by correcting the observed value to approximate that which would be expected if the patient’s hematocrit were within the normal range.

The urinary concentration of lead in normal adults generally is less than 80 μg/L (0.4 μM). Most patients with lead poisoning show concentrations of lead in urine of 150 to 300 μg/L (0.7 to 1.4 μM). However, in persons with chronic lead nephropathy or other forms of renal insufficiency, urinary excretion of lead may be within the normal range, even though blood lead concentrations are significantly elevated.

Because the onset of lead poisoning usually is insidious, it often is desirable to estimate the body burden of lead in individuals who are exposed to an environment that is contaminated with the metal. In the past, the edetate calcium disodium (CaNa₂EDTA) provocation test was used to determine whether there is an increased body burden of lead in those for whom exposure occurred much earlier. The provocation test is performed by intravenous administration of a single dose of CaNa₂EDTA (50 mg/kg), and urine is collected for 8 hours. The test is positive for children when the lead excretion ratio (micrograms of lead excreted in the urine per milligram of CaNa₂EDTA administered) is greater than 0.6; it also may be useful for therapeutic chelation in children with blood levels of 25 to 45 μg/dl. This test is not used in symptomatic patients or in those whose concentration of lead in blood is greater than 45 μg/dl because these patients require the proper therapeutic regimen with chelating agents (see below). Neutron activation analysis or fluorometric assays, available only as research methods, may offer a unique in vivo approach to the diagnosis of lead burden in the future.

**Organic Lead Poisoning.** Tetraethyl lead and tetramethyl lead are lipid-soluble compounds that are absorbed readily from the skin, GI tract, and lungs. The toxicity of tetraethyl lead is believed to be due to its metabolic conversion to triethyl lead and inorganic lead.

The major symptoms of intoxication with tetraethyl lead are referable to the CNS: insomnia, nightmares, anorexia, nausea and vomiting, diarrhea, headache, muscular weakness, and emotional instability (Seshia et al., 1978). Subjective CNS symptoms such as irritability, restlessness, and anxiety are next evident, usually accompanied by hypothermia, bradycardia, and hypotension. With continued exposure, or in the case of intense short-term exposure, CNS manifestations progress to delusions, ataxia, exaggerated muscular movements, and finally, a maniacal state.

The diagnosis of poisoning by tetraethyl lead is established by relating these signs and symptoms to a history of exposure. The urinary excretion of lead may increase markedly, but the concentration of lead in blood remains nearly normal. Anemia and basophilic stippling of erythrocytes are uncommon in organic lead poisoning. There is little effect on the metabolism of porphyrins, and erythrocyte protoporphyrin concentrations are inconsistently elevated (Garrettson, 1983). In the case of severe exposure, death may occur within a few hours or may be delayed for several weeks. If the patient survives the acute phase of organic lead poisoning, recovery usually is complete; however, instances of residual CNS damage have been reported.

**Treatment of Lead Poisoning.** Initial treatment of the acute phase of lead intoxication involves supportive measures. Prevention of further exposure is important. Seizures are treated with diazepam or phenytoin (see Chapter 19), fluid and electrolyte balances must be maintained, and cerebral edema is treated with mannitol and dexamethasone or controlled hyperventilation. The concentration of lead in blood should be determined or at least a blood sample obtained for analysis prior to initiation of chelation therapy.

Chelation therapy is indicated in symptomatic patients or in patients with a blood lead concentration in excess of 50 to 60 μg/dl (about 2.5 μM). Four chelators are employed: edetate calcium disodium (CaNa₂EDTA), dimercaprol [British antilewisite (BAL)], D-penicillamine, and succimer [2,3-dimercaptosuccinic acid (DMSA), CHEMET]. CaNa₂EDTA and dimercaprol usually are used in combination for lead encephalopathy.

CaNa₂EDTA. CaNa₂EDTA is initiated at a dose of 30 to 50 mg/kg per day in two divided doses either by deep intramuscular injection or slow intravenous infusion for up to 5 consecutive days. The first dose of CaNa₂EDTA should be delayed until 4 hours after the first dose of dimercaprol. An additional course of CaNa₂EDTA may be given after an interruption of 2 days. Each course of therapy with CaNa₂EDTA should not exceed a total dose of 500 mg/kg. Urine output must be monitored because the chelator–lead complex is believed to be nephrotoxic. Treatment with CaNa₂EDTA can alleviate symptoms quickly. Colic may disappear within 2 hours; paresis and tremor cease after 4 or 5 days; and coproporphyrinuria, stippled erythrocytes, and gingival lead lines tend to decrease in 4 to 9 days. Urinary elimination of lead usually is greatest during the initial infusion.

Dimercaprol. Dimercaprol is given intramuscularly at a dose of 4 mg/kg every 4 hours for 48 hours, then every 6 hours for 48 hours, and finally, every 6 to 12 hours for an additional 7 days. The combination of dimercaprol and CaNa₂EDTA is more effective than either chelator alone (Chisolm, 1973).

D-Penicillamine. In contrast to CaNa₂EDTA and dimercaprol, penicillamine is effective orally and may be included in the regimen at a dosage of 250 mg given four times daily for 5 days. During chronic therapy with penicillamine, the dose should not exceed 40 mg/kg per day.

Succimer. Succimer is the first orally active lead chelator available for children, with a safety and efficacy profile that surpasses that of D-penicillamine. Succimer usually is given every 8 hours (10 mg/kg) for 5 days and then every 12 hours for an additional 2 weeks.

**General Principles.** In any chelation regimen, the blood lead concentration should be reassessed 2 weeks after the regimen has been completed; an additional course of therapy may be indicated if blood lead concentrations rebound.

Treatment of organic lead poisoning is symptomatic. Chelation therapy will promote excretion of the inorganic lead produced from the metabolism of organic lead, but the increase is not dramatic.

**Mercury**

Mercury was an important constituent of drugs for centuries as an ingredient in many diuretics, antibacterials, anti-septics, skin ointments, and laxatives. More specific, effective, and safer modes of therapy now have replaced the mercurials, and drug-induced mercury poisoning has become rare. However, mercury has a number of impor-
tant industrial uses (Table 65–2), and poisoning from occupational exposure and environmental pollution continues to be an area of concern. There have been epidemics of mercury poisoning among wildlife and human populations in many countries. With very few exceptions and for numerous reasons, such outbreaks were misdiagnosed for months or even years. Reasons for these tragic delays included the insidious onset of the affliction, vagueness of early clinical signs, and the medical profession’s unfamiliarity with the disease (Gerstner and Huff, 1977).

**Chemical Forms and Sources of Mercury.** With regard to the toxicity of mercury, three major chemical forms of the metal must be distinguished: mercury vapor (elemental mercury), salts of mercury, and organic mercurials. Table 65–3 indicates the estimated daily retention of various forms of mercury from various sources.

Elemental mercury is the most volatile of the metal’s inorganic forms. Human exposure to mercury vapor is mainly occupational. Extraction of gold with mercury and then heating the amalgam to drive off the mercury is a technique that has been used extensively by gold miners and still is used today in some developing countries. Chronic exposure to mercury in ambient air after inadvertent mercury spills in poorly ventilated rooms, often scientific laboratories, can produce toxic effects. Mercury vapor also can be released from silver-amalgam dental restorations. In fact, this is the main source of mercury exposure to the general population, but the amount of mercury released does not appear to be of significance for human health (Eley and Cox, 1993) except for allergic contact eczema seen in a few individuals.

Salts of mercury exist in two states of oxidation—as monovalent mercurous salts or as divalent mercuric salts. Mercurous chloride (Hg₂Cl₂), or calomel, the best-known mercurous compound, was used in some skin creams as an antiseptic and was employed as a diuretic and cathartic. Mercuric salts are the more irritating and acutely toxic form of the metal. Mercuric nitrate was a common industrial hazard in the felt-hat industry more than 400 years ago. Occupational exposure produced neurological and behavioral changes depicted by the Mad Hatter in Lewis Carroll’s *Alice’s Adventures in Wonderland*. Mercuric chloride (Hg₂Cl₂), once a widely used antiseptic, also was used commonly for suicidal purposes. Mercuric salts still are employed widely in industry, and industrial discharge into rivers has introduced mercury into the environment in many parts of the world. The main industrial uses of inorganic mercury today are in chloralkali production and in electronics. Other uses of the metal include the manufacturing of plastics, fungicides, and germicides and the formulation of amalgams in dentistry.

The organomercurials in use today contain mercury with one covalent bond to a carbon atom. Members of this heterogeneous group of compounds have varying abilities to produce toxic effects. The alkylmercury salts are by far the most dangerous of these compounds; methylmercury is the most common. Alkylmercury salts have been used widely as fungicides and have produced toxic effects in humans. Major incidents of human poisoning from the inadvertent consumption of mercury-treated seed grain have occurred in Iraq, Pakistan, Ghana, and Guatemala. The most catastrophic outbreak occurred in Iraq in 1972. During the fall of 1971, Iraq imported large quantities of seed (wheat and barley) treated with methylmercury and distributed the grain for spring planting. Despite official warnings, the grain was ground into flour and made into bread. As a result, 6530 victims were hospitalized, and 500 died (Bakir et al., 1973, 1980).

</table>
Minamata disease also was due to methylmercury. In the Japanese town of Minamata, the major industry was a chemical plant that emptied its effluent directly into Minamata Bay. The chemical plant used inorganic mercury as a catalyst, and some of it was methylated before it entered the bay. In addition, microorganisms can convert inorganic mercury to methylmercury; the compound then is taken up rapidly by plankton algae and is concentrated in fish via the food chain. Residents of Minamata who consumed fish as a large portion of their diet were the first to be poisoned. Eventually, 121 persons were poisoned, and 46 died (McAlpine and Araki, 1958; Smith and Smith, 1975; Tamashiro et al., 1985). In the United States, human poisonings have resulted from ingestion of meat from pigs fed grain treated with an organomercurial fungicide. Because of concerns about methylmercury accumulation in fish, the Food and Drug Administration (FDA) recommends that pregnant or nursing women, women of childbearing age, and young children avoid eating large fish (e.g., shark, swordfish, king mackerel, and tilefish) and limit their intake of albacore tuna to 6 ounces per week.

In other instances, exposure to mercury was intentional. For example, thimerosal (CH$_3$CH$_2$—Hg—S—C$_6$H$_4$—COOH) has been used as an antibacterial additive to biologics and vaccines since the 1930s. However, concerns about the possibility of health risks from thimerosal in vaccines have been debated, especially the possibility that the ethylmercury thiosalicylate preservative in hepatitis B immunoglobulin (HBIG) could release ethylmercury and cause severe mercury intoxication (Lowell et al., 1996; Ball et al., 2001). These concerns were based on the assumption that ethylmercury, for which there is limited toxicologic information, is toxicologically similar to its close chemical relative, methyl mercury (CH$_3$—Hg$^+$), about which much is known (Clarkson, 2002).

A study by the FDA determined that there is a significant safety margin incorporated into all the acceptable mercury exposure limits. Furthermore, there are no data or evidence of any harm caused by the level of exposure that some children may have encountered in following the existing immunization schedule. Nevertheless, the availability of vaccines with alternate preservatives led to a statement calling for removal of all vaccines containing thimerosal (Joint Statement of the American Academy of Pediatrics and the United States Public Health Service, 1999; Ball et al., 2001). This practice remains in place today, even though subsequent studies have failed to demonstrate any health risk associated with vaccines containing thimerosal (Verstraeten et al., 2003; Heron et al., 2004).

Chemistry and Mechanism of Action. Mercury readily forms covalent bonds with sulfur, and it is this property that accounts for most of the biological properties of the metal. When the sulfur is in the form of sulfhydryl groups, divalent mercury replaces the hydrogen atom to form mercaptides, X—Hg—SR and Hg(SR)$_2$, where X is an electronegative radical and R is protein. Organic mercurials form mercaptides of the type R—Hg—SR'. Even in low concentrations, mercurials are capable of inactivating sulfhydryl groups of enzymes and thus interfering with cellular metabolism and function. The affinity of mercury for thiols provides the basis for treatment of mercury poisoning with such agents as dimercaprol and penicillamine. Mercury also combines with phosphoryl, carboxyl, amide, and amine groups.

Absorption, Biotransformation, Distribution, and Excretion. Elemental Mercury. Elemental mercury is not particularly toxic when ingested because of very low absorption from the GI tract; this is due to the formation of droplets and because the metal in this form cannot react with biologically important molecules. However, inhaled mercury vapor is completely absorbed by the lung and then is oxidized to the divalent mercuric cation by catalase in the erythrocytes (Magos et al., 1978). Within a few hours, the deposition of inhaled mercury vapor resembles that after ingestion of mercuric salts, with one important difference: Because mercury vapor crosses membranes much more readily than does divalent mercury, a significant amount of the vapor enters the brain before it is oxidized. CNS toxicity is thus more prominent after exposure to mercury vapor than to divalent forms of the metal.

Inorganic Salts of Mercury. The soluble inorganic mercuric salts (Hg$^{2+}$) gain access to the circulation when taken orally. GI absorption is approximately 10% to 15% of that ingested, and a considerable portion of the Hg$^{2+}$ may remain bound to the alimentary mucosa and the intestinal contents. Insoluble inorganic mercurous compounds, such as calomel (Hg$_2$Cl$_2$), may undergo some oxidation to soluble compounds that are more readily absorbed. Inorganic mercury has a markedly nonuniform distribution after absorption. The highest concentration of Hg$^{2+}$ is found in the kidneys, where the metal is retained longer than in other tissues. Concentrations of inorganic mercury are similar in whole blood and plasma. Inorganic mercurials do not readily pass across the blood–brain barrier or the placenta. The metal is excreted in the urine and feces with a half-life of about 60 days (Friberg and Vostal, 1972); studies in laboratory animals indicate that fecal excretion is quantitatively more important (Klaassen, 1975).

Organic Mercurials. Organic mercurials are absorbed more completely from the GI tract than are the inorganic salts because they are more lipid soluble and less corrosive to the intestinal mucosa. Their uptake and distribution are depicted in Figure 65–3A. More than 90% of methylmercury is absorbed from the human GI tract. The organic mercurials cross the blood–brain barrier and the placenta and thus produce more neurological and teratogenic effects than do the inorganic salts. Methylmercury combines with cysteine to form a structure similar to methionine, and the complex is transported by the large neutral amino acid carrier present in capillary endothelial cells (Clarkson, 1987) (Figure 65–3B). Organic mercurials are distributed more uniformly to the various tissues than are the inorganic salts (Klaassen, 1975). A significant portion of the body burden of organic mercurials is in the red blood cells. The ratio of the concentration of organomercurial in erythrocytes to that in plasma varies with the compound; for methylmercury, it approximates 20:1 (Kershaw et al., 1980). Mercury concentrates in hair because of its high sulfhydryl content. The carbon–mercury bond of some organic mercurials is cleaved after absorption; with methylmercury, the cleavage is quite slow, and the inorganic mercury formed is not thought to play a major role in methylmercury toxicity. Aryl mercurials, such as merculphen, usually contain a labile mercury–carbon bond; their toxicity is similar to that of inorganic mercury. Methylmercury in humans is excreted mainly in the feces in the form of a glutathione conjugate; less than 10% of a dose appears in urine (Bakir et al., 1980). The half-life of methylmercury in the blood of humans is between 40 and 105 days (Bakir et al., 1973).

Toxicity. Elemental Mercury. Short-term exposure to the vapor of elemental mercury may produce symptoms within several hours, including weakness, chills, metallic taste, nausea, vomiting, diarrhea, dyspnea, cough, and a feeling of tightness in the chest. Pulmonary toxicity may progress to an interstitial pneumonitis with severe compromise of respiratory function. Recovery, although usually complete, may be complicated by residual interstitial fibrosis.
D. Inorganic Salts of Mercury. Inorganic ionic mercury (e.g., mercuric chloride) can produce severe acute toxicity. Precipitation of mucous membrane proteins by mercuric salts results in an ashen-gray appearance of the mucosa of the mouth, pharynx, and intestine and also causes intense pain, which may be accompanied by vomiting. The vomiting is perceived to be protective because it removes unabsorbed mercury from the stomach; assuming that the patient is awake and alert, vomiting should not be inhibited. The local corrosive effect of ionic inorganic mercury on the GI mucosa results in severe hematochezia with evidence of mucosal sloughing in the stool. Hypovolemic shock and death can occur in the absence of proper treatment, which can overcome the local effects of inorganic mercury.

Systemic toxicity may begin within a few hours of exposure to mercury and last for days. A strong metallic taste is followed by stomatitis with gingival irritation, foul breath, and loosening of the teeth. The most serious and frequent systemic effect of inorganic mercury is renal toxicity. Acute tubular necrosis occurs after short-term exposure, leading to oliguria or anuria. Renal injury also follows long-term exposure to inorganic mercury, where glomerular injury predominates. This results from direct effects on the glomerular basement membrane and later indirect effects mediated by immune complexes (Goyer and Clarkson, 2001).

The symptom complex of acrodynia (pink disease) also commonly follows chronic exposure to inorganic mercury ions. Acrodynia is an erythema of the extremities, chest, and face with photosensitivity; fever, chills, and loosening of the teeth. The most serious and frequent systemic effect of inorganic mercury is renal toxicity. Acute tubular necrosis occurs after short-term exposure, leading to oliguria or anuria. Renal injury also follows long-term exposure to inorganic mercury, where glomerular injury predominates. This results from direct effects on the glomerular basement membrane and later indirect effects mediated by immune complexes (Goyer and Clarkson, 2001).

Chapter 65  /  Heavy Metals and Heavy-Metal Antagonists

Figure 65–3. Uptake and relative distribution of organic mercurials. A. The intestinal uptake and subsequent distribution of organic mercurials, such as methylmercury, throughout the body. a. Conjugation with glutathione (GSH), shown as CH₃—Hg—SG. b. Secretion of conjugate into bile. c. Reabsorption in gallbladder. d. Remaining Hg enters intestinal tract. B. Uptake of the methylmercury complex by capillaries. The ability of organic mercurials to cross the blood–brain barrier and the placenta contributes to their greater neurological and teratogenic effects when compared with inorganic mercury salts. Note the structural similarity of the methylmercury complex to methionine, CH₃SCH₂CH₂—CH(NH₃⁺)COO⁻.

Chronic exposure to mercury vapor produces a more insidious form of toxicity that is dominated by neurological effects (Friberg and Vostal, 1972). The syndrome, termed the asthenic vegetative syndrome, consists of neurasthenic symptoms in addition to three or more of the following findings: goiter, increased uptake of radioiodine by the thyroid, tachycardia, labile pulse, gingivitis, demyelination, and increased mercury in the urine (Goyer and Clarkson, 2001). With continued exposure to mercury vapor, tremor becomes noticeable, and psychological changes consist of depression, irritability, excessive shyness, insomnia, reduced self-confidence, emotional instability, forgetfulness, confusion, impatience, and vasomotor disturbances (such as excessive perspiration and uncontrolled blushing, which together are referred to as erethism). Common features of intoxication from mercury vapor are severe salivation and gingivitis. The triad of increased excitability, tremors, and gingivitis has been recognized historically as the major manifestation of exposure to mercury vapor when mercury nitrate was used in the fur, felt, and hat industries. Renal dysfunction also has been reported to result from long-term industrial exposure to mercury vapor. The concentrations of mercury vapor in the air and mercury in urine that are associated with the various effects are shown in Figure 65–4.

Diagnosis of Mercury Poisoning. A history of exposure to mercury, either industrial or environmental, is obviously valuable in making the diagnosis of mercury poisoning. Otherwise, clinical suspicions can be confirmed by laboratory analysis. The upper limit of a nontoxic concentration of mercury in blood generally is considered to be 3 to 4 μg/dl (0.15 to 0.20 μM). A concentration of mercury in blood in excess of 4 μg/dl (0.20 μM) is unexpected in normal, healthy adults and suggests the need for environmental evaluation and medical examination to assess the possibility of adverse health effects. Because methylmercury is concentrated in erythrocytes and inorganic mercury is not, the
distribution of total mercury between red blood cells and plasma may indicate whether the patient has been poisoned with inorganic or organic mercury. Measurement of total mercury in red blood cells gives a better estimate of the body burden of methylmercury than it does for inorganic mercury. A rough guide to the relationship between concentrations of mercury in blood and the frequency of symptoms that result from exposure to methylmercury is shown in Table 65–4. Concentrations of mercury in plasma provide a better index of the body burden of inorganic mercury, but the relationship between body burden and the concentration of inorganic mercury in plasma is not well documented. This may relate to the importance of timing of measurement of the blood sample relative to the last exposure to mercury. The relationship between the concentration of inorganic mercury in blood and toxicity also depends on the form of exposure. For example, exposure to vapor results in concentrations in brain approximately 10 times higher than those that follow an equivalent dose of inorganic mercuric salts.

The concentration of mercury in the urine also has been used as a measure of the body burden of the metal. The normal upper limit for excretion of mercury in urine is 5 μg/L. There is a linear relationship between plasma concentration and urinary excretion of mercury after exposure to vapor; in contrast, the excretion of mercury in urine is a poor indicator of the amount of methylmercury in the blood because it is eliminated mainly in feces (Bakir et al., 1980).

SOURCE: Based on data in Bakir et al., 1973.
Hair is rich in sulphydryl groups, and the concentration of mercury in hair is about 300 times that in blood. Human hair grows about 20 cm a year, and a history of exposure may be obtained by analysis of different segments of hair.

**Treatment of Mercury Poisoning.** Measurement of the concentration of mercury in blood should be performed as soon as possible after poisoning with any form of the metal.

**Elemental Mercury Vapor.** Therapeutic measures include immediate termination of exposure and close monitoring of pulmonary status. Short-term respiratory support may be necessary. Chelation therapy, as described below for inorganic mercury, should be initiated immediately and continued as indicated by the clinical condition and the concentrations of mercury in blood and urine.

**Inorganic Mercury.** Prompt attention to fluid and electrolyte balance and hematological status is of critical importance in moderate-to-severe oral exposures. Emesis can be induced if the patient is awake and alert, although emesis should not be induced where there is corrosive injury. If ingestion of mercury is more than 30 to 60 minutes before treatment, emesis may have little efficacy. With corrosive agents, endoscopic evaluation may be warranted, and coagulation parameters are important. Activated charcoal is recommended by some, although it lacks proven efficacy. Administration of charcoal may make endoscopy difficult or impossible.

**Chelation Therapy.** Chelation therapy with dimercaprol (for high-level exposures or symptomatic patients) or penicillamine (for low-level exposures or asymptomatic patients) is used routinely to treat poisoning with either inorganic or elemental mercury. Recommended treatment includes dimercaprol 5 mg/kg intramuscularly initially, followed by 2.5 mg/kg intramuscularly every 12 to 24 hours for 10 days. Penicillamine (250 mg orally every 6 hours) may be used alone or following treatment with dimercaprol. The duration of chelation therapy will vary, and progress can be monitored by following concentrations of mercury in urine and blood. The orally effective chelator succimer appears to be an effective chelator for mercury (Campbell et al., 1986; Fournier et al., 1988; Bluhm et al., 1992), although it has not been approved by the FDA for this purpose.

The dimercaprol–mercury chelate is excreted into both bile and urine, whereas the penicillamine–mercury chelate is excreted only into urine. Thus penicillamine should be used with extreme caution when renal function is impaired. In fact, hemodialysis may be necessary in the poisoned patient whose renal function declines. Chelators still may be used because the dimercaprol–mercury complex is removed by dialysis (Giunta et al., 1983).

**Organic Mercury.** The short-chain organic mercurials, especially methylmercury, are the most difficult forms of mercury to mobilize from the body presumably because of their poor reactivity with chelating agents. Dimercaprol is contraindicated in methylmercury poisoning because it increases brain concentrations of methylmercury in experimental animals. Although penicillamine facilitates the removal of methylmercury from the body, it is not clinically efficacious, and large doses (2 g/day) are needed (Bakir et al., 1980). During the initial 1 to 3 days of administration of penicillamine, the concentration of mercury in the blood increases before it decreases, probably reflecting the mobilization of metal from tissues to blood at a rate more rapid than that for excretion of mercury into urine and feces.

Methylmercury compounds undergo extensive enterohepatic recirculation in experimental animals. Therefore, introduction of a nonabsorbable mercury-binding substance into the intestinal tract should facilitate their removal from the body. A polythiol resin has been used for this purpose in humans and appears to be effective (Bakir et al., 1973). The resin has certain advantages over penicillamine. It does not cause redistribution of mercury in the body with a subsequent increase in the concentration of mercury in blood, and it has fewer adverse effects than do sulphydryl agents that are absorbed. Clinical experience with various treatments for methylmercury poisoning in Iraq indicates that penicillamine, N-acetylpenicillamine, and an oral nonabsorbable thiol resin all can reduce blood concentrations of mercury; however, clinical improvement was not clearly related to reduction of the body burden of methylmercury (Bakir et al., 1980).

Conventional hemodialysis is of little value in the treatment of methylmercury poisoning because methylmercury concentrates in erythrocytes, and little is contained in the plasma. However, it has been shown that L-cysteine can be infused into the arterial blood entering the dialyzer to convert methylmercury into a diffusible form. Both free cysteine and the methylmercury–cysteine complex form in the blood and then diffuse across the membrane into the dialysate. This method has been shown to be effective in humans (Al-Abbasi et al., 1978). Studies in animals indicate that succimer may be more effective than cysteine in this regard (Kostyniak, 1982).

**Arsenic**

Arsenic was used more than 2400 years ago in Greece and Rome as a therapeutic agent and as a poison. The foundations of many modern concepts of chemotherapy derive from Ehrlich’s early work with organic arsenicals, and such drugs once were a mainstay of chemotherapy. Although use of arsenicals as chemotherapeutics has declined, reports still emerge about their effectiveness, as shown by the use of arsenic trioxide in the treatment of acute promyelocytic leukemia (Chen et al., 1996; Soignet et al., 1998) (see Chapter 51). Arsenicals also remain important in the treatment of certain tropical diseases, such as African trypanosomiasis (see Chapter 40). In the United States, the impact of arsenic on health is predominantly from industrial and environmental exposures. (For a review, see NRC, 1999.)

Arsenic is found in soil, water, and air as a common environmental toxicant. Well water in sections of Argentina, Chile, and Taiwan has especially high concentrations of arsenic, which results in widespread poisoning. Large numbers of people in Bangladesh and West Bengal, India, are exposed to high concentrations of arsenic in their well water used for drinking. There also are high concentrations of arsenic in the water in many parts of the western United States. The element usually is not mined as such but is recovered as a by-product from the smelting of copper, lead, zinc, and other ores. This can release arsenic into the environment. Mineral-spring waters and the effluent from geothermal power plants leach arsenic from soils and rocks containing high concentrations of the metal. Arsenic also is present in coal at variable concentrations and is released into the environment during combustion. Application of pesticides and herbicides containing arsenic has increased its environmental dispersion. The major source of occupational exposure to arsenic-containing compounds is from the manufacture of arsenical herbicides and pesticides (Landrigan, 1981). Fruits and vegetables sprayed
with arsenicals may be a source of this element, and it is concentrated in many species of fish and shellfish. Arsenicals sometimes are added to the feed of poultry and other livestock to promote growth. The average daily human intake of arsenic is about 10 μg. Almost all this is ingested with food and water.

Arsenic is used as arsenic and as arsenic trioxide in the manufacture of most computer chips using silicon-based technology. Gallium arsenide is used in the production of compound (types III to V) semiconductors that are used for making light-emitting diodes (LEDs), as well as laser and solar devices. In the manufacture of both computer chips and semiconductors, metallic arsenic also may be used or produced as a by-product of the reaction chambers. Chromated copper arsenate (CCA) was used as a common treatment for outdoor lumber until 2004, although this should not pose a health risk unless treated wood is burned in fireplaces or wood-stoves (Hall, 2002).

Chemical Forms of Arsenic. The arsenic atom exists in the elemental form and in trivalent and pentavalent oxidation states. The toxicity of a given arsenical is related to the rate of its clearance from the body and therefore to its degree of accumulation in tissues. In general, toxicity increases in the sequence of organic arsenicals < As₃⁺ < As₅⁺ < arsenic (AsH₃).

The organic arsenicals contain arsenic covalently linked to a carbon atom, where arsenic exists in the trivalent or pentavalent state. Arsenophenamine contains trivalent arsenic; sodium arsanilate contains arsenic in the pentavalent form. The organic arsenicals usually are excreted more rapidly than are the inorganic forms.

Mechanism of Action. Arsenate (pentavalent) uncouples mitochondrial oxidative phosphorylation. The mechanism is thought to be related to competitive substitution of arsenate for inorganic phosphate in the formation of adenosine triphosphate, with subsequent formation of an unstable arsenate ester that is hydrolyzed rapidly. This process is termed arsenoysis.

Trivalent arsenicals, including inorganic arsenite, are regarded primarily as sulphydryl reagents. As such, trivalent arsenicals inhibit many enzymes by reacting with biological ligands containing available —SH groups. The pyruvate dehydrogenase system is especially sensitive to trivalent arsenicals because of their interaction with two sulphydryl groups of lipoic acid to form a stable six-membered ring, as shown below:

Absorption, Distribution, and Excretion. The absorption of poorly water-soluble arsenicals, such as As₂O₃, depends on the physical state of the compound. Coarsely powdered material is less toxic because it can be eliminated in feces before it dissolves. The arsenite salts are more soluble in water and are better absorbed than the oxide. Experimental evidence has shown a high degree of GI absorption (80% to 90%) of both trivalent and pentavalent forms of arsenic.

The distribution of arsenic depends on the duration of administration and the particular arsenical involved. Arsenic is stored mainly in liver, kidney, heart, and lung. Much smaller amounts are found in muscle and neural tissue. Because of the high sulphydryl content of keratin, the highest concentrations of arsenic are found in hair and nails. Deposition in hair starts within 2 weeks of administration, and arsenic stays fixed at this site for years. Because of its chemical similarity to phosphorus, it is deposited in bone and teeth and is retained there for long periods. Arsenic readily crosses the placenta, and fetal damage has been reported. Concentrations of arsenic in human umbilical cord blood are equivalent to those in the maternal circulation.

Arsenic is readily biotransformed in both laboratory animals and humans (Figure 65–5). The pentavalent arsenic (arsenate) is coupled to the oxidation of glutathione (GSH) to GSSG to form the trivalent arsenic (arsenite). Arsenite undergoes oxidative methylation to pentavalent methylarsonic acid (MMAV) catalyzed by arsenite methyltransferase. MMAV is reduced by MMAV reductase to trivalent monomethyl arsenious acid (MMAIII), which can undergo further oxidative methylation via MMA methyltransferase to dimethylarsenic acid (DMAVIII).

Arsenic is eliminated by many routes (e.g., feces, urine, sweat, milk, hair, skin, and lungs), although most is excreted in urine in humans. The half-life for the urinary excretion of arsenic is 3 to 5 days, much shorter than those of the other metals discussed. While it once was thought that the methylated forms of arsenic are less reactive with tissue constituents, less cytotoxic, and more readily excreted than the inorganic acid, studies have shown that methylation to monomethylarsonenic (III) acid or reduction of dimethyl arsenic acid to its trivalent state actually increases the toxicity and carcinogenicity of arsenic owing to increased affinity for sulphydryl groups (Petrick et al., 2000; Thomas et al., 2001). In humans, the urinary content of metabolites is 10% to 30% inorganic arsenic, 10% to 20% monomethylarsenate, and 60% to 80% dimethylarsenite (Vahter and Concha, 2001). Formation of trivalent mono- or dimethyl arsenic metabolites promotes biliary rather than renal excretion (Gregus et al., 2000).

Pharmacological and Toxicological Effects of Arsenic. Arsenicals have varied effects on many organ systems, as summarized below.

Cardiovascular System. Acute and subacute doses of inorganic arsenic induce mild vasodilation. This may lead to an occult edema,
particular, which has been mistaken for a healthy weight gain and misinterpreted as a “tonic” effect of arsenic. Larger acute and subacute doses evoke capillary dilation; increased capillary permeability may occur in all capillary beds but is most pronounced in the splanchnic area. Transudation of plasma also may occur, and the decrease in intravascular volume may be significant. Serious cardiovascular effects include hypotension, congestive heart failure, and cardiac arrhythmias. Long-term exposure results in peripheral vascular disease (Engel et al., 1994), more specifically gangrene of the extremities, especially of the feet, often referred to as blackfoot disease. Myocardial damage and hypotension may become evident after more prolonged exposure to arsenic.

Gastrointestinal Tract. Acute or subacute exposure to arsenic can produce GI disturbances that range from mild abdominal cramping and diarrhea to severe hemorrhagic gastroenteritis associated with shock. With chronic exposure to arsenic, GI effects usually are not observed. Small doses of inorganic arsenicals, especially the trivalent compounds, cause mild splanchnic hyperemia. Capillary transudation of plasma, resulting from larger doses, produces vesicles under the GI mucosa. These eventually rupture, epithelial fragments slough off, and plasma is discharged into the lumen of the intestine, where it coagulates. Tissue damage and the bulk cathartic action of the increased fluid in the lumen lead to increased peristalsis and characteristic watery diarrhea. Normal proliferation of the epithelium is suppressed, which accentuates the damage. Soon the feces become bloody. Damage to the upper GI tract usually results in hematemesis. Stomatitis also may be evident. The onset of GI symptoms may be so gradual that the possibility of arsenic poisoning may be overlooked.

Kidneys. The action of arsenic on the renal capillaries, tubules, and glomeruli may cause severe renal damage. Initially, the glomeruli are affected, and proteinuria results. Varying degrees of tubular necrosis and degeneration occur later. Oliguria with proteinuria, hematuria, and casts frequently result from arsenic exposure.

Skin. Skin is a major target organ of arsenic. Diffuse or spotted hyperpigmentation over the trunk and extremities usually is the first effect observed with chronic arsenic ingestion. Depending on the amount of exposure to arsenic, hyperpigmentation can be observed within 6 months. The hyperpigmentation of chronic arsenic exposure commonly appears in a finely freckled “raindrop” pattern, progressing within a period of years to palmar-plantar hyperkeratosis. Long-term ingestion of low doses of inorganic arsenicals causes cutaneous vasodilation and a “milk and roses” complexion. Eventually, skin cancer is observed, as described below.

Nervous System. High-dose acute or subacute exposure to arsenic can cause encephalopathy; however, the most common arsenic-induced neurological lesion is a peripheral neuropathy with a stocking/glove distribution of dysesthesia. The syndrome is similar to acute inflammatory demyelinating polyradiculoneuropathy (Guillain-Barré syndrome) (Donofrio et al., 1987). This is followed by muscular weakness in the extremities, and with continued exposure, deep-tendon reflexes diminish, and muscular atrophy follows. The cerebral lesions are mainly vascular in origin and occur in both the gray and white matter; characteristic multiple symmetrical foci of hemorrhagic necrosis occur.

Blood. Inorganic arsenicals affect the bone marrow and alter the cellular composition of the blood. Hematological evaluation usually reveals anemia with slight-to-moderate leukopenia; eosinophilia also may be present. Anisocytosis becomes evident with increasing exposure to arsenic. The vascularity of the bone marrow is increased. Some of the chronic hematological effects may result from impaired absorption of folic acid. Serious, irreversible blood and bone marrow disturbances from organic arsenicals are rare.

Liver. Inorganic arsenicals and a number of now-obsolete organic arsenicals are particularly toxic to the liver and produce fatty infiltration, central necrosis, and cirrhosis. The damage may be mild or so severe that death may ensue. The injury generally is to the hepatic parenchyma, but in some cases the clinical picture may closely resemble occlusion of the common bile duct, the principal lesions being pericholangitis and bile thrombi in the finer biliary radicles.

Carcinogenesis. The association of arsenic exposure and skin tumors was noted more than 100 years ago in patients treated with arsenicals. The International Agency for Research on Cancer concluded that inorganic arsenic is a skin and lung (via inhalation) carcinogen in humans (International Agency for Research on Cancer, 1980). Studies indicate that in Taiwan, Argentina, and Chile, where drinking water contained very high concentrations of arsenic (at least several hundred micrograms per deciliter), an increased incidence of bladder and lung cancer was due to arsenic exposure. Increased risks of other cancers, such as kidney and liver cancer, also have been reported, but the association with arsenic is not as high as for the tumors just noted.

Other. Apart from the various direct toxicities already mentioned, epidemiological studies demonstrate that inorganic arsenic exerts other adverse effects, examined in a variety of population-based epidemiological studies and clinical reports, including diseases of the cerebrovascular systems and hypertension. Chronic exposure to arsenic has been associated with increased prevalence of diabetes mellitus, goiter, hepatomegaly, and respiratory system dysfunctions (Thomas et al., 2001).

Acute Arsenic Poisoning. Federal restrictions on the allowable content of arsenic in food and in the occupational environment not only have improved safety procedures and decreased the number of intoxications but also have decreased the amount of arsenic in use; only the annual production of arsenic-containing herbicides is increasing.

The incidence of accidental, homicidal, and suicidal arsenic poisoning has diminished greatly in recent decades. Previously, arsenic in the form of As$_2$O$_3$ was a common cause of poisoning because it was readily available, practically tasteless, and had the appearance of sugar.
GI discomfort usually is experienced within an hour after intake of an arsenical, although it may be delayed as much as 12 hours after oral ingestion if food is in the stomach. Burning lips, constriction of the throat, and difficulty in swallowing may be the first symptoms, followed by excruciating gastric pain, projectile vomiting, and severe diarrhea. Oliguria with proteinuria and hematuria usually is present; eventually, anuria may occur. The patient often complains of marked skeletal muscle cramps and severe thirst. As the loss of fluid proceeds, symptoms of shock appear. Hypoxic convulsions may occur terminally; coma and death ensue. In severe poisoning, death can occur within an hour, but the usual interval is 24 hours. With prompt application of corrective therapy, patients may survive the acute phase of the toxicity only to develop neuropathies and other disorders. In a series of 37 such patients, 37 had peripheral neuropathy, and 5 had encephalopathy. The motor system appears to be spared only in the mildest cases; severe crippling is common (Jenkins, 1966).

**Chronic Arsenic Poisoning.** The most common early signs of chronic arsenic poisoning are muscle weakness and aching, skin pigmentation (especially of the neck, eyelids, nipples, and axillae), hyperkeratosis, and edema. GI involvement is less prominent in long-term exposures. Other signs and symptoms that should arouse suspicion of arsenic poisoning include garlic odor of the breath and perspiration, excessive salivation and sweating, stomatitis, generalized itching, sore throat, coryza, lacrimation, numbness, burning or tingling of the extremities, dermatitis, vitiligo, and alopecia. Poisoning may begin insidiously with symptoms of weakness, languor, anorexia, occasional nausea and vomiting, and diarrhea or constipation. Subsequent symptoms may simulate acute coryza. Dermatitis and keratosis of the palms and soles are common features. Mee’s lines are found characteristically in the fingernails (white transverse lines of deposited arsenic that usually appear 6 weeks after exposure). Because the fingernail grows at a rate of 0.1 mm/day, the approximate time of exposure can be determined. Desquamation and scaling of the skin may initiate an exfoliative process involving many epithelial structures of the body. The liver may enlarge, and obstruction of the bile ducts may result in jaundice. Eventually cirrhosis may occur from the hepatotoxic action. Renal dysfunction also may be encountered. As intoxication advances, encephalopathy may develop. Peripheral neuritis results in motor and sensory paralysis of the extremities; in contrast to lead palsy, the legs usually are more severely affected than the arms. The bone marrow is seriously damaged by arsenic, and all hematological elements may be affected with severe exposure.

**Treatment of Arsenic Poisoning.** After short-term exposure to arsenic, routine measures are taken to stabilize the patient and prevent further absorption of the poison. In particular, attention is directed to the intravascular volume status because the effects of arsenic on the GI tract can result in fatal hypovolemic shock. Hypotension requires fluid replacement and may necessitate pharmacological support with pressor agents such as dopamine.

**Chelation Therapy.** Chelation therapy often is begun with dimercaprol (3 to 4 mg/kg intramuscularly every 4 to 12 hours) until abdominal symptoms subside and charcoal (if given initially) is passed in the feces. Oral treatment with penicillamine then may be substituted for dimercaprol and continued for 4 days. Penicillamine is given in four divided doses to a maximum of 2 g/day. If symptoms recur after cessation of chelation therapy, a second course of penicillamine may be instituted. Succimer (2,3-dimercaptopropanic acid), a derivative of dimercaprol, is efficacious in the treatment of arsenic poisoning (Graziano et al., 1978; Lenz et al., 1981; Fournier et al., 1988) but is approved by the FDA only for lead chelation in children.

After long-term exposure to arsenic, treatment with dimercaprol and penicillamine also may be used, but oral penicillamine alone usually is sufficient. The duration of therapy is determined by the clinical condition of the patient, and the decision is aided by periodic determinations of urinary arsenic concentrations. Adverse effects of the chelating agents may limit the usefulness of therapy (see below). Dialysis may become necessary with severe arsenic-induced nephropathy; successful removal of arsenic by dialysis has been reported (Vaziri et al., 1980).

**Arsine.** Arsine gas, generated by electrolytic or metallic reduction of arsenic in nonferrous metal products, is a rare cause of industrial intoxication. Rapid and often fatal hemolysis is a unique characteristic of arsenic poisoning and probably results from arsine combining with hemoglobin and then reacting with oxygen to cause hemolysis. A few hours after exposure, headache, anorexia, vomiting, paresthesia, abdominal pain, chills, hemoglobinuria, bilirubinemia, and anuria occur. The classic arsine triad of hemolysis, abdominal pain, and hematuria is noteworthy. Jaundice appears after 24 hours. A coppery skin pigmentation is observed frequently and is thought to be due to methemoglobin. Kidneys of persons poisoned by arsine characteristically contain hemoglobin casts, and there is cloudy swelling and necrosis of the cells of the proximal tubule. If the patient survives the severe hemolysis, death may result from renal failure. Because the hemoglobin–arsine complex cannot be dialyzed, exchange transfusion is recommended in severe cases; forced alkaline diuresis also may be employed (see Chapter 64). Dimercaprol has no effect on the hemolysis, and beneficial effects on renal function have not been established; it therefore is not recommended.

It should be noted that arsenic is a trace contaminant of other metals, such as lead; contact of these unrefined metals with acid may produce arsine (and/or stibine from antimony).

**Cadmium**

Cadmium ranks close to lead and mercury as a metal of current toxicological concern. It occurs in nature in association with zinc and lead, and extraction and processing of these metals often lead to environmental contamination with cadmium. The element was discovered in 1817 but was seldom used until its valuable metallurgical properties were discovered approximately 50 years ago. A high resistance to corrosion, valuable electrochemical properties, and other useful chemical properties account for cadmium’s wide applications in electroplating and galvanization and its use in plastics, paint pigments (cadmium yellow), and nickel–cadmium batteries. Applications for production of cadmium will continue to increase. Because less than 5% of the metal is recycled, environmental pollution is an important consideration. Coal and other fossil fuels contain cadmium, and their combustion releases the element into the environment.

Workers in smelters and other metal-processing plants may be exposed to high concentrations of cadmium in the air; however, for
most of the population, food is the major source of cadmium. Uncontaminated foodstuffs contain less than 0.05 μg cadmium per gram wet weight, and the average daily intake is about 50 μg. Cereal grains, such as rice and wheat, concentrate cadmium; thus, when they are grown in soils with naturally high concentrations of cadmium or polluted with cadmium, these grains can have high cadmium content. Drinking water normally does not contribute significantly to cadmium intake, but cigarette smoking does because the tobacco plant also concentrates cadmium. One cigarette contains 1 to 2 μg cadmium, and with even 10% pulmonary absorption (Elinder et al., 1983), the smoking of one pack of cigarettes per day results in a dose of approximately 1 mg cadmium per year from smoking alone. Shellfish and animal liver and kidney can have concentrations of cadmium higher than 0.05 μg/g, even under normal circumstances. When foods such as rice and wheat are contaminated by cadmium in soil and water in which they grew, the concentration of the metal may increase considerably (1 μg/g).

**Absorption, Distribution, and Excretion.** Cadmium occurs only in one valency state (2+) and does not form stable alkyl compounds or other organometallic compounds of known toxicological significance.

Cadmium is absorbed poorly from the GI tract, in the range of 1.5% to 5% (Engstrom and Nordberg, 1979; Rahola et al., 1972). Absorption from the respiratory tract is higher; cigarette smokers may absorb 10% to 40% of inhaled cadmium (Friberg et al., 1974). Cadmium absorption is higher in pregnant than nonpregnant rats apparently owing to an increased expression of divalent metal transporter 1 (DMT-1). The main function of DMT-1 is to facilitate iron absorption, so its levels increase during pregnancy owing to an increased need for iron. However, DMT-1 also is capable of transporting cadmium, which explains the observed increase in cadmium absorption (Leazer et al., 2002).

After absorption, cadmium is transported in blood, bound mainly to blood cells and albumin. Cadmium initially is distributed to the liver and then redistributes slowly to the kidney as cadmium–metallothionein (Cd–MT). After distribution, approximately 50% of the total-body burden is found in the liver and kidney. Metallothionein is a low-molecular-weight protein with high affinity for metals such as cadmium and zinc. One-third of its amino acid residues are cysteine. Metallothionein is inducible by exposure to several metals, including cadmium, and elevated concentrations of this metal-binding protein protect against cadmium toxicity by preventing the interaction of cadmium with other functional macromolecules (Klaassen et al., 1999).

The half-life of cadmium in the body is 10 to 30 years. Thus the metal is prone to accumulation, and with continuous environmental exposure, tissue concentrations of the metal increase throughout life. The body burden of cadmium in a 50-year-old adult in the United States is about 30 mg. Overall, fecal elimination of the metal, which is quantitatively more important than urinary excretion, becomes significant only after substantial renal toxicity has occurred (see Goering and Klaassen, 1984).

**Acute Cadmium Poisoning.** Acute poisoning usually results from inhalation of cadmium dusts and fumes (usually cadmium oxide) or from the ingestion of cadmium salts. The early toxic effects are due to local irritation. In the case of oral intake, these include nausea, vomiting, salivation, diarrhea, and abdominal cramps; the vomitus and diarrhea often are bloody. In the short term, inhaled cadmium is more toxic. Signs and symptoms, which appear within a few hours, include irritation of the respiratory tract with severe, early pneumonitis, chest pains, nausea, dizziness, and diarrhea. Toxicity may progress to fatal pulmonary edema or residual emphysema with peribronchial and perivascular fibrosis (Zavon and Meadows, 1970).

**Chronic Cadmium Poisoning.** The toxic effects of long-term exposure to cadmium differ somewhat with the route of exposure. The kidney is affected following either pulmonary or GI exposure; marked effects are observed in the lungs only after exposure by inhalation.

**Kidney.** Figure 65–6 illustrates how cadmium is thought to produce renal toxicity. Although some cadmium is excreted with the bile, a cadmium–metallothionein complex can transport cadmium to the kidney, where it is released as inorganic cadmium. A sufficient concentration (200 μg/g) damages the cells of the proximal tubule, resulting in proteinuria (Dudley et al., 1985). With more severe exposure, glomerular injury occurs, filtration is decreased, and aminoaciduria, glycosuria, and proteinuria occur. The nature of the glomerular injury is unknown but may involve an autoimmune component.

Excretion of β₂-microglobulin in urine is a sensitive but not specific index of cadmium-induced nephrotoxicity (Piscator and Peterson, 1977; Lauwerys et al., 1979). Although measurement of urine β₂-microglobulin is part of the Occupational Safety and Health Administration (OSHA) standard for monitoring cadmium poisoning, the concentration of β₂-microglobulin in the urine may not be the best marker for exposure. Retinol-binding protein may be a better marker, but its measurement generally is not available.

**Lung.** The consequence of excessive inhalation of cadmium fumes and dusts is loss of ventilatory capacity, with a corresponding increase in residual lung volume. Dyspnea is the most frequent complaint of patients with cadmium-induced lung disease. The pathogenesis of cadmium-induced emphysema and pulmonary fibrosis is not well understood (Davison et al., 1988); however, cadmium specifically inhibits the synthesis of plasma α₁-antitrypsin (Chowdhury and Louria, 1976), and severe α₁-antitrypsin deficiency of genetic origin is associated with emphysema in humans.

**Cardiovascular System.** Perhaps the most controversial issue concerning the effects of cadmium on human beings is the suggestion that the metal plays a significant causal role in hypertension (Schroeder, 1965). An initial epidemiological study indicated that individuals dying from hypertension had significantly higher concentrations of cadmium and higher cadmium-to-zinc ratios in their kidneys than people dying of other causes. Others have found similar correlations (Third and Fischer, 1976). However, consistent effects of cadmium on the blood pressure of experimental animals have not been observed, and hypertension is not prominent in industrial cadmium poisoning.

**Bone.** There may be an interaction among cadmium, nutrition, and bone disease. Body stores of calcium have been found to be decreased in subjects exposed to cadmium occupationally (Scott et al., 1980). This presumed effect of cadmium may be due to interference with renal regulation of calcium and phosphate balance.

**Testis.** Testicular necrosis, a common characteristic of short-term exposure to cadmium in experimental animals, is uncommon with long-term low-level exposure (Kotsonis and Klaassen, 1978) and has not been observed in men.

**Cancer.** Cadmium produces tumors in a number of organs when administered to laboratory animals (Waalke et al., 1992). Evidence that cadmium is a human carcinogen is based mainly on epidemiological studies from workers exposed occupationally to cadmium. These investigations primarily have identified tumors of the lungs and, to a lesser extent, prostate, kidney, and stomach. The Interna-
Section XV / Toxicology

The National Agency for Cancer Research (1993) has concluded that the data are sufficient to classify cadmium as a human carcinogen.

**Treatment of Cadmium Poisoning.** Effective therapy for cadmium poisoning is difficult to achieve. After short-term inhalation, the patient must be removed from the source, and pulmonary ventilation should be monitored carefully. Respiratory support and steroid therapy may become necessary.

**Chelation Therapy.** Although there is no proven benefit, some clinicians recommend chelation therapy with CaNa$_2$EDTA. The dose of CaNa$_2$EDTA is 75 mg/kg per day in three to six divided doses for 5 days. After a minimum of 2 days without treatment, a second 5-day course is given. The total dose of CaNa$_2$EDTA per 5-day course should not exceed 500 mg/kg. Animal studies suggest that chelation therapy should be instituted as soon as possible after cadmium exposure because a rapid decrease in effectiveness of chelation therapy occurs in parallel with distribution to sites inaccessible to the chelators (Cantilena and Klaassen, 1982a). The use of dimercaprol and substituted dithiocarbamates appears promising for individuals chronically exposed to cadmium (Jones et al., 1991).

**Iron.**

Although iron is not an environmental poison, accidental intoxication with ferrous salts used to treat iron deficiency is a frequently encountered source of poisoning in young children. Iron is discussed further in Chapter 53.

**Radioactive Heavy Metals.**

The widespread production and use of radioactive heavy metals for nuclear generation of electricity, nuclear weapons, laboratory research, manufacturing, and medical diagnosis have generated unique problems in dealing with accidental poisoning by such metals. Because the toxicity of radioactive metals is almost entirely a consequence of ionizing radiation, the therapeutic objective following exposure is not only chelation of the metals but also their removal from the body as rapidly and completely as possible.

Treatment of the acute radiation syndrome is largely symptomat-ic. Attempts have been made to investigate the effectiveness of organic reducing agents, such as mercaptamine (cysteamine), administered to prevent the formation of free radicals. Success has been limited.

Major products of a nuclear accident or the use of nuclear weapons include $^{239}$Pu, $^{137}$Cs, $^{144}$Ce, and $^{90}$Sr. Isotopes of strontium and radium are extremely difficult to remove from the body with chelating agents. Several factors are involved in the relative resistance of radioactive metals to chelation therapy; these include the affinity of these particular metals for individual chelators and the observation that radiation from Sr and Ra in bone destroys nearby capillaries, thereby decreasing blood flow and isolating the radioisotopes. Many chelating agents have been used experimentally, including CaNa$_3$DTPA (pentetic acid; see below), which has been shown to be effective against $^{239}$Pu (Jones et al., 1986). One gram of CaNa$_3$DTPA, administered by slow intravenous drip on alternate days three times per week has enhanced excretion fifty to one hundredfold in animals and in human subjects exposed in accidents. As is seen commonly with heavy-metal poisoning, effectiveness of treatment diminishes very rapidly with an increasing delay between exposure and the initiation of therapy.

**HEAVY-METAL ANTAGONISTS.**

**Edetate Calcium Disodium.**

**Ethylenediaminetetraacetic acid** (EDTA), its sodium salt (edetate disodium, Na$_2$EDTA), and a number of closely related compounds chelate many divalent and trivalent metals. The cation used to make a water-soluble salt of EDTA has an important role in the toxicity of the chela-
tor. Na<sub>2</sub>EDTA causes hypocalcemic tetany. However, edetate calcium disodium (CaNa<sub>2</sub>EDTA) can be used for treatment of poisoning by metals that have higher affinity for the chelating agent than does Ca<sup>2+</sup>.

**Chemistry and Mechanism of Action.** The structure of CaNa<sub>2</sub>EDTA is as follows:

![EDETATE CALCIUM DISODIUM](image)

The pharmacological effects of CaNa<sub>2</sub>EDTA result from formation of chelates with divalent and trivalent metals in the body. Accessible metal ions (both exogenous and endogenous) with a higher affinity for CaNa<sub>2</sub>EDTA than Ca<sup>2+</sup> will be chelated, mobilized, and usually excreted. Because EDTA is charged at physiological pH, it does not significantly penetrate cells; its volume of distribution approximates extracellular fluid space. Experimental studies in mice have shown that administration of CaNa<sub>2</sub>EDTA mobilizes several endogenous metallic cations, including those of zinc, manganese, and iron (Cantilena and Klaassen, 1982b). The main therapeutic use of CaNa<sub>2</sub>EDTA is in the treatment of metal intoxications, especially lead intoxication.

**Absorption, Distribution, and Excretion.** Less than 5% of CaNa<sub>2</sub>EDTA is absorbed from the GI tract. After intravenous administration, CaNa<sub>2</sub>EDTA disappears from the circulation with a half-life of 20 to 60 minutes. In blood, all the drug is found in plasma. About 50% is excreted in urine in 1 hour and more than 95% in 24 hours. For this reason, adequate renal function is necessary for successful therapy. Renal clearance of the compound in dogs equals that of insulin, and glomerular filtration accounts entirely for urinary excretion. Altering either the pH or the rate of flow of urine has no effect on the rate of excretion. There is very little metabolic degradation of EDTA. The drug is distributed mainly in the extracellular fluids, but very little gains access to the spinal fluid (5% of the plasma concentration).

**Toxicity.** Rapid intravenous administration of Na<sub>2</sub>EDTA causes hypocalcemic tetany. However, a slow infusion (<15 mg/minute) administered to a normal individual elicits no symptoms of hypocalcemia because of the ready availability of extracellular stores of Ca<sup>2+</sup>. In contrast, CaNa<sub>2</sub>EDTA can be administered intravenously in relatively large quantities with no untoward effects because the change in concentration of Ca<sup>2+</sup> in the plasma and total body is negligible.

**Renal Toxicity.** The principal toxic effect of CaNa<sub>2</sub>EDTA is on the kidney. Repeated large doses of the drug cause hydropic vacuolization of the proximal tubule, loss of the brush border, and eventually, degeneration of proximal tubular cells (Catsch and Harmuth-Hoene, 1979). Changes in distal tubules and glomeruli are less conspicuous. The early renal effects usually are reversible, and urinary abnormalities disappear rapidly on cessation of treatment.

Renal toxicity may be related to the large amounts of chelated metals that transit the renal tubule in a relatively short period during drug therapy. Some dissociation of chelates may occur because of competition for the metal by physiological ligands or because of pH changes in the cell or the lumen of the tubule. However, a more likely mechanism of toxicity may be interaction between the chelator and endogenous metals in proximal tubular cells.

**Other Side Effects.** Other less serious side effects have been reported with use of CaNa<sub>2</sub>EDTA, including malaise, fatigue, and excessive thirst, followed by the sudden appearance of chills and fever. This, in turn, may be followed by severe myalgia, frontal headache, anorexia, occasional nausea and vomiting, and rarely, increased urinary frequency and urgency. Other possible undesirable effects include sneezing, nasal congestion, and lacrimation; glycosuria; anemia; dermatitis with lesions strikingly similar to those of vitamin B<sub>6</sub> deficiency; transitory lowering of systolic and diastolic blood pressures; prolonged prothrombin time; and T-wave inversion on the electrocardiogram.

**Pentetic Acid (DTPA).** Diethylenetriaminepentaacetic acid (DTPA), like EDTA, is a polycarboxylic acid chelator, but it has somewhat greater affinity for most heavy metals. Many investigations in animals have shown that the spectrum of clinical effectiveness of DTPA is similar to that of EDTA. Because of its relatively greater affinity for metals, DTPA has been tried in cases of heavy-metal poisoning that do not respond to EDTA, particularly poisoning by radioactive metals. Unfortunately, success has been limited probably because DTPA also has limited access to intracellular sites of metal storage. Because DTPA rapidly binds Ca<sup>2+</sup>, CaNa<sub>2</sub>DTPA is employed. The use of DTPA is investigational.
**Dimercaprol**

Dimercaprol was developed during World War II as an antidote to lewisite, a vesicant arsenical war gas, hence its alternative name, *British antilewisite* (BAL). Arsenicals would form a very stable and relatively nontoxic chelate ring with the dimercaprol (2,3-dimercaptopropanol). Pharmacological investigations revealed that this compound would protect against the toxic effects of other heavy metals as well.

**Chemistry.** Dimercaprol has the following structure:

```
H  H  H  H
H—C—C—C—H
SH SH OH
```

**DIMERCAPROL**

It is an oily fluid with a pungent, disagreeable odor typical of mercaptans. Because of its instability in aqueous solutions, peanut oil is the solvent employed in pharmaceutical preparations. Dimercaprol and related thiols are readily oxidized.

**Mechanism of Action.** The pharmacological actions of dimercaprol result from formation of chelation complexes between its sulfhydryl groups and metals. The molecular properties of the dimercaprol–metal chelate have considerable practical significance. With metals such as mercury, gold, and arsenic, the strategy is to attain a stable complex to promote elimination of the metal. Dissociation of the complex and oxidation of dimercaprol can occur *in vivo*. Furthermore, the sulfur–metal bond may be labile in the acidic tubular urine, which may increase delivery of metal to renal tissue and increase toxicity. The dosage regimen therefore is designed to maintain a concentration of dimercaprol in plasma adequate to favor the continuous formation of the more stable 2:1 (BAL–metal) complex and its rapid excretion. However, because of pronounced and dose-related side effects, excessive plasma concentrations must be avoided. The concentration in plasma therefore must be maintained by repeated fractional dosage until the offending metal can be excreted.

Dimercaprol is much more effective when given as soon as possible after exposure to the metal because it is more effective in preventing inhibition of sulphydryl enzymes than in reactivating them. Dimercaprol antagonizes the biological actions of metals that form mercapto- and metalchelates with essential cellular sulphydryl groups, principally arsenic, gold, and mercury. It also is used in combination with CaNa₂EDTA to treat lead poisoning, especially when evidence of lead encephalopathy exists. Intoxication by selenites, which also oxidize sulphydryl enzymes, is not influenced by dimercaprol.

**Absorption, Distribution, and Excretion.** Dimercaprol cannot be administered orally; it is given by deep intramuscular injection as a 100 mg/ml solution in peanut oil, and thus it should not be used in patients who are allergic to peanuts or peanut products. Peak concentrations in blood are attained in 30 to 60 minutes. The half-life is short, and metabolic degradation and excretion are essentially complete within 4 hours.

**Toxicity.** In humans, the administration of dimercaprol produces a number of side effects that usually are more alarming than serious. Reactions to dimercaprol occur in approximately 50% of subjects receiving 5 mg/kg intramuscularly. The effects of repeated administration of this dose are not cumulative if an interval of at least 4 hours elapses between injections. One of the most consistent responses to dimercaprol is a rise in systolic and diastolic arterial pressures, accompanied by tachycardia. The rise in pressure may be as great as 50 mmHg in response to the second of two doses (5 mg/kg) given 2 hours apart. The pressure rises immediately but returns to normal within 2 hours.

Other signs and symptoms of dimercaprol toxicity, many of which tend to parallel the change in blood pressure in time and intensity, are the following, listed in approximate order of frequency: nausea and vomiting; headache; a burning sensation in the lips, mouth, and throat and a feeling of constriction, sometimes pain, in the throat, chest, or hands; conjunctivitis, blepharospasm, lacrimation, rhinorrhea, and salivation; tingling of the hands; a burning sensation in the penis; sweating of the forehead, hands, and other areas; abdominal pain; and the occasional appearance of painful sterile abscesses at the injection site. Symptoms often are accompanied by a feeling of anxiety and unrest. Because the dimercaprol–metal complex breaks down easily in an acidic medium, production of an alkaline urine protects the kidney during therapy. Children react as do adults, although approximately 30% also may experience a fever that disappears on withdrawal of the drug. A transient reduction in the percentage of polymorphonuclear leukocytes may be observed. Dimercaprol also may cause hemolytic anemia in patients deficient in glucose-6-phosphate dehydrogenase. Dimercaprol is contraindicated in patients with hepatic insufficiency, except when this is a result of arsenic poisoning.
Succimer

Succimer (2,3-dimercaptosuccinic acid, CHEMET) is an orally effective chelator that is chemically similar to dimercaprol but contains two carboxylic acids that modify both the distribution and chelating spectrum of the drug. Succimer has the following structure:

After its absorption in humans, succimer is biotransformed to a mixed disulfide with cysteine (Aposhian and Aposhian, 1990), the structure of which is as follows:

Succimer produces a lead diuresis with a subsequent lowering of blood lead levels and attenuation of the untoward biochemical effects of lead, manifested by normalization of δ-ALA dehydrase activity (Graziano et al., 1992). The succimer–lead chelate also is eliminated in bile; the fraction eliminated undergoes enterohepatic circulation.

A desirable feature of succimer is that it does not significantly mobilize essential metals such as zinc, copper, or iron. Animal studies suggest that succimer is effective as a chelator of arsenic, cadmium, mercury, and other metals (Aposhian and Aposhian, 1990). Toxicity with succimer is less than that with dimercaprol perhaps because its relatively lower lipid solubility minimizes its uptake into cells. Nonetheless, transient elevations in hepatic transaminases are observed following treatment with succimer. The most commonly reported adverse effects of succimer treatment are nausea, vomiting, diarrhea, and loss of appetite. Rashes also have been reported that may necessitate discontinuation of therapy.

Succimer has been approved in the United States for treatment of children with blood lead levels in excess of 45 μg/dl.

Penicillamine

Penicillamine was first isolated in 1953 from the urine of patients with liver disease who were receiving penicillin. Discovery of its chelating properties led to its use in patients with Wilson’s disease and heavy-metal intoxications.

Chemistry. Penicillamine is D-β,β-dimethylcysteine. Its structure is as follows:

The D-isomer is used clinically, although the L-isomer also forms chelation complexes. Penicillamine is an effective chelator of copper, mercury, zinc, and lead and promotes the excretion of these metals in the urine.

Absorption, Distribution, and Excretion. Penicillamine is well absorbed (40% to 70%) from the GI tract and therefore has a decided advantage over many other chelating agents. Food, antacids, and iron reduce its absorption. Peak concentrations in blood are obtained between 1 and 3 hours after administration (Netter et al., 1987). Unlike cysteine, its nonmethylated parent compound, penicillamine is somewhat resistant to attack by cysteine desulfhydrase or L-amino acid oxidase. As a result, penicillamine is relatively stable in vivo. Hepatic biotransformation is responsible for most of the degradation of penicillamine, and very little is excreted unchanged. Metabolites are found in both urine and feces (Perrett, 1981).

Therapeutic Uses. Penicillamine (CUPRIMINE, DEPEN) is available for oral administration. For chelation therapy, the usual adult dose is 1 to 1.5 g/day in four divided doses (see sections under individual metals). The drug should be given on an empty stomach to avoid interference by metals in food. In addition to its use as a chelating agent for the treatment of copper, mercury, and lead poisoning, penicillamine is used in Wilson’s disease (hepatolenticular degeneration owing to an excess of copper), cystinuria, and rheumatoid arthritis (rarely). For the treatment of Wilson’s disease, 1 to 2 g/day usually is administered in four doses. The urinary excretion of copper should be monitored to determine whether the dosage of penicillamine is adequate.

N-Acetylpenicillamine is more effective than penicillamine in protecting against the toxic effects of mercury presumably because it is even more resistant to metabolism.

The rationale for the use of penicillamine in cystinuria is that penicillamine reacts with the poorly soluble cysteine in a thiol–disulfide exchange reaction and forms a relatively water-soluble cysteine–penicillamine mixed disulfide. In cystinuria, the urinary excretion of cystine is used to adjust dosage, although 2 g/day in four divided doses usually is employed.

The mechanism of action of penicillamine in rheumatoid arthritis remains uncertain, although suppression of the disease may result from marked reduction in concentrations of IgM rheumatoid factor. A single daily dose of 125 to 250 mg usually is used to initiate therapy, with dosage increases at intervals of 1 to 3 months as necessary to a typical range of 500 to 750 mg/day. Because of toxicity, the drug is used rarely today in this setting.

Other experimental uses of penicillamine include the treatment of primary biliary cirrhosis and scleroderma. The mechanism of action of penicillamine in these diseases also may involve effects on immunoglobulins and immune complexes (Epstein et al., 1979).
Toxicity. With long-term use, penicillamine induces several cutaneous lesions, including urticaria, macular or papular reactions, pemphigoid lesions, lupus erythematosus, dermatomyositis, adverse effects on collagen, and other less serious reactions, such as dryness and scaling. Cross-reactivity with penicillin may be responsible for some episodes of urticarial or maculopapular reactions with generalized edema, pruritus, and fever that occur in as many as one-third of patients taking penicillamine. For a detailed review of the adverse dermatological effects of penicillamine, see Levy and coworkers (1983).

The hematological system also may be affected severely; reactions include leukopenia, aplastic anemia, and agranulocytosis. These may occur at any time during therapy, and they may be fatal. Patients obviously must be monitored carefully.

Renal toxicity induced by penicillamine usually is manifested as reversible proteinuria and hematuria, but it may progress to the nephrotic syndrome with membranous glomerulopathy. More rarely, fatalities have been reported from Goodpasture’s syndrome (Hill, 1979).

Toxicity to the pulmonary system is uncommon, but severe dyspnea has been reported from penicillamine-induced bronchoalveolitis. Myasthenia gravis also has been induced by long-term therapy with penicillamine (Gordon and Burnside, 1977). Less serious side effects include nausea, vomiting, diarrhea, dyspepsia, anorexia, and a transient loss of taste for sweet and salt, which is relieved by supplementation of the diet with copper. Contraindications to penicillamine therapy include pregnancy, a previous history of penicillamine-induced agranulocytosis or aplastic anemia, or the presence of renal insufficiency.

Trientine

Penicillamine is the drug of choice for treatment for Wilson’s disease. However, the drug produces undesirable effects, as discussed earlier, and some patients become intolerant. For these individuals, trientine (triethylenetetramine dehydrochloride, Cuprider) is an acceptable alternative. Trientine is an effective cupriuretic agent in patients with Wilson’s disease, although it may be less potent than penicillamine. The drug is effective orally. Maximal daily doses of 2 g for adults or 1.5 g for children are taken in two to four divided portions on an empty stomach. Trientine may cause iron deficiency; this can be overcome with short courses of iron therapy, but iron and trientine should not be ingested within 2 hours of each other.

Deferoxamine

Deferoxamine is isolated as the iron chelate from Strepomyces pilosus and is treated chemically to obtain the metal-free ligand. Deferoxamine has the desirable properties of a remarkably high affinity for ferric iron (Ka = 1031) coupled with a very low affinity for calcium (KCa = 10²). Studies in vitro have shown that it removes iron from hemosiderin and ferritin and, to a lesser extent, from transferrin. Iron in hemoglobin or cytochromes is not removed by deferoxamine. The structure of deferoxamine is

\[
\text{H}_2\text{N} \rightarrow \text{[CH}_2\text{b}_5\text{N} \rightarrow \text{C} \rightarrow \text{[CH}_2\text{b}_2\text{N} \rightarrow \text{C} \rightarrow \text{N} \rightarrow \text{[CH}_2\text{b}_5\text{N} \rightarrow \text{C} \rightarrow \text{CH}_3}
\]

DEFEROXAMINE

Deferoxamine (defer ox amine mesylate, Desferal Mesylate) is poorly absorbed after oral administration, and parenteral administration is required in most cases. For severe iron toxicity (serum iron levels greater than 500 μg/dl), the intravenous route is preferred. The drug is administered at 10 to 15 mg/kg per hour by constant infusion. Faster rates of infusion (45 mg/kg per hour) have been used in a few cases; rapid boluses usually are associated with hypotension. Deferoxamine may be given intramuscularly in moderately toxic cases (serum iron 350 to 500 μg/dl) at a dose of 50 mg/kg with a maximum dose of 1 g. Hypotension also can occur with the intramuscular route.

For chronic iron intoxication (e.g., thalassemia), an intramuscular dose of 0.5 to 1.0 g/day is recommended, although continuous subcutaneous administration (1 to 2 g/day) is almost as effective as intravenous administration (Propper et al., 1977). When blood is being transfused to patients with thalassemia, 2.0 g deferoxamine (per unit of blood) should be given by slow intravenous infusion (rate not to exceed 15 mg/kg per hour) during the transfusion but not by the same intravenous line. Deferoxamine is not recommended in primary hemochromatosis; phlebotomy is the treatment of choice. Deferoxamine also has been used for the chelation of aluminum in dialysis patients (Swartz, 1985).

Deferoxamine is metabolized principally by plasma enzymes, but the pathways have not yet been defined. The drug also is excreted readily in the urine.

Deferoxamine causes a number of allergic reactions, including pruritus, wheals, rash, and anaphylaxis. Other adverse effects include dysuria, abdominal discomfort, diarrhea, fever, leg cramps, and tachycardia. Occasional cases of cataract formation have been reported. Deferoxamine may cause neurotoxicity during long-term, high-dose therapy for transfusion-dependent thalas semia major; both visual and auditory changes have been described (Olivieri et al., 1986). A “pulmonary syndrome” has been associated with high-dose (10 to 25 mg/kg per hour) deferoxamine therapy (Freedman et al., 1990; Castriota-Scanderbeg et al., 1990); tachypnea, hypoxemia, fever, and eosinophilia are prominent symptoms. Contraindications to the use of deferoxamine include renal insufficiency and anuria; during pregnancy, the drug should be used only if clearly indicated.
An orally effective iron chelator now under clinical investigation, deferiprone (1,2-dimethyl-3-hydroxypropyridin-4-one), may be of value in patients with thalassemia major who are unable or unwilling to receive deferoxamine (Olivieri et al., 1995). Combination therapy with deferoxamine also is under investigation.

BIBLIOGRAPHY

**MONOGRAPHS AND REVIEWS**

This page intentionally left blank
When the physician’s treatment plan for the patient involves the prescribing of one or more medications, Robert Burns’ law too often prevails: “The best-laid schemes o’ mice an’ men gang aft a-gley.” From the wrong drug prescribed to the wrong dosage or administration schedule advised, dispensed, or administered, the impact of medication misadventures are a tremendously costly problem. This appendix provides a primer on the proper approach to the medication prescription and order process and a resource for practitioners in effectively providing pharmaceutical care for their patients.

**THE MECHANICS OF PRESCRIPTION ORDER WRITING**

**History.** Knowledge of ancient prescriptions can be found in both Chinese (Chen and Qian, 1989) and Egyptian writings (Karenberg and Leitz, 2001). The use of the symbol Rx to denote the modern prescription is rooted in ancient alchemical practice of obscure origin. Rx may be derived from the Egyptian “Eye of Horus” symbol (⪀) denoting health, or may be a symbolic appeal by physicians to the god Jupiter for a prescription’s success. More commonly, Rx is said to be an abbreviation for the Latin word recipere, meaning “take” or “take thus” as a direction to a pharmacist, preceding the physician’s “recipe” for preparing a medication. What is clear is the origin of the abbreviation “Sig” for the Latin “Signatura,” used on the prescription to mark the directions for administration of the medication.

Early medicines were made up of multiple ingredients requiring complex preparation, and Latin was adopted as the standard language of the prescription to ensure understanding and consistency. Latin is no longer the international language of medicine, but a number of commonly used abbreviations derive from old Latin usage.

**Current Practice.** Today, the prescription consists of the superscription, the inscription, the subscription, the signa, and the name and signature of the prescriber, all contained on a single form (Figure AI–1).

The *superscription* includes the date the prescription order is written; the name, address, weight, and age of the patient; and the Rx. The body of the prescription, or *inscription*, contains the name and amount or strength of the drug to be dispensed, or the name and strength of each ingredient to be compounded. The *subscription* is the instruction to the pharmacist, usually consisting of a short sentence such as: “make a solution,” “mix and place into 30 capsules,” or “dispense 30 tablets.” The *signa* or “Sig” is the instruction for the patient as to how to take the prescription, interpreted and transposed onto the prescription label by the pharmacist. In the United States these should always be written in English. Many physicians continue to use Latin abbreviations; for example, “1 cap tid pc,” will be interpreted by the pharmacist as “take one capsule three times daily after meals.” However, the use of Latin abbreviations for these directions only mystifies the prescription. This can be a hindrance to proper patient-physician communication and is an otherwise unnecessary source of potential dispensing errors. Since the pharmacist always writes the label in English (or as appropriate in the language of the patient), the use of such abbreviations or symbols is unnecessary and discouraged.

The instruction “take as directed” is not satisfactory and should be avoided by the physician. Such directions assume an understanding on the part of the patient that may not be realized and inappropriately exclude the pharmacist from the pharmaceutical care process. Such directions can only be seen as inadequate by the pharmacist, who must determine the intent of the physi-
cian before dispensing the medication, and who shares the responsibility for safe and proper use of the medication by the patient. The best directions to the patient will include a reminder of the intended purpose of the medication by including such phrases as “for relief of pain,” or “to relieve itching.” The correct route of administration is reinforced by the choice of the first word of the directions. For an oral dosage form, the directions would begin with “take” or “give”; for externally applied products, the word “apply”; for suppositories, “insert”; and for eye, ear, or nose drops, “place” is preferable to “instill.”

Prescriptive Authority. In many states in the United States, health care practitioners other than M.D. and D.O. physicians can write prescriptions. Licensed physician’s assistants (P.A.), nurse practitioners, and pharmacists can prescribe medications under various circumstances.

Avoiding Confusion. Units of measure can lead to confusion and medication errors. Older systems of measure such as minims for volume (15 minims = 1 ml) and grains for weight (1 grain = 60 mg) are obscure and should not be used. Doses always should be listed by metric weight of active ingredient; doses for liquid medications should include the volume. Writing “μg” for micrograms can very easily be misinterpreted as milligrams (mg). Thus, if abbreviated, micrograms should be written “mcg” and milligrams as “mg”; a zero should be used before a decimal (0.X mg, rather than .X mg) but not after (use X mg rather than X.0 mg). The metric system should be used in place of common household measurements such as “drop-
perful” and “teaspoon” in the directions for the patient, and both the doctor and the pharmacist should be sure that the patient understands the measurement prescribed. For medical purposes, a “teaspoon” or “teaspoonful” dose is considered to be equivalent to 5 ml and a “tablespoon” to 15 ml, but the actual volumes held by ordinary household teaspoons and tablespoons are far too variable to be used reliably for measurement of medications. Prescribing oral medications in “drops” likewise can cause problems when accuracy of dose is important unless the patient understands that only the calibrated dropper provided by the manufacturer or pharmacist should be used to dispense the medication. Thus, one possible dosage for a pediatric iron product would be more accurately written “15 mg (0.6 ml) three times daily” instead of “one dropperful three times daily,” because a true dropperful could result in iron overdose.

Abbreviations are known to lead to dispensing errors (Teichman and Caffee, 2002). A prescription intending every-other-day dosing (qod) may be miswritten as “od” by the physician for “other-day dosing”; the pharmacist will interpret “od” as the abbreviation of the Latin for “right eye.” Once-daily dosing at bedtime (qhs) may be misinterpreted as “qhr” for every hour. The use of slash marks (/) to separate names and doses can result in the incorrect drug or dose being dispensed; the slash mark may be interpreted as a letter or number. When medications are measured in units, or international units, the abbreviation “U” or “IU” must NOT be used, as it leads to errors such as misinterpretation of “U” as zero or four, or “IU” as 10 or 14. The word “unit” should be written as such. Drug products available in the United States that are dosed in units (e.g., corticotropin) or international unit measures are “harmonized” by those responsible for drug standardization to avoid errors in dosing (see Drug Standards and Classification, below). Examples of confusion in the interpretation of a physician order abound (Kohn, 2001) and are considered further below. The critical message is that practitioners in the United States must write out the Rx fully in English if errors are to be avoided.

Proper Patient Information. The patient’s name and address are needed on the order to assure that the correct medication goes to the correct patient and also for identification and recordkeeping purposes. For medications whose dosage involves a calculation, a patient’s pertinent factors such as weight, age, or body surface area also should be listed on the prescription.

Prescribers often commit errors in dosage calculations (Lesar et al., 1997) that can be prevented (Kuperman et al., 2001). When prescribing a drug whose dosage involves a calculation based on body weight or surface area, it is good practice to include both the calculated dose and the dosage formula used, such as “240 mg every 8 hours (40 mg/kg per day)” to allow another health care professional to double-check the prescribed dosage. Pharmacists always should recalculate dosage equations when filling these prescriptions. Medication orders in hospitals and some clinic settings, such as those for antibiotics or antiseizure medications that are sometimes difficult to adequately dose (e.g., phenytoin), can specify the patient diagnosis and desired drug and request dosing by the clinical pharmacist.

All prescriptions should be written in ink; this practice is compulsory for schedule II prescriptions under the Controlled Substances Act of 1970, as erasures on a prescription easily can lead to dispensing errors or diversion of controlled substances.

Prescription pad blanks normally are imprinted with a heading that gives the name of the physician and the address and phone number of the practice site (Figure AI–1). When using institutional blanks that do not bear the physician’s information, the physician always should print his or her name and phone number on the face of the prescription to clearly identify the prescriber and facilitate communication with other health care professionals if questions arise. United States law requires that prescriptions for controlled substances include the name, address, and Drug Enforcement Agency (DEA) registration number of the physician.

The date of the prescription is an important part of the patient’s medical record, and it can assist the pharmacist in recognizing potential problems. For example, when an opioid is prescribed for pain due to an injury, and the prescription is presented to a pharmacist 2 weeks after issuance, the drug may no longer be indicated. Compliance behavior also can be estimated using the dates when a prescription is filled and refilled. The United States Controlled Substances Act requires that all orders for controlled substances (Table AI–1) be dated as of, and signed on, the day issued, and prohibits filling or refilling orders for substances in schedules III and IV more than 6 months after their date of issuance. When writing the original prescription, the physician should designate the number of refills he or she wishes the patient to have. For maintenance medications without abuse potential, it is reasonable to write for a 1-month supply and to mark the prescription form for refills to be dispensed over a period sufficient to supply the patient until the next scheduled visit to the physician. A statement such as “refill pm” (refill as needed) is not appropriate, as it could allow the patient to misuse the medicine or neglect medical appointments. If no refills are
Concern about the rising cost of health care has favored the dispensing of so-called “generic” drugs. A drug is called by its generic name (in the United States this is the U.S. Adopted Name or USAN) or the manufacturer’s proprietary name, called the trademark, trade name, or brand name. In most states in the United States, pharmacists have the authority to dispense generic drugs rather than brand name medications. The physician can request that the pharmacist not substitute a generic for a branded medication by indicating this on the prescription (“do not substitute”), although this is generally unnecessary since the FDA requires that generic medications meet the same bioequivalence standards as their brand-named counterparts. In some jurisdictions, prescriptions may not be filled with a generic substitution unless specifically permitted as stated on the prescription. Occasions when substituting generic medications is discouraged are limited to products with specialized release systems and narrow therapeutic indices, or when substantial patient confusion and potential noncompliance may be associated with substitution.

**Choice of Drug Product.** Inappropriate choice of drugs by physicians has been noted as a problem in prescribing. As learned recently with the cyclooxygenase 2 inhibitors, it cannot be assumed that a drug’s therapeutic promise or popularity is proof of its overall clinical superiority or safety (Topol, 2004). Physicians must rely on unbiased sources when seeking drug information that will influence their prescribing habits.

The amount to be dispensed should be clearly stated and should be only that needed by the patient. Excessive amounts should never be dispensed, as this is not only expensive to the patient, but may lead to accumulation of medicines, which can lead to harm to the patient or members of the patient’s family. It is far better to have several refills of a prescription than to have more than necessary prescribed at one time.

**The Prescription as a Commodity.** Prescribers must be aware that patients may visit their doctor to “get” a prescription. Indeed, in an era when the time spent between physician and patient is ever shorter due to limits and pressures of physician reimbursements, patients often feel that a trip to the doctor that does not result in a new prescription is somehow a failed visit or a lost opportunity. Similarly, physicians may feel that they have fulfilled their role if the patient leaves with a prescription. Physicians must be careful to educate their patients about the

importance of viewing medicines as only to be used when really needed and that remaining on a particular medicine when their condition is stable is far preferable to seeking the newest medications available.

**Prescription Drug Advertising.** The Federal Food, Drug, and Cosmetic Act as amended (Federal Food and Drug Administration Modernization Act of 1997) permits the use of print and television advertising of prescription drugs. The same statute and regulations apply regardless of the audience targeted by a prescription drug advertisement. The law requires that all drug advertisements contain (among other things) information in a brief summary relating to side effects, contraindications, and effectiveness. The current advertising regulations specify that this information disclosure needs to include all the risk information in a product’s approved labeling or must direct consumers to health care professionals to obtain this information. (Typically, print advertisements will include a reprinting of the risk-related sections of the product’s approved labeling [package insert], while television advertising will not.) In addition, advertisements cannot be false or misleading or omit material facts. They also must present a fair balance between effectiveness and risk information. It may be that the dramatizations employed by television commercials are a disservice to the physician’s ability to educate and care for the patient if such advertisements only create brand loyalty. Alternatively, patients who learn about drugs on television may interact more effectively with their health care providers by asking questions about the medicines they take.

The benefits of these types of direct-to-consumer (DTC) advertising, including internet advertising, are controversial (Findlay, 2001). Prescription drug advertising has alerted consumers to the existence of new drugs and the conditions they treat, but it has also increased consumer demand for drugs. This demand has increased the number of prescriptions being dispensed (raising sales revenues) and has contributed to the higher pharmaceutical costs borne by health insurers, government, and consumers. In the face of a growing demand for particular brand name drugs driven by advertising, physicians and pharmacists must be able to counsel patients effectively and provide evidence-based drug information to their patients.

**ERRORS IN DRUG ORDERS**

The Institute of Medicine (IOM) estimates that the number of medical errors in the United States annually that result in death is between 44,000 and 98,000 (Kohn et al., 1999). While there is some controversy about the IOM’s estimates (Sox and Woloshin, 2000), it is clear that the large number of medical errors includes medication errors resulting in adverse events, including death (Mangino, 2004). Databases of anonymously reported errors are maintained jointly by the Institute for Safe Medication Practices (ISMP), the United States Pharmacopeia Medication Errors Reporting Program (USP MERP), and the FDA’s MedWatch program. Adverse drug events occur in approximately 3% of hospitalizations, and this number is larger for special populations such as those in pediatric and neonatal intensive care units (Mangino, 2004).

By examining aspects of prescription writing that can cause errors and by modifying prescribing habits accordingly, the physician can improve the chance that the patient will receive the correct prescription, whether in a hospital or an outpatient setting. By being alert to common problems that can occur with medication orders, and communicating with the patient’s physician, pharmacists and other healthcare professionals can assist in reducing medication errors. Areas of particular concern in the preparation of medication orders in both the institutional and outpatient settings can be summarized as follows:

- All orders should be written using metric measurements of weight and volume.
- Arabic (decimal) numerals are preferable to Roman numerals, and in some instances it is preferable for numbers to be spelled out.
- Use leading zeros (0.125 mg, not .125 mg); never use trailing zeros (5 mg, not 5.0 mg).
- Avoid abbreviating drug names since this leads to numerous errors due to sound-alike names. For instance, NEUMEGA, an interleukin-11 product abbreviated IL-11, can be dispensed as PROLEUKIN, an interleukin-2 derivative, if Roman rather than Arabic numerals are used.
- Avoid abbreviating directions for drug administration; write directions out clearly in English.
- Some drug names sound alike when spoken and may look alike when spelled out. The United States Pharmacopeial Convention Medication Error Reporting Program maintains a current list of drug names that can be confused (http://www.usp.org). The list of alliterative drug names currently contains over 750 pairs of potentially confusing names that could lead to prescribing or dispensing errors harmful to patients. The alliterative drug names can be particularly problematic when giving verbal orders to pharmacists or other healthcare providers.
- The single most important measure to prevent dispensing errors based on sound-alike or look-alike drug names is for the physician to provide the patient’s diag-
nosis on the prescription order. For instance, an order for administration of magnesium sulfate must not be abbreviated “MS,” as this may result in administration of morphine sulfate. Including the therapeutic purpose and/or the patient’s diagnosis can prevent this error.

- Poor handwriting is a well-known and preventable cause of dispensing errors. Both physician and pharmacist share in the responsibility to prevent adverse drug events by writing prescriptions clearly and questioning intent whenever an order is ambiguous or potentially ambiguous.

**CONTROLLED SUBSTANCES**

The Drug Enforcement Agency (DEA), an agency in the Department of Justice, is responsible for the enforcement of the Federal Controlled Substances Act (CSA). The DEA regulates each step of the handling of controlled substances from manufacture to dispensing. The act provides a system that is intended to prevent diversion of controlled substances from legitimate uses. State agencies may impose additional regulations such as requiring that prescriptions for controlled substances be printed on triplicate or state-issued prescription pads or restricting the use of a particular class of drugs for specific indications. The most stringent law always takes precedence, whether it is federal, state, or local. Substances that come under the jurisdiction of the CSA are divided into five schedules (Table AI–1), but practitioners should note that individual states may have additional schedules. Criminal offenses and penalties for misuse generally depend on the schedule of a substance as well as the amount of drug in question.

Physicians must be authorized to prescribe controlled substances by the jurisdiction in which they are licensed and they must be registered with the DEA or exempted from registration as defined under the CSA. The number on the certificate of registration must be indicated on all prescription orders for controlled substances.

**Prescription Orders for Controlled Substances.** To be valid, a prescription for a controlled substance must be issued for a legitimate medical purpose by an individual practitioner acting in the usual course of his or her professional practice. An order that does not meet these criteria, such as a prescription issued as a means to obtain controlled substances for the doctor’s office use or to maintain addicted individuals is not considered a legitimate prescription within the meaning of the law, and thus does not protect either the physician who issued it or the pharmacist who dispensed it. Most states prohibit physicians from prescribing controlled substances for themselves; it is prudent to comply with this guideline even if it is not mandated by law.

**Execution of the Order.** Prescriptions for controlled substances should be dated and signed on the day of their issuance and must bear the full name and address of the patient and the printed name, address, and DEA number of the practitioner and should be signed the way one would sign a legal document. Preprinted orders are not allowed in most states, and presigned blanks are prohibited by federal law. When oral orders are not permitted (schedule II), the prescription must be written with ink or typewritten. The order may be prepared by a member of the physician’s staff, but the prescriber is responsible for the signature and any errors that the order may contain.

**Oral Order.** Prescriptions for schedule III, IV, and V medications may be telephoned to a pharmacy by a physician or by trusted staff in the same manner as a prescription for a noncontrolled substance, although it is in the physician’s best interest to keep his or her DEA number as private as reasonably possible (see Preventing Diversion, below). Schedule II prescriptions may be telephoned to a pharmacy only in emergency situations. To be an emergency: (1) immediate administration is necessary; (2) no appropriate alternative treatment is available; and (3) it is not reasonably possible for the physician to provide a written prescription prior to the dispensing.

For an emergency prescription, the quantity must be limited to the amount adequate to treat the patient during the emergency period, and the physician must have a written prescription delivered to the pharmacy for that emergency within 72 hours. If mailed, the prescription must be postmarked within 72 hours. The pharmacist must notify the DEA if this prescription is not received.

**Refills.** No prescription order for a schedule II drug may be refilled under any circumstance. For schedule III and IV drugs, refills may be issued either orally or in writing, not to exceed five refills or 6 months after the issue date, whichever comes first. Beyond this time, a new prescription must be ordered. For schedule V drugs, no restrictions are placed on the number of refills allowed, but if no refills are noted at the time of issuance, a new prescription must be made for additional drug to be dispensed.

**Preventing Diversion.** Prescription blanks often are stolen and used to sustain abuse of controlled substances and to divert legitimate drug products to the illicit mar-
Drugs are also grouped by their therapeutic category, drug sponsor, reference information, and structure diagram, if available. The USP maintains an electronic Web site that can be accessed for useful drug naming, classification, and standards information (http://www.usp.org).

In the United States, drug products are also coded under the National Drug Code. The NDC System was originally established as an essential part of out-of-hospital drug reimbursement under Medicare. In the United States, the NDC serves as a universal product identifier for drugs used in humans. The current edition of the National Drug Code Directory is limited to prescription drugs and a few selected over-the-counter products. Each drug product listed under the Federal Food, Drug, and Cosmetic Act is assigned a unique 10-digit, 3-segment number. This number, known as the National Drug Code (NDC) number, identifies the labeler/vendor, product, and package size. The labeler code is assigned by the FDA. The second segment, the product code, identifies a specific strength, dosage form, and formulation for a particular drug company. The third segment, the package code, identifies package sizes. Both the product and package codes are assigned by the manufacturer.

In addition to classification of drugs by therapeutic category, drugs are also grouped by control schedule. Drug schedules in the United States are listed in Table AI–I from schedule I to schedule V, and are discussed above as controlled substances. Drugs are also grouped by their potential for misuse under British and United Nations legal classifications as class A, B, or C. The classes are...
linked to maximum legal penalties in a descending order of severity, from A to C.

**COMPLIANCE**

Compliance may be defined as the extent to which the patient follows a regimen prescribed by a healthcare professional. The assumption that the doctor tells the patient what to do and then the patient meticulously follows orders is unrealistic. It must be recognized that the patient is the final and most important determinant of how successful a therapeutic regimen will be and should be engaged as an active participant who has a vested interest in its success. Whatever term is used—compliance, adherence, therapeutic alliance, or concordance—physicians must promote a collaborative interaction between doctor and patient in which each brings an expertise that helps to determine the course of therapy. The doctor is the medical expert; the patient is the expert on himself and his beliefs, values, and lifestyle. The patient’s quality-of-life beliefs may differ from the clinician’s therapeutic goals, and the patient will have the last word every time when there is an unresolved conflict.

Even the most carefully prepared prescription for the ideal therapy will be useless if the patient’s level of compliance is not adequate. Noncompliance may be manifest in drug therapy as intentional or accidental errors in dosage or schedule, overuse, underuse, early termination of therapy, or not having a prescription filled (Hagstrom et al., 2004). Therapeutic failures can result from patient noncompliance (Hobbs, 2004). Noncompliance always should be considered in evaluating potential causes of inconsistent or nonexistent response to therapy.

The reported incidence of patient noncompliance varies widely but is usually in the range of 30% to 60% (Zyczynski and Coyne, 2000); the rate for long-term regimens is approximately 50% and tends to increase over time (Sackett and Snow, 1979). Although they complain about the illogical nature of their patients’ noncompliance, healthcare professionals seem to have as much difficulty as the rest of the population in following health-related orders (Michalsen et al., 1997).

Direct costs associated with noncompliance have been estimated at $8.5 to $50 billion. Hundreds of variables have been identified that may influence compliance behavior in a specific patient or condition. A few of the most frequently cited are discussed here along with some suggestions for improving compliance, although none provides 100% compliance (Table AI–2).

### Table AI–2

<thead>
<tr>
<th>Suggestions for Improving Patient Compliance</th>
</tr>
</thead>
<tbody>
<tr>
<td>Provide respectful communication; ask patient how they take medicine.</td>
</tr>
<tr>
<td>Develop satisfactory, collaborative relationship between doctor and patient; encourage pharmacist involvement.</td>
</tr>
<tr>
<td>Provide and encourage use of medication counseling.</td>
</tr>
<tr>
<td>Give precise, clear instructions, with most important information given first.</td>
</tr>
<tr>
<td>Support oral instructions with easy-to-read written information.</td>
</tr>
<tr>
<td>Simplify whenever possible.</td>
</tr>
<tr>
<td>Use mechanical compliance aids as needed (sectioned pill boxes or trays, compliance packaging, color-coding).</td>
</tr>
<tr>
<td>Use optimal dosage form and schedule for the individual patient.</td>
</tr>
<tr>
<td>Assess patient’s literacy and comprehension and modify educational counseling as needed. Don’t rely on patient knowledge about his or her disease, alone, to improve compliance.</td>
</tr>
<tr>
<td>Find solutions when physical or sensory disabilities are present (use nonsafety caps on bottles, use large type on labels and written material, place tape marks on syringes).</td>
</tr>
<tr>
<td>Enlist support and assistance from family or caregivers.</td>
</tr>
<tr>
<td>Use behavioral techniques such as goal setting, self-monitoring, cognitive restructuring, skills training, contracts, and positive reinforcement.</td>
</tr>
</tbody>
</table>

The Patient–Provider Relationship. Patient satisfaction with the physician has a significant impact on compliance behavior and is one of few factors that the physician can directly influence. Patients are more likely to follow instructions and recommendations when their expectations for the patient–provider relationship and for their treatment are met. These expectations include not only clinical but also interpersonal competence, so cultivating good interpersonal and communication skills is essential.

When deciding upon a course of therapy, it can be useful to discuss a patient’s habits and daily routine as well as the therapeutic options with the patient. This information can help suggest cues for remembrance, such as storing a once-daily medicine atop the books on the bedside
Certain of these variables have been implicated in specific
tion level, intelligence, personality traits, and income.
isolated demographic variables such as age, sex, educa-
cation when the beliefs would suggest poor compliance as
to facilitate the provision of additional or corrective edu-
communication and a good patient–provider relationship
means to exercise a feeling of control over their situation,
tments, a desire to remove themselves from the sick role, a
their therapy, whether for convenience, personal experi-
ate aspects of their therapy may improve compliance, not
only by aiding memory and making the dosage form or
schedule more agreeable or convenient, but also by giving
patients a feeling of empowerment and emphasizing their
responsibility for the treatment outcome.

It is not unreasonable for the physician to ask the
patient whether he or she intends to adhere to the pre-
scribed therapy and to negotiate to get a commitment to
do so. Attempts should be made to resolve collaboratively
any conflicts that may hinder compliance.

Patients and Their Beliefs. Behavioral models suggest
that patients are more likely to be compliant when they
perceive that they are susceptible to the disease, that the
disease may have serious negative impact, that the ther-
apy will be effective, that the benefits outweigh the costs,
and they believe in their own efficacy to execute the ther-
apy. From the standpoint of compliance, the actual severity
of and susceptibility to an illness is not necessarily an
issue; rather, the patient’s perception of severity affects
compliance (Buckalew and Buckalew, 1995). Education
of the patient about his or her condition alone will not
improve compliance (Sackett et al., 1975).

Patients’ beliefs can lead them to deliberately alter
their therapy, whether for convenience, personal experi-
ments, a desire to remove themselves from the sick role, a
means to exercise a feeling of control over their situation,
or other reasons. This reinforces the need for excellent
communication and a good patient–provider relationship
to facilitate the provision of additional or corrective edu-
cation when the beliefs would suggest poor compliance as
an outcome.

It is difficult to predict whether a particular patient will
be compliant, as there is no consistent relationship with
isolated demographic variables such as age, sex, educa-
tion level, intelligence, personality traits, and income.
Certain of these variables have been implicated in specific
situations, but they cannot be applied to the population as
a whole. Social isolation generally has been found to be
associated with poor compliance, although family mem-
bers or other people close to the patient can undermine
compliance as easily as support it. As noted above, the
actual severity of the patient’s disease is not predictive of
compliance behavior, but characteristics of the disease
can make adherence less likely, as with certain neurode-
generative or psychiatric illnesses.

Pharmacists have a legal and professional responsibili-
ty to offer medication counseling in many situations—
even though practice environments are not always condu-
cive to its provision—and can educate and support
patients by discussing prescribed medications and their
use. Because they often see the patient more frequently
than does the physician, pharmacists who take the time to
inquire about a patient’s therapy can help identify compli-
ance and other problems and notify the physician as
appropriate.

Elderly patients often face a number of barriers to
compliance related to their age. Such barriers include
increased forgetfulness and confusion; altered drug dis-
position and higher sensitivity to some drug effects;
decreased social and financial support; decreased dexter-
ity, mobility, or sensory abilities; and an increased num-
ber of concurrent medicines used (both prescription and
over-the-counter), whose attendant toxicities and inter-
actions may cause decreased mental alertness or intoler-
able side effects. There are drugs known to be inappro-
priate to prescribe to elderly patients (Curtis et al., 2004;
Fick et al., 2003) and some that may adversely impact
compliance. Despite these obstacles, evidence does not
show that elderly patients in general are significantly
more noncompliant than any other age group. Still, the
United States population is aging, and elderly patients
consume a disproportionate amount of medicines and
health care resources, so there is great opportunity and
motivation to improve their drug-taking habits. Physi-
cians must be careful in choosing medications for the
elderly (Fick et al., 2003); pharmacists must pay particu-
lar attention to thorough and compassionate counseling
for elderly patients and should assist patients in finding
practical solutions when problems, such as polypharma-
cy, are noted.

The Therapy. Increased complexity and duration of
therapy are perhaps the best-documented barriers to com-
pliance. The patient for whom multiple drugs are pre-
scribed for a given disease or who has multiple illnesses
that require drug therapy will be at higher risk for non-
compliance, as will the patient whose disease is chronic.
The frequency of dosing of individual medications also can affect compliance behavior. Simplification, whenever possible and appropriate, is desirable.

The effects of the medication can make adherence less likely, as in the case of patients whose medicines cause confusion or other altered mental states. Unpleasant side effects from the medicine may influence compliance in some patients but are not necessarily predictive, especially if patient beliefs or other positive factors would tend to reinforce adherence to the regimen. A side effect that is intolerable to one patient may be of minor concern to another.

For most patients the cost of the medicine does not appear to be a major determinant of compliance (Buckalew and Buckalew, 1995), and even receiving free medicine does not guarantee clinically adequate adherence (Chisholm et al., 2000). However, the cost of medicine can be a heavy burden for patients with limited economic resources, and health care providers should be sensitive to this fact. While physicians often state that drug cost is an important factor in prescribing, their actual knowledge about prices is generally low (Reichert et al., 2000), even for products that they commonly prescribe (Hoffman et al., 1995). The availability of this information on hand-held medical PDAs (personal digital assistants) and from dispensing pharmacists now makes it convenient for physicians to include cost as a factor and to permit appropriate generic substitution when choosing therapy for their patients. A number of other useful sources of drug information are detailed in Chapter 5.

BIBLIOGRAPHY

APPENDIX

DESIGN AND OPTIMIZATION OF DOSAGE REGIMENS: PHARMACOKINETIC DATA

Kenneth E. Thummel, Danny D. Shen, Nina Isoherranen, Helen E. Smith

This appendix provides a summary of basic pharmacokinetic information pertaining to drugs that are in common clinical use and are delivered to the systemic circulation by parenteral or nonparenteral administration. Drugs designed exclusively for topical administration and those that are not significantly absorbed into the bloodstream (e.g., ophthalmic and some dermal applications) are not included (see Chapters 62 and 63). Pharmacokinetic data for many older drugs not included in this appendix can be found in earlier editions of this book.

A major objective of this appendix is to present pharmacokinetic data in a format that informs the clinician of the essential characteristics of drug disposition that form the basis of drug-dosage regimen design. Table A–II–1 contains quantitative information about the absorption, distribution, and elimination of drugs and the effects of disease states on these processes as well as information about the correlation of efficacy and toxicity with drug concentrations in blood/plasma. The general principles that underlie the design of appropriate maintenance dose and dosing interval (and, where appropriate, the loading dose) for the average patient are described in Chapter 1. Their application using the data in Table A–II–1 for individualization of dosage regimens is presented here.

To use the data that are presented, one must understand clearance concepts and their application to drug-dosage regimens. One also must know average values of clearance as well as some measures of the extent and kinetics of drug absorption and distribution. The text below defines the eight basic parameters that are listed in the tabular material for each drug and key factors that influence these values both in normal subjects and in patients with renal or liver disease. It obviously would be more straightforward if there were a consensus on a standard value for a given pharmacokinetic parameter; instead, literature estimates usually vary over a wide range, and a consensus set of pharmacokinetic values has been reached for only a limited number of drugs.

In Table A–II–1, a single set of values for each parameter and its variability in a relevant population has been selected from the literature, based on the scientific judgment of the authors. Most data are in the form of a study population mean value ± 1 standard deviation. However, some data are presented as mean and range of values (in parentheses) observed for the study population, i.e., the lowest and highest value reported. There are times when data are reported as a geometric mean with 95% confidence interval. If sufficient data were available, we present a range of mean values obtained from different studies of similar design in parentheses, sometimes below the primary study data. Occasionally, only a single mean value for the study population was available in the literature and is reported as such. Finally, some drugs can be administered intravenously in an unmodified form and orally as a prodrug. When relevant information about both the prodrug and the active molecule are needed, we have included both, using an abbreviation to indicate the species that was measured, followed by another abbreviation in parentheses to indicate the species that was dosed (e.g., G (V) indicates a parameter for ganciclovir after valganciclovir administration).

A number of recently approved drugs are actually the active metabolite or stereoisomer of a previously marketed drug. For example, desloratidine is the O-desmethyl-metabolite of loratidine, and esomeprazole is the active S-enantiomer of omeprazole. Instead of presenting the pair of drugs in separate tables, only the more established or more commonly used drug is listed, and relevant information on its...
alternate active form is presented in the same table. This approach has permitted us to include more drugs in the Appendix, hopefully without undue confusion. The only exception is with prednisone and prednisolone, which undergo inter-conversion in the body. We have also adopted this practice for inclusion of protein-based drugs (e.g., pegfilgrastim and darbepoetin) that have been modified to enhance the pharmacokinetic properties of the originally developed molecule.

Unless otherwise indicated in footnotes, data reported in the table are those determined in healthy adults. The direction of change for these values in particular disease states is noted below the average value. One or more references are provided for each of the established drugs, typically a paper or review on its clinical pharmacokinetics, which can then serve as a source for a broader range of papers for the interested reader. In some instances, we have relied on unpublished data provided by the drug sponsor in their package labeling.

### Tabulated Pharmacokinetic Parameters

Each of the eight parameters presented in Table A–II–1 has been discussed in detail in Chapter 1. The following discussion focuses on the format in which the values are presented as well as on factors (physiological or pathological) that influence the parameters.

**Bioavailability.** The extent of oral bioavailability is expressed as a percentage of the administered dose. This value represents the percent of administered dose that is available to the systemic circulation—the fraction of the oral dose that reaches the arterial blood in an active or prodrug form. Fractional availability ($F$), which appears elsewhere in this appendix, denotes the same parameter; this value varies from 0 to 1. Measures of both the extent and rate (see $T_{\text{max}}$) of availability are presented in the table. The extent of availability is needed for the design of an oral dosage regimen to achieve a specific target blood concentration. Values for multiple routes of administration are provided, when appropriate and available. In most cases, the tabulated value represents an absolute oral bioavailability that has been determined from a comparison of area under the plasma drug concentration time curve between the oral dose and an intravenous reference dose. For those drugs where intravenous administration is not feasible, an approximate estimate of oral bioavailability based on secondary information (e.g., urinary excretion of unchanged drug) is presented, or the column is left blank [denoted by a long dash (—)]. A dash will also appear when a drug is given by parenteral administration only.

A low bioavailability may result from a poorly formulated dosage form that fails to disintegrate or dissolve in the gastrointestinal fluids, degradative loss of drug in the gastrointestinal fluid, poor mucosal permeability, first-pass metabolism during transit through the intestinal epithelium, active efflux transport of drug back into the lumen, and first-pass hepatic metabolism or biliary excretion (see Chapter 1). In the case of drugs with extensive first-pass metabolism, hepatic disease may increase oral availability because hepatic metabolic capacity decreases and/or because vascular shunts develop around the liver.

**Urinary Excretion of Unchanged Drug.** The second parameter in Table A–II–1 is the amount of drug eventually excreted unchanged in the urine, expressed as a percentage of the administered dose. Values represent the percentage expected in a healthy young adult (creatinine clearance ≥ 100 ml/minute). When possible, the value listed is that determined after bolus intravenous administration of the drug, for which bioavailability is 100%. If the drug is given orally, this parameter may be underestimated due to incomplete absorption of the dose; such approximated values are indicated with a footnote. The parameter obtained after intravenous dosing is of greater utility because it reflects the relative contribution of renal clearance to total body clearance irrespective of bioavailability.

Renal disease is the primary factor that causes changes in this parameter. This is especially true when alternate pathways of elimination are available; thus, as renal function decreases, a greater fraction of the dose is available for elimination by other routes. Because renal function generally decreases as a function of age, the percentage of drug excreted unchanged also decreases with age when alternate pathways of elimination are available. In addition, for a number of weakly acidic and basic drugs with $pK_a$ values within the normal range for urine pH, changes in urine pH will affect their rate or extent of urinary excretion (see Chapter 1).

**Binding to Plasma Proteins.** The tabulated value is the percentage of drug in the plasma that is bound to plasma proteins at concentrations of the drug that are achieved clinically. In almost all cases, the values are from measurements performed in vitro (rather than from ex vivo measurements of binding to proteins in plasma obtained from patients to whom the drug had been administered). When a single mean value is presented, it signifies that there is no apparent change in percent bound over the range of plasma drug concentrations resulting from the usual clinical doses. In cases in which saturation of binding to plasma proteins is
approached within the therapeutic range of plasma drug concentrations, a range of bound percentages is provided for concentrations at the lower and upper limits of the range. For some drugs, there is disagreement in the literature about the extent of plasma protein binding; in those cases, the range of reported values is given.

Plasma protein binding is affected primarily by disease states, notably hepatic disease, renal failure, and inflammatory diseases, that alter the concentration of albumin, α1-acid glycoprotein, or other proteins in plasma that bind drugs. Uremia also changes the binding affinity of albumin for some drugs. Disease-induced changes in plasma protein binding can dramatically affect the volume of distribution, clearance, and elimination half-life of a drug.

**Plasma Clearance.** Total systemic clearance of drug from plasma or blood [see Equations (1–5) and (1–6), Chapter 1] is given in Table A–II–1. Clearance varies as a function of body size and, therefore, is presented most frequently in the table in units of ml · min⁻¹ · kg⁻¹ of body weight. Normalization to measures of body size other than weight may at times be more appropriate, such as normalization to body surface area in infants to better reflect the growth and development of the liver and kidneys. However, weight is easy to obtain, and its use often offsets any small loss in accuracy of clearance estimate, especially in adults. Exceptions to this rule are the anticancer drugs, for which dosage normalization to body surface area is conventionally used. When unit conversion was necessary, we used individual or mean body weight or body surface area (when appropriate) from the cited study, or if this was not available, we assumed a body mass of 70 kg or a body surface area of 1.73 m² for healthy adults.

In some cases, separate values for renal and nonrenal clearance also are provided. For some drugs, particularly those that are excreted predominantly unchanged in the urine, equations are given that relate total or renal clearance to creatinine clearance (also expressed as ml · min⁻¹ · kg⁻¹). For drugs that exhibit saturation kinetics, \( K_m \) and \( V_{max} \) are given and represent, respectively, the plasma concentration at which half of the maximal rate of elimination is reached (in units of mass/volume) and the maximal rate of elimination (in units of mass-time⁻¹·kg⁻¹ of body weight). \( K_m \) must be in the same units as the concentration of drug in plasma (\( C_p \)).

Intrinsic clearance from blood is the maximal possible clearance by the organ responsible for elimination when blood flow (delivery) of drug is not limiting. When expressed in terms of unbound drug, intrinsic clearance reflects clearance from intracellular water. Intrinsic clearance is tabulated for a few drugs. It is also mathematically related to the biochemical intrinsic clearance \( [V_{max} / (K_m + C)] \) determined *in vitro*. In almost all cases, clearances based on plasma concentration data are presented in Table A–II–1, because drug analysis is most often performed on plasma samples. The few exceptions where clearance from blood is presented are indicated by footnote. Clearance estimates based on blood concentration may be useful when a drug concentrates in the erythrocytes.

To be accurate, clearances must be determined after intravenous drug administration. When only nonparenteral data are available, the ratio of \( CL/F \) is given; values offset by the fraction availability (\( F \)) are indicated in a footnote. When a drug, or its active isomer for racemic compounds, is a substrate for a CYP or drug transporter, this information is provided in a footnote. This information is becoming increasingly important to understand pharmacokinetic variability due to genetic polymorphisms and to predict metabolically based drug-drug interactions. [For more extensive coverage of this topic, see Chapters 2, 3, and 4 and *Metabolic Drug Interactions*. (Levy, R.H., *et al.*, eds.) Lippincott Williams & Wilkins, Philadelphia, 2000.]

**Volume of Distribution.** The total body volume of distribution at steady state (\( V_{ss} \)) is given in Table A–II–1 and is expressed in units of l/kg or in units of l/m² for some anticancer drugs. Again, when unit conversion was necessary, we used individual or mean body weights or body surface area (when appropriate) from the cited study, or if such data were not available, we assumed a body mass of 70 kg or a body surface area of 1.73 m² for healthy adults.

When estimates of \( V_{ss} \) were not available, values for \( V_{area} \) were provided. \( V_{area} \) represents the volume at equilibrated distribution during the terminal elimination phase (see Equation 1-12). Unlike \( V_{ss} \), this volume term varies when drug elimination changes, even though there is no change in the distribution space. Because we may wish to know whether a particular disease state influences either the clearance or the tissue distribution of the drug, it is preferable to define volume in terms of \( V_{ss} \), a parameter that is theoretically independent of changes in the rate of elimination. Occasionally, the condition under which the distribution volume was obtained was not specified in the primary reference; this is denoted by the absence of a subscript.

As with clearance, \( V_{ss} \) usually is defined in the table in terms of concentration in plasma rather than blood. Further, if data were not obtained after intravenous administration of the drug, a footnote will make clear that the
Half-life. Half-life ($t_1$) is the time required for the plasma concentration to decline by one-half when elimination is first-order. It also governs the rate of approach to steady state and the degree of drug accumulation during multiple dosing or continuous infusion. For example, at a fixed dosing interval, the patient will be at 50% of steady state after one half-life, 75% of steady state after two half-lives, 93.75% of steady state after four half-lives, etc. Determination of half-life is straightforward when drug elimination follows a monoexponential pattern (i.e., one-compartment model). However, for a number of drugs, plasma concentration follows a multieponential pattern of decline over time. The mean value listed in Table A–II–1 corresponds to an effective rate of elimination that covers the clearance of a major fraction of the absorbed dose from the body. In many cases, this half-life refers to the rate of elimination in the terminal exponential phase. For a number of drugs, however, the half-life of an earlier phase is presented, even though a prolonged half-life may be observed at very low plasma concentrations when extremely sensitive analytical techniques are used. If the latter component accounts for 10% or less of the total area under the plasma concentration-time curve ($AUC$), predictions of drug accumulation in plasma during continuous or repetitive dosing will be in error by no more than 10% if this longer half-life is ignored. The clinician should know the half-life that will best predict drug accumulation in the patient, which will be the appropriate half-life to use for estimating the rate constant in Equations (1–19) through (1–21) (see Chapter 1) to predict time to steady state. It is this half-life of accumulation during multiple dosing that is given in Table A–II–1.

Half-life is usually independent of body size because it is a function of the ratio of two parameters, clearance and volume of distribution, each of which is proportional to body size. It should also be noted that the half-life is preferably obtained from intravenous studies, if feasible, because the half-life of decline in plasma drug concentration after oral dosing can be influenced by prolonged absorption, such as when slow release formulations are given. If the half-life is derived from an oral dose, this will be indicated in a footnote of Table A–II–1.

Time to Peak Concentration. Because clearance concepts are used most often in the design of multiple dosage regimens, the extent rather than the rate of availability is more critical to estimate the average steady-state concentration of drug in the body. In some circumstances, the degree of fluctuation in plasma drug concentration, i.e., peak and trough concentrations, which govern drug efficacy and side effects, can be greatly influenced by modulation of drug absorption rate through the use of sustained- or extended-release formulations. Controlled-release formulations often permit a reduction in dosing frequency from 3 or 4 times daily to once or twice daily. There also are drugs that are given on an acute basis, e.g., for the relief of breakthrough pain or to induce sleep, for which the rate of drug absorption is a critical determinant of onset of effect. Thus, information about the expected average time to achieve maximal plasma or blood concentration and the degree of interindividual variability in that parameter have been included in Table A–II–1.

The time required to achieve a maximal concentration ($T_{\text{max}}$) depends on the rate of drug absorption into blood from the site of administration and the rate of elimination. From mass balance principles, $T_{\text{max}}$ occurs when the rate of absorption equals the rate of elimination from the reference compartment. Prior to this time, absorption rate exceeds elimination rate, and the plasma concentration of drug increases. After the peak is reached, elimination rate exceeds the absorption rate and, at some point, defines the terminal elimination phase of the concentration-time profile.

The rate of drug absorption following oral administration will depend on the formulation and physicochemical properties of the drug, its permeability across the mucosal barrier, and the intestinal villous blood flow. For an oral dose, some absorption may occur very rapidly within the buccal cavity, esophagus, and stomach, or absorption may be delayed until the drug reaches the small intestine or until the local pH in the intestine permits drug release from the dosage formulation. In the most extreme case, the rate of absorption can be sufficiently controlled by the drug formulation to permit sustained or extended delivery as the dosage form traverses the entire length of the gastrointestinal tract. In some instances, the terminal elimination of drug from the body following a peak concentration reflects the slower rate of absorption and not elimination.

When more than one type of drug formulation is available commercially, we have provided absorption information for both the immediate- and sustained-release formulations. Not surprisingly, the presence of food in the gastrointestinal tract can alter both the rate and extent of drug availability. We have indicated with footnotes when the consumption of food near the time of drug ingestion may have a significant effect on the drug bioavailability.

Peak Concentration. There is no general agreement about the best way to describe the relationship between the concentration of drug in plasma and its effect. Many different kinds of data are present in the literature, and use of a single effect parameter or effective concentration is difficult. This is particularly true for antimicrobial agents...
because the effective concentration depends on the identity of the microorganism causing the infection. It also is important to recognize that concentration-effect relationships are most easily obtained at steady state or during the terminal log-linear phase of the concentration-time curve, when the drug concentration(s) at the site(s) of action are expected to parallel those in plasma. Thus, when attempting to correlate a blood or plasma level to effect, the temporal aspect of distribution of drug to its site of action must be taken into account.

Despite these limitations, it is possible to define the minimum effective or toxic concentrations for some of the drugs currently in clinical use. However, in reviewing the list of drugs approved within the last five years, it is rare to find a declaration of an effective concentration range, even in the manufacturer’s package labeling. Thus, it is necessary to infer therapeutic concentrations from concentrations observed following effective dosage regimens. For a given dosage regimen, a time-averaged steady-state blood or plasma concentration (i.e., \( C_{ss} \) as estimated by dividing the mean \( AUC \) by the duration of the dosing interval) and the associated interindividual variability might be one appropriate parameter to report; however, such data often are not available. Also, \( C_{ss} \) does not take into account the onset and offset of effect during fluctuation of plasma drug concentration over a dosing interval.

In some instances, drug efficacy may be more closely linked with peak concentration than with the average or trough concentration, and differences in peak concentration for special populations (e.g., elderly) sometimes are associated with increased incidence of drug toxicity.

For practical reasons, the most commonly reported parameter, \( C_{\text{max}} \) (peak concentration), is presented in Table A–II–1, rather than effective or toxic concentrations. This provides a more consistent body of information about drug exposure from which one can infer, if appropriate, efficacious or toxic blood levels. While the value reported is the highest that would be encountered in a given dose interval, \( C_{\text{max}} \) can be related to the trough concentration (\( C_{\text{min}} \)) through appropriate mathematical predictions (see Equation 1–21). Because peak levels will vary with dose, we have attempted to present concentrations observed with a customary dose regimen that is recognized to be effective in the majority of patients. When a higher or lower dose rate is used, the expected peak level can be adjusted by assuming dose proportionality, unless nonlinear kinetics are indicated. In some instances, only limited data pertaining to multiple dosing are available, so single-dose peak concentrations are presented. When specific information is available about an effective therapeutic range of concentrations or about concentrations at which toxicity occurs, it has been incorporated in a footnote. For individual drugs, the reader also is referred to the index to highlight pages where more detailed information is provided.

It is important to recognize that significant differences in \( C_{\text{max}} \), will occur when comparing similar daily-dose regimens for an immediate-release and sustained-release product. Indeed, the sustained-release product sometimes is administered to reduce peak-trough fluctuations during the dosing interval and to minimize swings between potentially toxic or ineffective drug concentrations. Again, we report \( C_{\text{max}} \) for both immediate-release and extended-release formulations, when available. In addition to parent drug concentrations, we have included information on any active metabolite that circulates at a concentration that may contribute to the overall pharmacological effect, particularly those active metabolites that accumulate with multiple dosing. Likewise, for chiral drugs whose stereoisomers differ in their pharmacological activity and clearance characteristics, we present information on the pharmacokinetics of the individual enantiomers or the active enantiomer that contributes most to the drug’s efficacy.

Although total drug or metabolite concentrations are reported, it is important to recognize that the concentration of unbound drug often determines the degree of pharmacological effect. Accordingly, changes in protein binding due to disease may be expected to cause changes in the total plasma concentration associated with desired or unwanted effects. However, the clinical outcome is not always affected because an increase in free fraction will also increase the apparent clearance of an orally administered drug and of a low extraction drug dosed intravenously. Under such a scenario, the mean unbound plasma concentration at steady state will not change with reduced or elevated plasma protein binding, despite a significant change in mean total drug concentration.

---

**ALTERATIONS OF PARAMETERS IN THE INDIVIDUAL PATIENT**

Dose adjustments for an individual patient should be made according to the manufacturer’s recommendation in the package labeling when available. This information is generally available when disease, age, or race has a significant impact on drug disposition, particularly for drugs that have been introduced within the last 10 years. In some cases, a significant difference in drug disposition from the “average” adult can be expected but may not
require dose adjustment because of a sufficiently broad therapeutic index. In other cases, dose adjustment may be necessary, but no specific information is available. Under these circumstances, an estimate of the appropriate dosing regimen can be obtained based on pharmacokinetic principles described in Chapter 1.

Unless otherwise specified, the values in Table A–II–2 represent mean values for populations of normal adults; it may be necessary to modify them for calculation of dosage regimens for individual patients. The fraction available (F) and clearance (CL) also must be estimated to compute a maintenance dose necessary to achieve a desired average steady-state concentration. To calculate the loading dose, knowledge of the volume of distribution is needed. The estimated half-life is used in deciding a dosing interval that provides an acceptable peak-trough fluctuation; note, this may be the apparent half-life following dosing of a slowly absorbed formulation. The values reported in the table and the adjustments apply only to adults; exceptions are footnoted. Although the values at times may be applied to children who weigh more than about 30 kg (after proper adjustment for size; see below), it is best to consult pediatrics textbooks or other sources for definitive advice.

For each drug, changes in the parameters caused by certain disease states are noted within the eight segments of the table. In all cases, the qualitative direction of changes is noted, such as ↓LD, which indicates a significant decrease in the parameter in a patient with liver disease. The relevant literature and the package label should be consulted for more definitive, quantitative information for dosage adjustment recommendations.

**Plasma Protein Binding.** Most acidic drugs that are extensively bound to plasma proteins are bound to albumin. Basic lipophilic drugs, such as propranolol, often bind to other plasma proteins (e.g., α₅-acid glycoprotein and lipoproteins). The degree of drug binding to proteins will differ in pathophysiological states that cause changes in plasma-protein concentrations. Significant pharmacokinetic effects from a change in plasma protein binding will be denoted under clearance or volume of distribution.

**Clearance.** For drugs that are partly or predominantly eliminated by renal excretion, plasma clearance changes in accordance with the renal function of an individual patient. This necessitates dosage adjustment that is dependent on the fraction of normal renal function remaining and the fraction of drug normally excreted unchanged in the urine. The latter quantity appears in the table; the former can be estimated as the ratio of the patient’s creatinine clearance (CLₐ) to a normal value (100 ml/minute per 70 kg body weight). If urinary creatinine clearance has not been measured, it may be estimated from the concentration of creatinine in serum (Cₐ). In men:

\[ CL_{cr}(\text{ml} \cdot \text{min}^{-1}) = \frac{[140 - \text{age (yr)}] \cdot [\text{weight (kg)}]}{72 \cdot [CL_{cr}(\text{mg/dl})]} \]  

(A–1)

For women, the estimate of \( CL_{cr} \) by the above equation should be multiplied by 0.85 to reflect their smaller muscle mass. The fraction of normal renal function \( (rfx_{pt}) \) is estimated from the following:

\[ rfx_{pt} = \frac{CL_{cr, pt}}{100 \text{ ml} \cdot \text{min}^{-1}} \]  

(A–2)

A more accurate measure of \( rfx_{pt} \) is seldom necessary because, given the considerable degree of interindividual variation in nonrenal clearance, the adjustment of clearance is an approximation. The following equation for adjustment of clearance uses the quantities discussed:

\[ rfx_{pt} = 1 - [fe_{nl} \cdot (1 - rfx_{pr})] \]  

(A–3)

where \( fe_{nl} \) is the fraction of systemic drug excreted unchanged in normal individuals (see Table A–II–1). The renal factor \( (rf_{pr}) \) is the value that, when multiplied by normal total clearance \( (CL_{pr}) \) from the table, gives the total clearance of the drug adjusted for the impairment in renal function.

**Example.** The clearance of vancomycin in a patient with reduced renal function (creatinine clearance = 25 ml/min per 70 kg) may be estimated as follows:

\[ rfx_{pt} = \frac{25 \text{ ml/min}}{100 \text{ ml/min}} = 0.25 \]

\[ fe_{nl} = 0.79 \text{ (see listing for vancomycin)} \]

\[ rf_{pr} = 1 - [0.79 \cdot (1 - 0.25)] = 0.41 \]

\[ CL_{pr} = (1.4 \text{ ml/minute per kg}) \cdot 0.41 = 0.57 \text{ ml/minute per kg} \]

Importantly, such a clearance adjustment should be regarded only as an initial step in optimizing the dosage regimen; depending on the patient’s response to the drug, further individualization may be necessary.

Conventionally, clearance is adjusted for the size of the patient to reflect a difference in the mass of the eliminating organ. For orally administered drugs, the applicability of such an adjustment may be limited by the available dosage strengths of commercial formulations. In some cases, scored tablets can be split or commercial tablet splitters are used to increase the range of available dosage strengths. However, this practice should be followed only with the recommendation of the drug manufacturer.
because splitting a tablet sometimes can compromise the bioavailability of a product.

With the exception of certain oncolytic agents, the data presented in the table are normalized to weight. Thus, interindividual variability in the weight-normalized clearance reflects a variation in the intrinsic metabolic or transport clearance and not the size of the organ. Further, these differences can be attributed to variable expression/function of metabolic enzymes or transporters. However, it is important to recognize that liver mass and total enzyme/transporter content may not increase or decrease in proportion to weight in obese or malnourished individuals. Alternative approaches such as normalization by body surface area or other measures of body mass may be more appropriate. For example, many of the drugs used to treat cancer are dosed according to body surface area (see Chapter 51). In the tabulation, if the literature reported dose per body surface area, we present the data in the same unit. If the cited clearance data were not normalized, but the preponderance of the literature utilized body surface area, we followed the practice of using values of body surface area from the literature source or a standard of 1.73 m² for a healthy adult.

**Volume of Distribution.** Volume of distribution should be adjusted for the modifying factors indicated in Table A–II–1 as well as for body size. Again, the data in the table most often are normalized to weight. Unlike clearance, volume of distribution in an individual is most often proportional to weight itself. Whether this applies to a specific drug depends on the actual sites of distribution of drug; no absolute rule applies.

Whether or not to adjust volume of distribution for changes in binding to plasma proteins cannot be decided in general; the decision depends critically on whether or not the factors that alter binding to plasma proteins also alter binding to tissue proteins. Qualitative changes in volume of distribution, when they occur, are indicated in the table.

### Half-Life

Half-life may be estimated from the adjusted values of clearance \( (CL_{pt}) \) and volume of distribution \( (V_{pt}) \) for the patient:

\[
t_{\frac{1}{2}} = \frac{0.693 \cdot V_{pt}}{CL_{pt}}
\]

Because half-life has been the parameter most often measured and reported in the literature, qualitative changes for this parameter are almost always given in the table.

### INDIVIDUALIZATION OF DOSAGE

By using the parameters for the individual patient, calculated as described above, initial dosing regimens may be chosen. The maintenance dosage rate may be calculated with Equation (1–18) using the estimated values for \( CL \) and \( F \) for the individual patient. As described above, the target concentration may have to be adjusted for changes in plasma protein binding in the patient, as described above. The loading dose may be calculated using Equation (1–22) and estimates for \( V_{ss} \) and \( F \). A particular dosing interval may be chosen; the maximal and minimal steady-state concentrations can be calculated by using Equations (1–20) and [(1–19) or (1–21)], and these can be compared with the known efficacious and toxic concentrations for the drug. As with the target concentration, these values may need to be adjusted for changes in the extent of plasma protein binding. Use of Equations (1–19) and (1–20) also requires estimates of values for \( F, V_{ss} \), and \( K \) \((K = 0.693/t_{\frac{1}{2}})\) for the individual patient.

Note that these adjustments of pharmacokinetic parameters for an individual patient are suggested for the rational choice of initial dosing regimen. As indicated in Chapter 1, steady-state measurement of drug concentrations in the patient then can be used as a guide to further adjust the dosage regimen. However, optimization of a dosage regimen for an individual patient ultimately will depend on the clinical response produced by the drug.

<sup>a</sup>Data for amphotericin B shown. Also formulated by liposomal encapsulation (ABELCET and AMBISOME); the distribution and CL properties of these products are different from the nonencapsulated form; a terminal t<sub>1</sub> of 173 ± 78 and 110 to 153 hours, respectively; however, an effective steady-state concentration can be achieved within 4 days. <sup>b</sup>Data for eight children (age 8 months to 14 years) yield a linear regression with CL decreasing with age: CL = −0.046 · age (years) + 0.86. Newborns show highly variable CL values. <sup>c</sup>Volume of central compartment. V<sub>c</sub> increases with dose from 3.4 l/kg for single 0.25 mg/kg doses to 8.9 l/kg for 1.5 mg/kg doses. <sup>d</sup>t<sub>1/2</sub> for multiple dosing. In single-dose studies, a prolonged dose-dependent t<sub>1/2</sub> is seen. <sup>e</sup>Following 0.5 mg/kg IV dose of amphotericin B given as a 1-hour infusion, once daily for 3 days. Whole blood concentrations (free and liposome encapsulated) of 1.7 ± 0.8 μg/ml and 83 ± 35 μg/ml were reported following a 5 mg · kg⁻¹ · day⁻¹ IV dose (presumed 60- to 120-min infusion) of ABELCET and AMBISOME, respectively.

<sup>a</sup>Benazepril (B) is a prodrug for the active metabolite, benazeprilat (BT). Minimum bioavailability of BT based on urinary recovery data.  
<sup>b</sup>Data for active metabolite; terminal <i>t</i><sub>1/2</sub> ~22 hours.  
<sup>c</sup>Following an oral dose of benazepril. BT is cleared by renal and biliary excretion.  
<sup>d</sup>CL/F and V<sub>area/F</sub> reported.  
<sup>e</sup>Following a single 10 mg oral dose given to healthy adults.  
<i>C</i><sub>max</sub> calculated from original data assuming a plasma density of 1 g/ml.

<sup>a</sup>Data from male and female subjects undergoing surgery. Bupropion is metabolized in the liver by both oxidative (N-dealkylation) and conjugative pathways.  
<sup>b</sup>CL, 60 ± 19 ml·min⁻¹·kg⁻¹; V<sub>ss</sub>, 3.2 l/kg; t<sub>1</sub>, 1.03 ± 0.22 hour; children 4 to 7 years of age.  
<sup>c</sup>Following a 0.3 mg IM, 4 mg sublingual (SL), 4 mg buccal (BC) dose.
**Bupropion**

*Data from healthy adult male volunteers. Bupropion appears to undergo extensive first-pass metabolism by CYP2B6 and other CYP isozymes. Some metabolites accumulate in blood and are active. *CL/F*, *Vss/F*, and *t1* reported for oral dose. Mean terminal *t1* from four different studies shown in parentheses. *CL/F* reduced, alcoholic liver disease. *CL/F* reduced, hepatic cirrhosis. Following a single 100 mg immediate release (IR) or 150 mg sustained release (SR) dose.

**References:**

**Buspirone**

*Data from healthy adult male subjects. No significant gender differences. Undergoes extensive CYP3A-dependent first-pass metabolism. The major metabolite (1-pyrimidinyl piperazine) is active in some behavioral tests in animals (one-fifth potency) and accumulates in blood to levels severalfold higher than buspirone. Bioavailability increased ~84%; appears to be secondary to reduced first-pass metabolism. *CL/F* reduced, mild renal impairment; unrelated to *CLcr*.

<sup>a</sup>A metabolite, carbamazepine-10,11-epoxide, is equipotent in animal studies. Its formation is catalyzed primarily by CYP3A and secondarily by CYP2C8. <sup>b</sup>Data from oral, multiple-dose regimen; values are CL/F and V<sub>area</sub>/F. <sup>c</sup>Data from multiple-dose regimen. Carbamazepine induces its own metabolism; for a single dose, CL/F = 0.36 ± 0.07 ml·min⁻¹·kg⁻¹ and t<sub>1/2</sub> = 36 ± 5 hours. CL also increases with dose. <sup>d</sup>Mean (range) steady-state concentration following a daily 18.4-mg/kg oral dose (immediate release) given to adult patients with epilepsy. Therapeutic range for control of psychomotor seizures is 4–10 μg/ml.

<sup>a</sup>Data from healthy subjects. Cleared primarily by CYP2C9 (polymorphic). <sup>b</sup>High-fat meal. Absolute bioavailability is unknown. <sup>c</sup>CL/F reduced, mild or moderate hepatic impairment. <sup>d</sup>CL/F increased, moderate renal impairment, but unrelated to CL<sub>cr</sub>. <sup>e</sup>Following a single 200 mg oral dose.

Active metabolite, desethylchloroquine, accounts for 20 ± 3% of urinary excretion; \( t_1 = 15 \pm 6 \) days. Racemic mixture; kinetic parameters for the two isomers are slightly different [e.g., mean residence time = 16.2 days and 11.3 days for the (R)-isomer and (S)-isomer, respectively].

Range of mean values from different studies (IV administration). \(^a\) Concentrates in red blood cells. Blood-to-plasma concentration ratio for racemate = 9. \(^a\) A longer \( t_1 \) (41 ± 14 days) has been reported with extended blood sampling. \(^c\) Following a single 300 mg IV (24 minute infusion) of chloroquine HCl, or IM or oral dose of chloroquine phosphate given to healthy adults. Effective concentrations against *Plasmodium vivax* and *Plasmodium falciparum* are 15 ng/ml and 30 ng/ml, respectively. Diplopia and dizziness can occur above 250 ng/ml.

**Range of mean values from different studies (IV administration).**

\(^a\) Administered as a racemic mixture; reported parameters are for racemic drug. Activity comes predominantly from S-(+) enantiomer, which has a 60% longer \( t_1 \) than the R-(–) enantiomer.

Renal elimination increases with increased urine flow and lower pH. \(^c\) Following a single 300 mg IV (24 minute infusion) of chloroquine HCl, or IM or oral dose of chloroquine phosphate given to healthy adults. Effective concentrations against *Plasmodium vivax* and *Plasmodium falciparum* are 15 ng/ml and 30 ng/ml, respectively. Diplopia and dizziness can occur above 250 ng/ml.

### CHLORPROMAZINE\(^a\) (Chapters 18, 37)

<table>
<thead>
<tr>
<th>Parameter</th>
<th>Value</th>
<th>Range</th>
<th>Mean Residence Time</th>
<th>Mode of Administration</th>
</tr>
</thead>
</table>
| Active metabolites, 7-hydroxychlorpromazine (\( t_1 = 25 \pm 15 \) hours) and possibly chlorpromazine N-oxide, yield AUCs comparable to the parent drug (single doses). \(^a\) After single dose. Bioavailability may decrease to about 20% with repeated dosing. \(^c\) Following a 100 mg oral dose given twice a day for 33 days to adult patients. Neurotoxicity (tremors and convulsions) occurs at concentrations of 750–1000 ng/ml.

### CHLORTHALIDONE (Chapter 28)

</tbody>
</table>

**Range of mean values from different studies (IV administration).**

\(^a\) Value is for 50 and 100 mg doses; renal \( CL \) is decreased at an oral dose of 200 mg, and there is a concomitant decrease in the percentage excreted unchanged. \(^b\) Chlorthalidone is sequestered in erythrocytes. \( t_1 \) is longer if blood, rather than plasma, is analyzed. Parameters reported based on blood concentrations. \(^c\) Following a single 50 mg oral dose (tablet) given to healthy male adults.

| ↑ Food | ↓ LD | ↓ LD | ↑ LD | ↑ LD |

<sup>a</sup>Data from patients with HIV infection and positive for CMV. Cidofovir is activated intracellularly by phosphokinases. For parenteral use. <sup>b</sup>Parameters reported for a dose given in the presence of probenecid. <sup>c</sup>CL reduced, mild renal impairment (cleared by high flux hemodialysis). <sup>d</sup>Following a single 5 mg/kg IV infusion given over 1 hour, with concomitant oral probenecid and active hydration.

<sup>a</sup>Patients with peptic ulcer disease. <sup>b</sup>Following a single 400 mg oral dose given after an overnight fast to healthy adults. A second peak (2 to 4 hours) is often observed when cimetidine is given after fasting but not when given with food. A concentration of 0.5–0.9 μg/ml will suppress >80% of basal acid secretion and >50% of food or gastrin-stimulated secretion and will maintain gastric pH ≥4 in patients with active peptic ulcer disease.

<sup>a</sup>Cinacalcet is a chiral molecule; the R-enantiomer is more potent than the S-enantiomer and is thought to be responsible for the drug’s pharmacological activity. Cinacalcet is metabolized primarily by CYP3A4, CYP2D6, and CYP1A2. <sup>b</sup>Unreported, but presumably negligible. <sup>c</sup>Following a single 75 mg oral dose.

<sup>a</sup>Citalopram is available either as a racemic mixture or as the pure active S-enantiomer escitalopram. Pharmacokinetic data after dosing of the racemate (Rac) and escitalopram (Es) are reported. No significant gender differences. Citalopram is metabolized by CYP2C19 (polymorphic) and CYP3A4 to desmethylcitalopram. <sup>b</sup>Data from CYP2C19 extensive metabolizers. CYP2C19 poor metabolizers exhibit a lower (~ 44%) CL/F and longer t<sub>1/2</sub> than extensive metabolizers. <sup>c</sup>CL/F and V/F for escitalopram reported. <sup>d</sup>Alcoholic, viral, or biliary cirrhosis. <sup>e</sup>Moderate renal impairment. <sup>f</sup>Following a single 40 mg (Rac) or 20 mg (Es) oral dose.

<sup>a</sup>Amphetamine is available as a racemate (Rac), dextro-isomer (Dextro), and a mixture of the two, in both immediate- and extended-release formulations. Pharmacokinetic data on both racemic and dextroamphetamine are presented.  
<sup>b</sup>Absolute bioavailability not reported; > 55% based on urine recovery of unchanged drug under acidic urine pH conditions.  
<sup>c</sup>Measured under uncontrolled urinary pH condition. Renal CL of amphetamine is dependent on urine pH. Acidification of urine results in increased urinary excretion, up to 55%.  
<sup>d</sup>CL/F and t<sub>1/2</sub> following oral dose to adults is reported.  
<sup>e</sup>t<sub>1/2</sub> in children reported.  
<sup>f</sup>Following a 20 mg immediate-release oral dose given once daily for more than a week. An extended-release formulation consisting of a mixture of dextroamphetamine and amphetamine salts (ADDERALL XR<sup>®</sup>) exhibits a delayed t<sub>max</sub> of ~7 hours.

<sup>a</sup>LANOXIN tablets; digoxin solutions, elixirs, and capsules may be absorbed more completely. <sup>b</sup>Equation applies to patients with some degree of heart failure. If heart failure is not present, the coefficient of CL<sub>cr</sub> is 1.0. Units of CL<sub>cr</sub> must be ml·min<sup>–1</sup>·kg<sup>–1</sup>. <sup>c</sup>In the occasional patient, digoxin is metabolized to an inactive metabolite, dihydrodigoxin, by gut flora. This results in a reduced oral bioavailability. <sup>d</sup>Following an oral dose of 0.31 ± 0.19 mg/day or 0.36 ± 0.19 mg/day in patients with congestive heart failure who exhibited no signs of digitalis toxicity (NT) or signs of toxicity (T), respectively. Concentrations >0.8 ng/ml are associated with inotropic effect. Concentrations of 1.7, 2.5, and 3.3 ng/ml are associated with a 10%, 50%, and 90% probability of digoxin-induced arrhythmias, respectively.

<sup>a</sup>Active metabolites, desacetyldiltiazem ($t_1/2 = 9 ± 2$ hours) and $N$-desmethyldiltiazem ($t_1/2 = 7.5 ± 1$ hours). Formation of desmethyl metabolite (major pathway of CL) catalyzed primarily by CYP3A. <sup>b</sup>More than a twofold decrease with multiple dosing. <sup>c</sup>$t_1/2$ for oral dose is 5 to 6 hours; does not change with multiple dosing. <sup>d</sup>Following single 120 mg oral dose to healthy adults.

**DONEPEZIL**

| Data from young, healthy male and female subjects. No significant gender differences. Metabolized by CYP2D6, CYP3A4, UGT. Absolute bioavailability is unknown, but the oral dose is reportedly well absorbed. A f<sub>s</sub> of 96% has also been reported. CL/F, V<sub>ss</sub>/F, and t<sub>1/2</sub> reported for oral dose. A CL/F reduced slightly (~20%), alcoholic cirrhosis. Following a 5 mg oral dose given once daily to steady state. |

| DOXEPIN |

| Active metabolite, desmethyldoxepin, has a longer t<sub>1/2</sub> (37 ± 15 hours). Calculated from results of oral administration only, assuming complete absorption, elimination by the liver, hepatic blood flow of 1.5 l/min, and equal partition between plasma and erythrocytes. Calculated assuming F = 0.30. V<sub>area</sub> reported. Trough concentrations of doxepin (D) and desmethyldoxepin (DD) following a 150 mg oral dose given once daily for 3 weeks to patients with depression. Peak/trough ratio <2. |

| DOXORUBICIN |

| Active metabolites; t<sub>1/2</sub> for doxorubicinol is 29 ± 16 hours. Prolonged when plasma bilirubin concentration is elevated; undergoes biliary excretion. Mean data for doxorubicin (D) and range of data for doxorubicinol (DL). High dose: a single 45–72 mg/m<sup>2</sup> high-dose 1 hour IV infusion given to patients with small cell lung cancer. Low dose: continuous IV infusion at a rate of 3.9 ± 0.65 mg/m<sup>2</sup> per day for 12.4 (2 to 50) weeks to patients with advanced cancer. |

aDecreases in plasma protein binding to 71 ± 3% in patients with uremia. bMean data following a single 100 mg IV dose (1-hour infusion) or range of mean data following a 100 mg oral dose given to adults.

c3 to 16 years of age, no difference in weight-adjusted CL/F compared to adult. dFollowing a 600 mg oral dose given daily to steady state.

dHydrolyzed by esterases to active metabolite, enalaprilic acid (enalaprilat); pharmacokinetic values and disease comparisons are for enalaprilat, following oral enalapril administration. eFor IV enalaprilat. fCL/F and Vss/F after multiple oral doses of enalapril. Values after single IV dose of enalapril are misleading because binding to ACE leads to a prolonged t1/2, which does not represent a significant fraction of the CL upon multiple dosing. gEstimated from the approach to steady state during multiple dosing. hMean values for enalaprilat following a 10 mg enalapril oral dose given daily for 8 days to healthy young adults. The EC50 for ACE inhibition is 5–20 ng/ml enalaprilat.
**ENOXAPARIN**<sup>a</sup> (Chapter 54)

| SC: 92 | —<sup>b</sup> | 0.3 ± 0.1<sup>c</sup> | 0.12 ± 0.04<sup>c</sup> | 3<sup>e</sup> | ACLM: 145 ± 45 ng/ml<sup>f</sup> |
| — | — | ↓ RD | ← RD | ↑ RD | BCLM: 414 ± 87 ng/ml<sup>f</sup> |

<sup>a</sup>Enoxaparin consists of low-molecular-weight heparin fragments of varying lengths. 43% is recovered in urine when administered as <sup>99</sup>Tc-labeled enoxaparin; 8% to 20% anti-Factor Xa activity.<sup>2</sup><sup>c</sup> CL/F<sup>c</sup> and V<sub>area</sub>/F for SC dose measured by functional assay for anti–Factor Xa activity.<sup>2</sup>

<sup>b</sup>Measured by functional assay of anti–Factor Xa activity. Using anti-IIa activity or displacement binding assay gives a <i>t<sub>1/2</sub></i> of approximately 1 to 2 hours.<sup>2</sup>

<sup>c</sup>Following a single 40 mg SC dose to healthy adult subjects. High affinity antithrombin III molecules: ACLM, above critical length molecules (anti–Factor Xa and IIa activity); BCLM, below critical length molecules (anti–Factor Xa activity).

**References:**

**ENTACAPONE**<sup>a</sup> (Chapter 20)

| 42 ± 9<sup>b</sup> | Negligible | 98 | 0.40 ± 0.16 | 0.28 ± 0.06<sup>d</sup> | 0.8 ± 0.2<sup>e</sup> | 4.3 ± 2.0 μg/ml<sup>f</sup> |
| — | — | 10.3 ± 1.74 | ← RD, LD | ↓ CHF, LD |

<sup>b</sup>Data from healthy male subjects. Eliminated primarily by biliary excretion. 9<sup>b</sup>The bioavailability of entacapone appears to be dose-dependent (increases from 29% to 46% over a 50-800 mg dose range).<sup>3</sup> Increased bioavailability, moderate hepatic impairment with cirrhosis.<sup>3</sup> Value represents the <i>t<sub>1/2</sub></i> for the initial distribution phase during which 90% of a dose is eliminated. The terminal <i>t<sub>1/2</sub></i> is 2.9 ± 2.0 hours.<sup>3</sup> Following a single 400 mg oral dose. No accumulation with multiple dosing.

**References:**

**EPLERENONE**<sup>a</sup> (Chapters 28, 31, 32)

| — | — | 33–60<sup>c</sup> | 2.4<sup>d</sup> | 0.6–1.3<sup>d</sup> | 4–6 | 1.8 ± 0.7<sup>e</sup> | 1.0 ± 0.3 μg/ml<sup>e</sup> |
| — | — | — | ↓ CHF, LD |

<sup>a</sup>Eplerenone is converted (reversibly) to an inactive ring-open hydroxy acid. Both eplerenone (E) and the hydroxy acid (EA) circulate in plasma; concentrations of E are much higher than EA. Irreversible metabolism is catalyzed predominantly by CYP3A4. Data for E in healthy male and female volunteers reported; no significant gender differences.<sup>3</sup> Recovered as E and EA following an oral dose. 4<sup>d</sup> Protein binding is concentration-dependent over the therapeutic range; lower at the highest concentration. <i>F<sub>area</sub></i>/<i>F</i> and <i>V<sub>area</sub></i>/<i>F</i> reported.<sup>3</sup> Following a 50 mg oral dose given once daily for 7 days.

<sup>a</sup>Epoetin alfa (E) data from male and female patients receiving continuous ambulatory peritoneal dialysis. Data shown are mean results from four different IV dosing studies. Darbepoetin alfa (DE) is a new analogue of E containing five rather than three N-linked carbohydrate chains. It is cleared more slowly from the body than E. DE data shown are for dialysis patients receiving IV darbepoetin once a week to steady state. For parenteral administration only. Bioavailability following SC administration is 22 (11–36) and 37 (30–50)% for E and DE, respectively. Following a single 120 units/kg SC dose of E. Following a single SC DE dose consisting of a peptide mass equivalent to 100 units/kg of E.

<sup>c</sup>Value for enteric-coated erythromycin base. Decreased concentrations in pregnancy possibly due to decreased bioavailability (or increased CL). Erythromycin base. Erythromycin is a CYP3A substrate; N-demethylation. It is also transported by P-glycoprotein, which may contribute to biliary excretion of parent drug and metabolites. Range of mean values of studies following a 250 mg oral enteric-coated free base in a capsule (B) given four times daily for 5 to 13 doses or a 250-mg film-coated tablet or capsule of erythromycin stearate (S) given four times daily for 5 to 12 doses.

Esomeprazole is the S-enantiomer of omeprazole. Both esomeprazole (Es) and racemic omeprazole (Rac) are available. Data for both formulations are reported. Bioavailability determined after multiple dosing. Lower Es values 64% (54–75%) reported for single dose. The metabolic CL of the Es is slower than that of the R-enantiomer. Both Es and Rac are metabolized by CYP2C19 (polymorphic) and CYP3A4. CL of Es and Rac is decreased and t1/2 increased in CYP2C19 poor metabolizers. Following a single 40 mg IV dose, CL of Es decreases and t1/2 increases with multiple dosing. Reduced CL and increased t1/2 in patients with severe (Childs Pugh Class C) hepatic insufficiency. Following a 40 mg oral dose of Es given once daily for 5 days to healthy subjects of unspecified CYP2C19 phenotype. Following a 20 mg oral dose of Rac given twice daily for 4 days to healthy subjects phenotyped as CYP2C19 extensive (EM) and poor (PM) metabolizers.

aEzetimibe is extensively metabolized to a glucuronide, which is more active than ezetimibe in inhibiting cholesterol absorption. Clinical effects are related to the total plasma concentration of ezetimibe and ezetimibe-glucuronide, with ezetimibe concentrations being only 10% of the total. bFor ezetimibe and ezetimibe-glucuronide. cCL/F and Vc/F for total (unconjugated and glucuronide conjugate) ezetimibe reported. dEzetimibe undergoes significant enterohepatic recycling leading to multiple secondary peaks. An effective t½ is estimated. eTotal (unconjugated and glucuronide conjugate) ezetimibe following a 10 mg oral dose given once daily for 10 days.

FELODIPINEa (Chapter 32)

| 15 ± 8                  | <1                    | 99.6 ± 02            | 12 ± 5b                | ↓ RD, Cirr          | 10 ± 3              | 14 ± 4            | IR: 0.9 ± 0.4d    | IR: 34 ± 26 nMd |

aRacemic mixture; S-(−)-enantiomer is active Ca²⁺ channel blocker; different enantiomer pharmacokinetics result in twofold higher than those of R-(+)-isomer. bUndergoes significant CYP3A-dependent first-pass metabolism in the intestine and liver. cMay be age-related rather than CHF-related. dFollowing a 10 mg oral immediate- (IR) or extended-release (ER) tablet given twice daily to steady state in healthy subjects. EC₅₀ for diastolic pressure decrease is 8 ± 5 nM in patients with hypertension.

FENOFIBRATEa (Chapter 35)

| 0.1–10c                 | >99                   | 0.45d                | 0.89d                  | 20–27               | IR: 6–8c            | I: 8.6 ± 0.9 μg/mlf |
| ←→ Food                | ↑ RD                  | ↓ RD                 | ↑RD                    | Mic: 4–6f           | Mic: 10.8 ± 0.6 μg/mlf |

aFenofibrate is a prodrug that is hydrolyzed by esterases to fenofibric acid, the pharmacologically active compound. All values reported are for fenofibric acid. bAbsolute bioavailability is not known. Recovery of radiolabeled dose in urine as fenofibric acid and its glucuronide is 60%. Immediate-release tablet and micronized capsule are bioequivalent. Bioavailability is increased when taken with a standard meal. cRecovery following oral dose. dCL/F and V/F reported. eFollowing a 300 mg immediate-release (IR) fenofibrate tablet given once daily to steady state. fFollowing a 200 mg micronized (Mic) capsule given once daily to steady state.

### Fentanyl (Chapters 13, 21)

|     | TM: ~50 | 8 | 84 ± 2 | 13 ± 2\(^a\) | 4.0 ± 0.4 | 3.7 ± 0.4 | TD: 35 ± 15\(^b\) | TM: 0.4 (0.3–6)\(^b\) | TD: 1.4 ± 0.5 ng/ml\(^b\) |
|-----|---------|---|--------|-------------|-----------|-----------|----------------|----------------|----------------|---|
|     | ↓ Aged ↔ Prem, Child | ↑ Neo | | | | | | | |

\(^a\)Metabolically cleared primarily by CYP3A to norfentanyl and hydroxy metabolites. \(^b\)Following a 5 mg transdermal (TD) dose administered at 50 μg/hour through a Duragesic system or a single 400-μg transmucosal (TM) dose. Postoperative and intraoperative analgesia occurs at plasma concentrations of 1 ng/ml and 3 ng/ml, respectively. Respiratory depression occurs above 0.7 ng/ml.

### Fexofenadine\(^a\) (Chapter 24)

|     | —\(^a\) | 12 | 60–70 | 9.4 ± 4.2\(^b\) | — | 14 ± 6\(^b\) | ↑ RD\(^c\) ↔ LD | 1.3 ± 0.6\(^d\) | 286 ± 143 ng/ml\(^d\) |
|-----|---------|---|-------|---------------|---|-----------|----------------|-----------|----------------|---|

\(^a\)Data from healthy adult male subjects. Absolute bioavailability is unknown. Negligible metabolism with 85% of a dose recovered in feces unchanged; a substrate for hepatic and intestinal p-glycoprotein efflux transporter. \(^b\)CL/F and \(t_1\) reported for oral dose. \(^c\)Mild renal impairment. \(^d\)Following a 60 mg oral dose twice a day to steady state.

### Filgrastim\(^a\) (Chapter 53)

|     | —\(^b\) | F: —\(^c\) | F/PF: negligible | F: 0.5–0.7\(^d\) | ↓ RD | F: 0.15 | F: 3.4–4.7 | F: 8\(^f\) | F: 11 (9–16) ng/ml\(^f\) |
|-----|---------|------------|-----------------|-----------------|-----|----------|-----------|-------|----------------|---|
|     | PF: negligible | F: 0.23 (0.07–0.26)\(^e\) | | | | | | | PF: 72 (24–96)\(^f\) |
|     | PF: 0.48\(^e\) | | | | | | | | PF: 114 (58–203) ng/ml\(^f\) |

\(^a\)Filgrastim (F) is a recombinant form of human G-CSF; it has an extra methionine residue and is non-glycosylated. A polyethyleneglycol conjugated analog, pegfilgrastim (PF), is also available for clinical use. In general, it is eliminated from the body more slowly than F by non-renal routes. Data from healthy male and female adults and patients with cancer following IV or SC administration. \(^b\)For parenteral use only. Bioavailability of F following SC dosing is 49% ± 9%. No data available for PF. \(^c\)F is filtered, reabsorbed, and catabolized in the kidney. It is also eliminated through binding to neutrophil receptors, endocytosis, and proteolytic degradation. In contrast, PF does not undergo renal elimination, presumably because of its larger hydrodynamic size; elimination of PF occurs primarily through neutrophil-mediated CL. \(^d\)CL of F reported for single dose at or below 4 μg/kg. CL of F increases with dose (>4 μg/kg) and with time (up to 10-fold) as absolute neutrophil count increases. \(^e\)CL/F, \(V_{area}/F\), and \(t_1\) of PF from SC dose reported. CL/F of PF decreases with increasing dose but increases over time with increased neutrophil counts. \(^f\)Following a single 5 μg/kg SC dose of F or a single 100 μg/kg SC dose of PF given 24 hours after chemotherapy.

*Eliminated primarily by CYP3A4-dependent metabolism. A major circulating metabolite, O-demethyl gefitinib, has pharmacological activity and may contribute to the efficacy. No apparent age or gender differences. Data from patients with cancer reported. CL can be increased and decreased by CYP3A inducers and inhibitors, respectively. Following a 225 mg oral dose given once daily for 14 days in patients with cancer.

*Data from patients with leukemia. Rapidly metabolized intracellularly to di- and triphosphate active products; IV administration. Weight-normalized CL is ~25% lower in women, compared to men. Vₘ and t₁ are reported to increase with long duration of IV infusion. Steady-state concentration during a 10 mg/m² per min infusion for 120-640 minutes.

*Following a 600 mg oral dose given twice daily to steady state.
**Gentamicin** has a very long terminal \( t_1 \) of 53 ± 25 hours (slow release from tissues), which accounts for urinary excretion for up to 3 weeks after a dose. Following a single 100 mg IV infusion (1 hour) or IM injection given to healthy adults.

**GLIMEPIRIDE**

<table>
<thead>

<sup>a</sup>Metabolized by N-acetyltransferase 2 (polymorphic). Data for slow acetylators (SA) and rapid acetylators (RA) reported. <sup>b</sup>It is usually stated that isoniazid is completely absorbed; however, good estimates of possible loss due to first-pass metabolism are not available. Absorption is decreased by food and antacids. <sup>c</sup>Recovery after oral administration; assay includes unchanged drug and acid-labile hydrazones. Higher percentages have been noted after IV administration, suggesting significant first-pass metabolism. <sup>d</sup>CL/F and V<sub>ss</sub>/F reported. <sup>e</sup>Decrease in CL<sub>NR</sub>/F as well as CL<sub>R</sub>. <sup>f</sup>Following a single 400 mg oral dose to healthy rapid and slow acetylators.

<sup>a</sup>Naturally occurring precursor to dopamine. <sup>b</sup>Values obtained with concomitant carbidopa (inhibitor of dopa decarboxylase). <sup>c</sup>Following a single 125 mg oral dose of levodopa given with carbidopa (100 mg 1 hour prior to and 50 mg 6 hours after levodopa) in young (Y) and elderly (E) subjects.

<sup>b</sup>Data from healthy adult male subjects. Gender and age differences related to renal function. <sup>c</sup>CL/F reduced, mild to severe renal impairment (not cleared by hemodialysis). <sup>g</sup>Following a single 500 mg oral dose. No significant accumulation with once-daily dosing.

Active metabolite, monoethylglycylxylidide (MEGX), is 60% to 80% as potent as lidocaine; concentrations reach 36 ± 26% of those of parent drug, but it is only 15 ± 3% protein bound.

Preparations available only for parenteral administration because of extensive and variable first-pass metabolism. Formation of MEGX is catalyzed predominantly by CYP3A.

Decrease (~40%) on day 3 after surgery; returns to normal by day 7. Decrease CL with increasing age noted in patients with MI. Increase in CL when infused longer than 24 hours, probably related to increased plasma protein binding.

Therapeutic range of blood concentrations for control of ventricular arrhythmias. Levels of 6–10 and >10 μg/ml cause occasional and frequent toxicity, respectively.

<sup>a</sup>Currently formulated in combination with ritonavir (Kalletra®). Ritonavir inhibits the CYP3A-dependent metabolism of lopinavir, enhancing its bioavailability, increasing plasma concentrations (50- to 100-fold), and extending its t<sub>1/2</sub>. Pharmacokinetic data from male and female patients with HIV are reported.  

<sup>b</sup>Absolute bioavailability is not known; the relative bioavailability increases with a high-fat meal.  

<sup>c</sup>CL<sub>F</sub> and V<sub>area</sub>/F reported; calculated from steady-state AUC data.  

<sup>d</sup>Following a 400/100 mg lopinavir/ritonavir oral dose given twice daily in combination with stavudine and lamivudine to steady state.  

| **LORATADINE**<sup>a</sup> (Chapter 24) | | | | | | | |
| L: —<sup>b</sup> | L: Negligible | L: 97 | L: 142 ± 57<sup>d</sup> | 120 ± 80<sup>d</sup> | L: 8 ± 6 | L: 2.0 ± 0<sup>e</sup> | L: 3.4 ± 3.4 ng/ml<sup>f</sup> |

| | | | | | | | |

<sup>a</sup>Loratadine (L) is converted to a major active metabolite, desloratadine (DL). Almost all patients achieve higher plasma concentrations of DL than of L. Desloratadine (Clarinex<sup>®</sup>) was recently approved for similar clinical indications as L. It too is eliminated by metabolism to an active metabolite, 3-hydroxydesloratadine (HDL), but the responsible enzyme(s) is not known. Approximately 7-20% of patients are slow metabolizers of DL; frequency varies with ethnicity.  

<sup>b</sup>Bioavailability of L and DL is not known; L is probably low due to extensive first-pass metabolism.  

<sup>c</sup>Plasma protein binding of HDL is 85–89%.  

<sup>d</sup>CL<sub>F</sub> calculated from AUC data following single 5-20 mg oral doses given to healthy adults.  

<sup>e</sup>Mean for L and DL following a 10 mg oral L dose (CLARITIN-D 24 HOUR) given once daily for 7 days to healthy adults.  

<sup>f</sup>Mean for DL and HDL following a 5 mg oral DL dose (CLARINEX®) given once daily for 10 days to healthy adults.

<sup>a</sup>Meperidine undergoes P450-dependent N-demethylation to normeperidine. Metabolite is not an analgesic but is a potent CNS-excitatory agent and is associated with adverse side effects of meperidine. <sup>b</sup>Meperidine is a weak base (\(pK_a = 8.6\)) and is excreted to a greater extent in the urine at low urinary pH and to a lesser extent at high urinary pH. <sup>c</sup>Correlates with the concentration of \(\alpha_1\)-acid glycoprotein. <sup>d</sup>A longer \(t_1/2\) (7 hours) is also observed. <sup>e</sup>Following a continuous 24 mg/hr IV infusion or 100 mg IM injection every 4 hours to steady state. Postoperative analgesia occurs at 0.4–0.7 μg/ml.

### MERCAPTOPURINE\(^a\) (Chapter 51)

| 12 ± 7\(^b\) | 22 ± 12 | 19 | 11 ± 4\(^c\) | 0.56 ± 0.38 | 0.90 ± 0.37 |

Oral (–): 2.4 ± 0.4\(^d\)
Oral (+): 2.8 ± 0.4\(^d\)
IV: 6.9 \(\mu M\)\(^d\)
Oral (–): 0.74 ± 0.28 \(\mu M\)
Oral (+): 3.7 ± 0.6 \(\mu M\)

\(^a\)Inactive prodrug is metabolized intracellularly to 6-thioinosinate. Pharmacokinetic values for mercaptopurine are reported. \(^b\)Increases to 60% when first-pass metabolism is inhibited by allopurinol (100 mg, three times daily). \(^c\)Metabolically cleared by xanthine oxidase and thiopurine methyltransferase (polymorphic). Despite inhibition of intrinsic \(CL\) by allopurinol, hepatic metabolism is limited by blood flow, and \(CL\) is thus little changed by allopurinol. \(^d\)Following an IV infusion of 50 mg/m\(^2\) per hour to steady state in children with refractory cancers or a single oral dose of 75 mg/m\(^2\) with (+) or without (–) allopurinol pretreatment.

**References:**

### METAXALONE (Chapter 20)

| —\(^a\) | —\(^b\) | — | 14 ± 7\(^c\) | — |

Fasted: 9.2 ± 4.8\(^d\)
Fed: 2.4 ± 1.2\(^d\)
Fasted: 3.0 ± 1.2\(^e\)
Fed: 4.9 ± 2.3\(^e\)

Fasted: 1.7 \(\mu g/ml\)\(^e\)
Fed: 4.9 \(\mu g/ml\)

\(^a\)Absolute bioavailability is not known. \(^b\)Unknown, but probably negligible, as the drug is extensively metabolized. \(^c\)\(CL/F\) reported; data collected following a single 400 mg oral dose taken with a meal. \(^d\)Apparent \(t_1\) following a 400 mg oral dose. The drug may exhibit an absorption-limited terminal \(t_1\) in the fasted state. A value of ~2.4 hours is seen after drug administration with a high-fat meal and may represent the true systemic elimination \(t_1\). \(^e\)Following a single 800 mg oral dose in the fasted and fed state.

**Reference:**

### METFORMIN\(^a\) (Chapter 60)

| 52 ± 5 \(\text{(40–55)}\) | 99.9 ± 0.5 \(\text{(79–100)}\) | Negligible | 7.62 ± 0.30 \(\text{(6.3–10.1)}\) | 1.12 ± 0.08\(^c\) \(\text{(0.9–3.94)}\) | 1.74 ± 0.20\(^c\) \(\text{(1.5–4.5)}\) | 1.9 ± 0.4\(^d\) \(\text{(1.5–3.5)}\) | 1.6 ± 0.2 \(\mu g/ml\)\(^d\) \(\text{(1.0–3.1)}\) |

\(^a\)Data from healthy male and female subjects. No significant gender differences. Shown in parentheses are mean values from different studies. \(^b\)\(CL/F\) reduced, mild to severe renal impairment. \(^c\)Larger volume of distribution (4 l/kg) and longer \(t_1\) (4.5 hours) also reported. \(^d\)Following a single 0.5 g oral dose (tablet) and range for a 0.5–1.5 g oral dose.

<sup>a</sup>Racemic mixture; except for protein-binding measures (d-methadone slightly higher % bound), no kinetic parameters reported for individual enantiomers. <sup>b</sup>Inversely correlated with urine pH. <sup>c</sup>V<sub>area</sub> reported. Directly correlated with urine pH. <sup>d</sup>Following a single 10-mg IV bolus dose in patients with chronic pain or a 0.12–1.9 mg/kg oral dose, once daily for at least 2 months in subjects with opioid dependency. Levels >100 ng/ml prevent withdrawal symptoms; EC<sub>50</sub> for pain relief and sedation in cancer patients is 350 ± 70 μM at 24 hours, >1 μM at 48 hours, or >0.1 μM at 72 hours after the dose.

**Methotrexate**<sup>a</sup> (Chapters 51, 52, 62)

| | | | | | | | |
| 70 ± 27<sup>b,c</sup> | 81 ± 9 | 46 ± 11 | 2.1 ± 0.8 | ↓ RD | ↑, ↔ Child | 0.55 ± 0.19 | ↔ RA | 7.2 ± 2.1<sup>d</sup> | SC: 0.9 ± 0.2<sup>e</sup> | SC: 1.1 ± 0.2 μM<sup>e</sup> | IV: 37–99 μM<sup>e</sup> |

<sup>a</sup>The 7-hydroxy metabolite exhibits plasma concentrations approaching that of parent drug. Metabolite may have both therapeutic and toxic effects. <sup>b</sup>Bioavailability may be as low as 20% when doses exceed 80 mg/m². <sup>c</sup>IM bioavailability is only slightly higher. <sup>d</sup>Exhibits triexponential elimination kinetics. A shorter <i>t<sub>1</sub></i> (2 hours) is seen initially, and a longer (52 hours) terminal <i>t<sub>1</sub></i> has been observed with increased assay sensitivity. <sup>e</sup>Following a 15 mg SC dose given once weekly to steady state in adult patients with inflammatory bowel disease. Initial steady-state concentrations in young (1.5–22 years old) leukemia patients receiving a 500 mg/m² loading dose given over 1 hour followed by an infusion of 196 mg/m² per hour for 5 hours. Bone marrow toxicity associated with concentrations >10 μM at 24 hours, >1 μM at 48 hours, or >0.1 μM at 72 hours after the dose.

**Methylphenidate**<sup>a</sup> (Chapter 10)

| (+): 22 ± 8 | (+): 1.3 ± 0.5 | (+/-): 15–16 | (+): 6.7 ± 2.0<sup>b</sup> | (+): 2.7 ± 1.1 | (+): 6.0 ± 1.7<sup>c</sup> | (+): 2.4 ± 0.8<sup>cd</sup> | (+): 18 ± 4.3 ng/ml<sup>f</sup> |
| (--): 5 ± 3 | (--): 0.6 ± 0.3 | | | (-): 1.8 ± 0.9 | (-): 3.6 ± 1.1 | (-): 2.1 ± 0.6<sup>d</sup> | (-): 3.0 ± 0.9 ng/ml<sup>f</sup> |

<sup>a</sup>Methylphenidate is available as a racemate and the active (+)-dextro-enantiomer, dexamethylphenidate. Methylphenidate and dexamethylphenidate are extensively metabolized, primarily through ester hydrolysis to ritalinic acid. Data are those of enantiomers following racemate administration to healthy adult male subjects. No significant gender differences. <sup>b</sup>The (+)-enantiomer exhibits dose-dependent kinetics at high doses of racemate, with a ~ 50% reduction in CL/F between a 10–40-mg dose. When dexamethylphenidate is given alone, its <i>t<sub>1</sub></i> is 2.2 hours, and peak time is 1–1.5 hours. <sup>c</sup>Following a single 40 mg oral dose (immediate release). Longer peak time (3–5 hours) and lower peak concentration reported for sustained-released oral formulation.

<sup>a</sup>Data for racemic mixture reported. Metabolism of less active R–(−)-enantiomer (CL<sub>F</sub> = 28 ml · min<sup>−1</sup> · kg<sup>−1</sup>; V<sub>ss</sub> · F = 7.6 l/kg; t<sub>1/2</sub> = 2.7 hours) is slightly faster than that of more active S–(+)–enantiomer (CL<sub>F</sub> = 20 ml · min<sup>−1</sup> · kg<sup>−1</sup>; V<sub>ss</sub> · F = 5.5 l/kg; t<sub>1/2</sub> = 3 hours).<sup>b</sup>Metabolically cleared by CYP2D6 (polymorphic). Compared to extensive metabolizers, individuals who are poor metabolizers will have an increased oral bioavailability, a lower CL, and a longer t<sub>1/2</sub> (7.6 ± 1.5 vs. 2.8 ± 1.2 hours) and will excrete more unchanged drug in urine (15 ± 7 vs. 3.2 ± 3%) due to reduced hepatic metabolism.<sup>c</sup>Following a single 100 mg oral dose in CYP2D6 extensive (EM) and poor (PM) metabolizer patients with hypertension. Plasma concentrations of the more active S-enantiomer are ~35% higher than the R-antipode in CYP2D6 EM. No stereochemical difference was observed in PM subjects. EC<sub>50</sub> for decreased heart rate during peak submaximal exercise testing was 16 ± 7 ng/ml; EC<sub>50</sub> for decreased systolic blood pressure during exercise testing was 25 ± 18 ng/ml.

| Active metabolite, morphine-6-glucuronide; t1/2 = 4.0 ± 1.5 hours. Steady-state ratio of active metabolite to parent after oral dosing = 4.9 ± 3.8. In renal failure, t1/2 increases to 50 ± 37 hours, resulting in significant accumulation of active glucuronide metabolite. Decreased in children undergoing cardiac surgery requiring inotropic support. Following a single 10 mg IV dose (bolus with 5-minute blood sample), a 10 mg/70 kg IM, a 10 mg/70 kg immediate-release oral (PO-IR) dose, or a 50 mg sustained-release oral dose (PO-SR). Minimum analgesic concentration is 15 ng/ml. |

</table>

\(^a\)Data from healthy subjects and patients with HIV infection. No significant gender differences. Nelfinavir is metabolized by multiple cytochrome CYP isozymes, including CYP3A4. \(^b\)Absolute bioavailability is unknown; reported to vary between 20% to 80% when taken without or with food. \(^c\)CL/F, \(V_{ss}/F\), and \(t_1\) reported for oral dose. \(^d\)CL/F increased, children 2 to 7 years and 7 to 13 years of age. \(^e\)Following a 750 mg dose given three times daily for 28 days in adults.

NEOSTIGMINE (Chapter 8)

| RD | 67 | 16.7 ± 5.4 | 1.4 ± 0.5 | 1.3 ± 0.8 | 200–350 ng/mL\(^b\) |

\(^a\)Absorption is presumed to be less than complete because oral dose must greatly exceed IV dose to achieve a similar effect. Nasal absorption is greater than oral absorption. \(^b\)Following a single dose of 0.07 mg/kg IV (sample at 2 minutes) to surgical patients.

NEVIRAPINE\(^a\) (Chapter 50)

| 93 ± 9 | <3% | 60 | SD: 0.23–0.77\(^b\) | MD: 0.89\(^b\) | SD: 1.2 ± 0.09\(^b\) | SD: 45\(^b\) | MD: 1.2\(^b\) | MD: 25–35\(^b\) | 2–4\(^d\) | SD: 2 ± 0.4 \(\mu \text{g/mL}\) | MD: 4.5 ± 1.9 \(\mu \text{g/mL}\) |

\(^a\)Data from healthy adult and HIV-infected subjects. No significant gender differences. Metabolized by CYP3A. \(^b\)Range of CL/F and V/F reported. Nevirapine appears to autoinduce its own metabolism. CL/F increases and \(t_1\) decreases from a single dose (SD) to multiple doses (MD). \(^c\)Patients <8 years. \(^d\)Following a single 200 mg oral dose (SD) and 200 mg given twice daily to steady state (MD).

[^a]: Niacin (nicotinic acid) is metabolized to nicotinamide, which in turn is converted to the coenzyme NAD and other inactive metabolites. It also undergoes direct glycine conjugation to nicotinuric acid.[^b]: The absolute bioavailability is not known. Niacin is well-absorbed but undergoes first-pass metabolism. Absorption is improved when taken with a low-fat meal.[^c]: Recovery of unchanged drug after multiple oral dose administration.[^d]: CL calculated from C∞ (6.6 ± 2.4 µg/ml) during an IV infusion of niacin. Niacin metabolic CL appears to be saturable.[^e]: Estimated from the terminal log-linear portion of a disappearance curve following the end of a 0.1 mg·kg⁻¹·min⁻¹ IV infusion in two subjects.[^f]: Following a single 1 g or 2 g oral dose of extended-release (ER) NIASPAN®. Markedly disproportional increases in plasma concentrations with increasing dose.

### NITROGLYCERIN<sup>a</sup> (Chapters 31, 32)

| Oral: <1   | <1    | —              | 195 ± 86<sup>c</sup> | 3.3 ± 1.2<sup>c,d</sup> | 2.3 ± 0.6 min | SL: 0.09 ± 0.03<sup>e</sup> | IV: 3.4 ± 1.7 ng/ml<sup>f</sup> |
| SL: 38 ± 26<sup>b</sup> | Top: 72 ± 20 |

<sup>a</sup>Dinitrate metabolites have weak activity compared to nitroglycerin (<10%), but because of prolonged $t_1$ (~40 min), they may accumulate during administration of sustained-release preparations to yield concentrations in plasma 10- to 20-fold greater than parent drug. <sup>b</sup>Following sublingual dose rinsed out of mouth after 8 minutes. Rinse contained 31 ± 19% of the dose. <sup>c</sup>Following a 40–100 minute IV infusion. <sup>d</sup>$V_{area}$ reported. <sup>e</sup>Steady-state concentration following a 20–54 μg/min IV infusion over 40–100 minutes or a 0.4 mg sublingual (SL) dose. Levels of 1.2 to 11 ng/ml associated with a 25% drop in capillary wedge pressure in patients with CHF. $T_{max}$ for topical (Top) and transdermal (TD) preparations also reported.

### NORTRIPTYLINE<sup>a</sup> (Chapter 17)

| 51 ± 5     | 2 ± 1 | 92 ± 2 <sup>↑</sup> HL | 7.2 ± 1.8<sup>b</sup> <sup>↓</sup> Aged, Inflam | 18 ± 4<sup>c</sup> <sup>↑</sup> Aged | 31 ± 13<sup>b</sup> ↔ Smk, RD | 7–10 | 138 (40–350) nM<sup>d</sup> |

<sup>a</sup>Active metabolite, 10-hydroxynortriptyline, accumulates to twice the concentration of nortriptyline in extensive metabolizers. Formation of 10-hydroxynortriptyline is catalyzed by CYP2D6 (polymorphic). <sup>b</sup>For poor metabolizers, $CL/F$ is lower (5.3 vs. 19.3 ml · min<sup>−1</sup> · kg<sup>−1</sup>) and $t_1$ longer (54 vs. 21 hours) than that of extensive metabolizers. <sup>c</sup>$V_{area}$ reported. <sup>d</sup>Mean following a 125 mg oral dose given once daily to healthy adults to steady state. Antidepressant effect observed at levels of 190 to 570 nM. Appears less effective at plasma concentrations above 570 nM.

### OLANZAPINE<sup>a</sup> (Chapter 18)

| ~60<sup>b</sup> | 7.3 | 93 | 6.2 ± 2.9<sup>c</sup> ↔ RD, Cirr | 16.4 ± 5.1<sup>c</sup> <sup>↑</sup> Aged | 33.1 ± 10.3 | 6.1 ± 1.9<sup>d</sup> | 12.9 ± 7.5 ng/ml<sup>f</sup> |

<sup>a</sup>Data from male and female schizophrenic patients. Metabolized primarily by UGT, CYP1A2, and flavin-containing monooxygenase. <sup>b</sup>Bioavailability estimated from parent-metabolite recovery data. <sup>c</sup>Summary of $CL/F$ and $V_{area}/F$ for 491 subjects receiving an oral dose. $CL/F$ segregates by sex (F/M) and smoking status (NS/S): M, S > F, S > M, NS > F, NS. <sup>d</sup>Following a single 9.5 ± 4 mg oral dose to healthy males; $C_{max,ss}$ ~ 20 ng/ml following a 10 mg oral dose given once daily.

<sup>a</sup>Data from healthy female subjects. No significant gender differences. Racemic mixture; anticholinergic activity resides predominantly with R-enantiomer; no stereoselectivity exhibited for antispasmodic activity. Oxybutynin undergoes extensive first-pass metabolism to N-desethyloxybutynin (DEO), an active, anticholinergic metabolite. Metabolized primarily by intestinal and hepatic CYP3A. Racemic oxybutynin kinetic parameters reported.

<sup>b</sup>Data reported for a 1 mg IV dose, assuming a 70 kg body weight. A larger volume (2.8 l/kg) and longer $t_{1/2}$ (5.3 hours) reported for 5 mg IV dose. Exhibits a longer apparent $t_{1/2}$ following oral dosing due to absorption rate-limited kinetics: immediate-release (IR) $t_{1/2} = 9 ± 2$ hours; extended-release (XL) $t_{1/2} = 14 ± 3$ hours. The apparent $t_{1/2}$ for DEO was 4.0 ± 1.4 hours and 8.3 ± 2.5 hours for IR and XL formulations, respectively.

<sup>c</sup>Following a dose of 5 mg immediate-release (IR) given three times daily or 15 mg extended-release (XL) given once daily for 4 days. Peak DEO levels at steady state were 45 and 23 ng/ml for IR and XL, respectively.

<sup>a</sup>Oxycodone is metabolized primarily by CYP3A4/5, with a minor contribution from CYP2D6. Oxymorphone is an active metabolite produced by CYP2D6-mediated O-dealkylation. The circulating concentrations of oxymorphone are too low to contribute significantly to the opioid effects of oxycodone. Data from healthy males and females reported.

<sup>b</sup>Values reported for OXYCONTIN<sup>®</sup> (oxycodeone controlled release) and immediate-release tablets.

<sup>c</sup>Up to 19% excreted unchanged after an oral dose.

<sup>d</sup>The apparent $t_{1/2}$ for controlled-release oral formulation is ~ 5 hours; most likely reflects absorption-limited terminal elimination kinetics. Following 10 mg of OXYCONTIN<sup>®</sup> (CR) given twice daily to steady state or a 5 mg immediate-release tablet (IR) given every 6 hours to steady state.

*Penicillin G (Pen G) available in various very soluble (short acting, SA) and less soluble (long acting, LA) salt forms. Procaine and benzathine salts are two long-acting forms. Data are from adults and older children. *Oral absorption of Pen G is irregular and variable due to its instability in stomach acid and inactivation during first-pass through the liver. Value is the maximum fraction recovered unchanged in urine following oral administration. *Tri-exponential elimination; t1 for intermediate phase reported. Terminal t1 is ∼3 hours and most likely reflects slow redistribution from tissues. *Following single 180 mg oral suspension of Pen G (PO), 600 mg IM dose of short-acting crystalline Pen G (SA), 187.5 mg IM dose of procaine Pen G (Pro), and 750 mg IM dose of benzathine Pen G (Benz).

## PHENOBARBITAL (Chapters 16, 19)

| 100 ± 11 | 24 ± 5a ↔ Cirr, AVH 51 ± 3 ↓ Neo 0.062 ± 0.013 ↑ Preg, Child, Neo 0.54 ± 0.03 ↑ Neo 99 ± 18 ↑ Cirr, Aged 2–4b ↔ Epilep, Neo |
|-----------|----------------------------------|----------------------------|-----------------|----------------|----------------|
| 2–4b      | 13.1 ± 4.5 µg/mlb |

*Phenobarbital is a weak acid (pKa = 7.3); urinary excretion is increased at an alkaline pH; it also is reduced with decreased urine flow. *Mean steady-state concentration following a 90 mg oral dose given daily for 12 weeks to patients with epilepsy. Levels of 10–25 µg/ml provide control of tonic-clonic seizures and 15 µg/ml for control of febrile convulsions in children. Levels >40 µg/ml can cause toxicity; 65–117 µg/ml produce stage III anesthesia—comatose but reflexes present; 100–134 µg/ml produce stage IV anesthesia—no deep-tendon reflexes.

*Prednisolone and prednisone are interconvertible; an additional 3% ± 2% is excreted as prednisone. bExtent of binding to plasma proteins is dependent on concentration over range encountered. cTotal CL increases as protein binding is saturated. CL of unbound drug increases slightly but significantly with increasing dose. dV increases with dose due to saturable protein binding. eChanges are for unbound drug. fFollowing a 30 mg oral dose given twice daily for 3 days to healthy male adults. The ratio of prednisolone/prednisone is dose-dependent and can vary from 3 to 26 over a prednisolone concentration range of 50–800 ng/ml.

**References:**
aActive metabolite, N-acetylprocainamide (NAPA); CL = 3.1 ± 0.4 ml · min⁻¹ · kg⁻¹, V = 1.4 ± 0.2 l/kg, and t½ = 6.0 ± 0.2 hours. bCL calculated using units of ml · min⁻¹ · kg⁻¹ for CLcr. CL depends on NAT2 acetylation phenotype. Use a mean value of 2.2 if phenotype unknown. cLeast square mean values following 1000 mg oral dose, given twice daily to steady state in male (M) and female (F) adults. Mean peak NAPA concentrations were 2.0 and 2.2 μg/ml for male and female adults, respectively; tmax = 4.1 and 4.2 hours.

### PROPOFOL

| (Chapter 13) | — | 98.3–98.8c | 27 ± 5 | 1.7 ± 0.7f | 3.5 ± 1.2f | — | SS: 3.5 ± 0.06 μg/ml | E: 1.1 ± 0.4 μg/ml |
| —b | — | 98.3–98.8c | 27 ± 5 | 1.7 ± 0.7f | 3.5 ± 1.2f | — | SS: 3.5 ± 0.06 μg/ml | E: 1.1 ± 0.4 μg/ml |

Data from patients undergoing elective surgery and healthy volunteers. Propofol is extensively metabolized by UGTs. bFor IV administration only. cFraction bound in whole blood. Concentration-dependent; 98.8% at 0.5 μg/ml and 98.3 at 32 μg/ml. CL and central volume increased in patients with renal disease. Least square mean values for procainamide and NAPA increased in patients with renal disease. Least square mean values following 1000 mg oral dose, given twice daily to steady state in male (M) and female (F) adults. Mean peak NAPA concentrations were 2.0 and 2.2 μg/ml for male and female adults, respectively; tmax = 4.1 and 4.2 hours.

### PROPRANOLOL

| (Chapters 10, 31, 32, 34) | 26 ± 10 | <0.5 | 87 ± 6b | 16 ± 5c,d | 4.3 ± 0.6c | 3.9 ± 0.4c | P: 1.5e | P: 49 ± 8 ng/ml |
| — | 26 ± 10 | <0.5 | 87 ± 6b | 16 ± 5c,d | 4.3 ± 0.6c | 3.9 ± 0.4c | P: 1.5e | P: 49 ± 8 ng/ml |

Racemic mixture. For S-(-)-enantiomer (100-fold more active) compared to R-(+)-enantiomer, CL is 19% lower and Varea is 15% lower, because of a higher degree of protein binding (18% less free drug), and no difference in t½. Active metabolite, 4-hydroxypropranolol (HP). Drugs are bound primarily to α1-acid glycoprotein, which is elevated with a number of inflammatory conditions. Based on blood measurements; blood-to-plasma concentration ratio = 0.89 ± 0.03. CYP2D6 catalyzes the formation of 4-hydroxy metabolite; CYP1A2 is responsible for most of the N-desisopropyl metabolite; UGT catalyzes major conjugation pathway of elimination. Following a single 80 mg oral dose given to healthy adults. Plasma accumulation factor was 3.6-fold after 80 mg four times daily to steady state. A concentration of 20 ng/ml gave a 50% decrease in exercise-induced cardioacceleration. Antianginal effects are manifest at 15 to 90 ng/ml. A concentration up to 1000 ng/ml may be required for control of ventricular arrhythmias.

aData from healthy adult male and female subjects. bAt a high urine pH (>7.0), pseudoephedrine is extensively reabsorbed; $t_1$ increases and $CL$ decreases. c$CL/F$, $V_F$, and $t_1$ reported for oral dose. dRange of mean values from different studies following a single 60 mg immediate-release tablet or syrup (IR), or 120 mg controlled-release capsule (CR) oral dose.

**PYRAZINAMIDE**a (Chapter 47)

| | | | | | | | |
| —b | 4–14c | 10 | 1.1 (0.2–2.3)d | 0.57 (0.13–1.04)d | 6 (2–23) | 1–2e | 35 (19–103) μg/mlf |

Pyrazinamide is hydrolyzed in the liver to an active metabolite, 2-pyrazinoic acid. Reported peak 2-pyrazinoic acid concentrations range from 0.1- to 1-fold that of parent drug. Pyrazinamide data reported are for male and female adults with tuberculosis. aAbsolute bioavailability is not known, but the drug is well absorbed based on recovery of parent drug and metabolites (70%). bRecovery unchanged following an oral dose; the recovery of pyrazinoic acid is 37 ± 5%. c$CL/F$ and $V_{aex/F}$ reported. dFollowing a 15–53 mg/kg daily oral dose to steady state.

**QUETIAPINE**a (Chapter 18)

| | | | | | | | |
| 9↑ Food | <1% | 83 | 19 ↓ Aged ↔ RD ↓ LD | 10 ± 4 | 6 | 1–1.8 | 278 ng/mlb |

aNo significant gender differences. Extensively metabolized through multiple pathways, including sulfoxidation, N- and O-dealkylation catalyzed by CYP3A4. Two minor active metabolites. bFollowing a 250 mg oral dose given daily for 23 days in patients with schizophrenia.

**QUINAPRIL**a (Chapters 30, 32, 33)

Active metabolite, 3-hydroxyquinidine ($t_1/2 = 12 ± 3$ hours; percent bound in plasma = 60 ± 10). Metabolically cleared primarily by CYP3A. Following a 400 mg IV dose (22-minute infusion) of quinidine gluconate or a single 400 mg oral dose of immediate-release (IR) quinidine sulfate or a 300 mg dose of extended-release (ER) quinidine sulfate (QUINIDEX) to healthy adults. Specific assay methods for quinidine show >75% reduction in frequency of premature ventricular contractions at levels of 0.7–5.9 μg/ml, but active metabolite was not measured; therapeutic levels of 2–7 μg/ml reported for nonspecific assays.

Data from normal adults (N-A) and range of means from different studies of adults (M-A) or children (M-C) with malaria reported. Correlates with serum $\alpha_1$-acid glycoprotein levels. Binding is increased in severe malaria. From patients with malaria. Following single 10 mg/kg dose given as a 0.5–4 hour IV infusion or orally (PO) to children or adults with malaria. A level >0.2 μg/ml for unbound drug is targeted for treatment of *falciparum* malaria. Oculotoxicity and hearing loss/tinnitus associated with unbound concentrations >2 μg/ml.

<sup>a</sup>Active desacetyl metabolite.  
<sup>b</sup>Absolute bioavailability is not unknown, although some studies indicate complete absorption. Such reports presumably refer to rifampin plus its desacetyl metabolite because considerable first-pass metabolism is expected.  
<sup>c</sup>Not observed with 300 mg doses, but pronounced differences with 900 mg doses.  
<sup>d</sup>$t_1$ is longer with high single doses.  
<sup>e</sup>$t_1$ is shorter (1.7 ± 0.5) and CL/F is higher after repeated administration. Rifampin is a potent enzyme (CYP3A and others) inducer and appears to autoinduce its own metabolism.  
<sup>f</sup>Following a 600 mg dose given once daily for 15 to 18 days to patients with tuberculosis.

| **RILUZOLE**<sup>a</sup> (Chapter 20) | | | | | | | |
| 64 (30–100) ↓ Food<sup>b</sup> | <1 | 98 | 5.5 ± 0.9 LD ↓ | 3.4 ± 0.6 | 14 ± 6 | 0.8 ± 0.5<sup>c</sup> | 173 ± 72 ng/ml<sup>f</sup> |

<sup>a</sup>Eliminated primarily by CYP1A2-dependent metabolism; metabolites are inactive. Involvement of CYP1A2 may contribute to ethnic (lower CL/F in Japanese) and gender (lower CL in women) differences and inductive effects of smoking (higher CL in smokers).  
<sup>b</sup>High-fat meal.  
<sup>c</sup>Following a 50 mg oral dose taken twice daily to steady state.

| **RISEDRONATE** (Chapter 61) | | | | | | | |
| <1<sup>a</sup> | 87 (73–102) | 24 | 1.5 (1.2–1.9) ↓ RD | 6.3 ± 1.5 | 200 (183–218)<sup>b</sup> | 1.7 ± 1.2<sup>c</sup> | 2.8 ± 0.3 ng/ml<sup>f</sup> |

<sup>a</sup>Food affects the extent of bioavailability; recommended to be taken 30 minutes prior to the first meal of the day. Data from healthy men and women reported; no significant gender differences.  
<sup>b</sup>Exhibits multi-exponential elimination. The plasma $t_1$ for the first and second exponential phases is 0.9 and 13 hours, respectively. The longer terminal $t_1$ reported is thought to represent dissociation of risedronate from the surface of bone.  
<sup>c</sup>Following a 5 mg oral dose given once daily to healthy men.

<sup>a</sup>Active metabolite, 9-hydroxyrisperidone, is the predominant circulating species in extensive metabolizers and is equipotent to parent drug. 9-Hydroxyrisperidone has a <i>t</i><sub>1/2</sub> of 20 ± 3 hours. In extensive metabolizers, 35% ± 7% of an IV dose is excreted as this metabolite; its elimination is primarily renal and therefore correlates with renal function. 9-Hydroxyrisperidone is catalyzed by CYP2D6. Parameters reported for extensive metabolizers. In poor metabolizers, <i>F</i> is higher; about 20% of an IV dose is excreted unchanged, 10% as the 9-hydroxy metabolite; <i>CL</i> is slightly less than 1 ml · min<sup>−1</sup> · kg<sup>−1</sup>, and <i>t</i><sub>1/2</sub> is similar to that of the active metabolite, about 20 hours. 77% for 9-hydroxyrisperidone. Changes in elderly due to decreased renal function affecting the elimination of the active metabolite. Mean steady-state trough concentration for risperidone (R) and total active (TA) drug, risperidone + 9-OH-risperidone, following a 3 mg oral dose given twice daily to patients with chronic schizophrenia. No difference in total active drug levels between CYP2D6 extensive and poor metabolizers.

<sup>b</sup>Ritonavir is extensively metabolized primarily by CYP3A4. It also appears to induce its own <i>CL</i> with single- (SD) to multiple-dose (MD) administration. Also used in combination with saquinavir; saquinavir has no significant effect on the pharmacokinetics of ritonavir. Absolute bioavailability unknown (>60% absorbed); food elicits a 15% increase in oral <i>AUC</i> for capsule formulation. <i>CL/F, V<sub>area</sub>/F</i>, and <i>t</i><sub>1/2</sub> reported for oral dose. <i>CL/F</i> reduced slightly and <i>t</i><sub>1/2</sub> increased slightly, moderate liver impairment. Following a 600 mg oral dose given twice daily to steady state.

<sup>a</sup>Rivastigmine is metabolized by cholinesterase. No apparent gender differences. Following a 6-mg oral dose, bioavailability increases with dose; following a 3-mg dose, the median bioavailability is 36%. IV dose of 2 mg. The pharmacodynamic <i>t</i><sub>1</sub> is approximately 10 hours due to tight binding to acetylcholinesterase. Following oral administration of 6 mg capsule. Peak concentrations increase more than proportionally at doses above 3 mg.

Data from healthy adult male (M) and female (F) subjects. Oxidative deamination catalyzed by MAO-A is the primary route of elimination. N-desmethyl rizatriptan (DMR) is a minor metabolite (~14%) that is active and accumulates in blood. Evidence of minor dose-dependent metabolic CL and urinary excretion. CL/F reduced, moderate hepatic impairment. CL/F reduced, severe renal impairment. Following a 10 mg single (SD) and multiple (MD; 10 mg every 2 hours × 3 doses × 4 days) oral dose. DMR peak concentration is 8.5 and 26.2 ng/ml with SD and MD, respectively.

*MAO-B active metabolite: l-(−)-desmethylselegiline. Extensive first-pass metabolism; estimate of CL/F reported. Blood-to-plasma concentration ratio = 1.3–2.2 for parent drug and ~0.55 for N-desmethyl metabolite. CL/F for N-desmethylselegiline assuming quantitative conversion of parent to this metabolite. For parent and N-desmethyl metabolite. $t_1/2$ for methamphetamine (major plasma species) and amphetamine are 21 and 18 hours, respectively. Mean data for selegiline (S) and its active metabolite, N-desmethylselegiline (DS), following a single 10 mg oral dose given to adults.

*Absolute bioavailability is not known (>44% absorbed); undergoes extensive first-pass metabolism to essentially inactive metabolites; catalyzed by multiple cytochrome P450 isoforms. CL/F reported. Following a dose titration up to 200 mg given once daily for 30 days to healthy male (M) and female (F) adults.

*Data from healthy male subjects. Sildenafil is metabolized primarily by CYP3A and secondarily by CYP2C9. Piperazine N-desmethyl metabolite is active (~50% parent) and accumulates in plasma (~40% parent). CL/F reduced, mild to moderate hepatic impairment. CL/F reduced, severe renal impairment. Increased unbound concentrations. Following a single 50 mg oral (solution) dose.

Simvastatin is a lactone prodrug that is hydrolyzed to the active corresponding \( \beta \)-hydroxy acid. Values reported are for the disposition of the acid. \(^a\)The \( \beta \)-hydroxy acid can be reconverted back to the lactone; irreversible oxidative metabolites are generated by CYP3A. \(^b\)Data for active inhibitors (AI, ring-opened molecule) and total inhibitors (TI) following a 40 mg oral dose given once daily for 17 days to healthy adults.

*Tenofovir is formulated as an ester prodrug, Viread® (tenofovir disoproxil fumarate), for oral administration. *Bioavailability under fasted state reported; increased to 39% with high-fat meal. *Data reported for steady-state 3 mg/kg IV dose given once a day for 2 weeks to HIV-1 infected male and female adults. *Longer apparent plasma t₁⁄₂ (17 hours) reported for steady-state oral dosing; this may reflect a longer duration of blood sampling; also, phosphorylated ‘active’ metabolite exhibits a longer intracellular t₁⁄₂ (60 hours). *Following a 300 mg oral dose given once a day with a meal to steady state.

**Tetracycline** (Chapter 46)

| 77 | 58 ± 8 | 65 ± 3 | 1.67 ± 0.24 | 1.5 ± 0.1<sup>a</sup> | 10.6 ± 1.5 | Oral: 4 | IV: 16.4 ± 1.2 μg/ml<sup>b</sup> Oral: 2.3 ± 0.2 μg/ml<sup>b</sup> |

*Plasma CL reportedly reduced in patients with hypertension. *Following a 1 mg oral dose (tablet) given to healthy volunteers.

\(^a\)Nonlinear kinetics due to saturable metabolism, especially in children at steady state. Ratio of percent increase in steady-state concentration to percent increase in dose was greater than 1.5 in 15% of children changed to a higher dose. Metabolically cleared primarily by CYP1A2 and by CYP3A4 to a lesser extent. \(^b\)CL increased and t\(_1\)\(_2\) decreased as a result of enzyme induction by antiepileptic drugs. \(^c\)Following a 200 mg oral dose (aminophylline) given three times daily for 5 days, a 400 mg oral dose (THEO-DUR) given twice daily for 5 days, or a 800 mg oral dose (THEO-24) given once daily for 5 days, all to healthy adults. Sustained release formulations were taken 1 hour prior to a high-fat meal. Levels of 5 to 15 μg/ml are considered therapeutic; a level >20 μg/ml is potentially toxic.

**Table A-II–1  Pharmacokinetic Data (Continued)**

*Data from healthy adult male and female subjects and patients with epilepsy. Metabolized primarily by UGT and CYP3A. *CL/F, Varea/F, and t1 reported for oral dose. *CL/F increased in adult and pediatric patients receiving enzyme-inducing antiepileptic drugs. *Weight-adjusted CL/F higher in children (3 to 10 years of age) than in adults. *CL/F reduced, moderate hepatic impairment. Following a single 8 mg oral dose (SD) or a 3 mg oral dose given three times daily for 4 days (MD). Diurnal variation (lower Cmax in P.M. than A.M.).
Bioavailability estimate based on recovery of oral dose in urine and expected negligible first-pass metabolism. CL/F, V/F, and \( t_1 \) reported for oral dose. Metabolized primarily by CYP2C9 (polymorphic). Following a single 500 mg oral dose. A level of 80-240 \( \mu \)g/ml associated with a >25% decrease in blood glucose concentration.

### TOLTERODINE

| EM: 26 ± 18 | EM: negligible | T: 96.3 | EM: 9.6 ± 2.8 | EM: 1.7 ± 0.4 | EM: 2.3 ± 0.3 | EM: 1.2 ± 0.5\(^c\) | EM: 5.2 ± 5.7 ng/ml\(^d\) |
| PM: 91 ± 40 | PM: <2.5 | 5-HM: 64 | PM: 2.0 ± 0.3 | PM: 1.5 ± 0.4 | PM: 9.2 ± 1.2 | PM: 1.9 ± 1.0\(^c\) | PM: 38 ± 15 ng/ml\(^d\) |
| EM: ↑ Food | ↓ LD\(^b\) | | | | | | |

Data from healthy adult male subjects. No significant gender differences. Tolterodine (T) is metabolized primarily by CYP2D6 to an active (100% potency) metabolite, 5-hydroxytoiletidine (5-HM), in extensive metabolizers (EM); \( t_1 \) 5-HM = 2.9 ± 0.4 hours. Also metabolized by CYP3A to an N-desalkyl product, particularly in poor metabolizers (PM). CL/F reduced and AUC 5-HM unbound increased, hepatic cirrhosis. Following a 4 mg oral dose given twice daily for 8 days. Peak concentration of 5-HM was 5 ± 3 ng/ml for EM.

### TOPIRAMATE

| ≥70\(^b\) | 70–97 | 13–17 | 0.31–0.51\(^c\) | 0.6–0.8\(^c\) | 19–23\(^c\) | 1.7 ± 0.6\(^i\) | 5.5 ± 0.6 \( \mu \)g/ml\(^f\) |
| | | | ↑ Child\(^d\) | | | | |
| | | | ↓ RD\(^e\) | | | | |

Data from healthy adult male and female subjects and patients with partial epilepsy. Estimate of bioavailability based on urine recovery of unchanged drug. CL/F, V/F, and \( t_1 \) reported for oral dose. Patients receiving concomitant therapy with enzyme-inducing anticonvulsants drugs exhibit increased CL/F, decreased \( t_1 \). CL/F increased, <4 years (substantially), and 4 to 17 years of age. CL/F reduced, moderate-to-severe renal impairment (drug cleared by hemodialysis). Following a 400 mg oral dose given twice daily to steady state in patients with epilepsy.

<sup>a</sup>Data from healthy adult male and female subjects and female patients with breast cancer. Toremifene (T) is metabolized by CYP3A to N-desmethyltreomifene (DMT), a metabolite that accumulates in blood and has anti-estrogenic activity. Toremifene appears to undergo enterohepatic recycling, prolonging its apparent t<sub>1/2</sub>.<br><sup>b</sup>CL/F, V<sub>area</sub>/F, and t<sub>1/2</sub> reported for oral dose. <sup>c</sup>CL/F reduced, hepatic cirrhosis or fibrosis.<br><sup>d</sup>Following a 60 mg oral dose given once daily to steady state in patients with breast cancer. <sup>f</sup>T: 2.3 ± 1.4<sup>c</sup> | T: 592 ± 178 ng/ml<sup>f</sup> | M1: 2.4 ± 1.1<sup>c</sup> | M1: 110 ± 32 ng/ml<sup>f</sup> |
Tramadol is available as a racemic mixture. At steady state, the plasma concentration of (+) (1R,2R)-tramadol is ~30% higher than that of (–) (1S,2S)-tramadol. Both isomers contribute to analgesia. Data reported are for total (+ and –) tramadol. Tramadol (T) is metabolized by CYP2D6 to an active O-desmethyl-metabolite (M1); there are other CYP-catalyzed metabolites. Recovery following an oral dose reported. Following a 100 mg immediate-release tablet given every 6 hours for 7 days.

<sup>a</sup>Data from healthy male and female adults. Valacyclovir is a L-valine prodrug of acyclovir. Extensive first-pass conversion by intestinal (gut wall and lumenal) and hepatic enzymes. Parameters refer to acyclovir (A) and valacyclovir (V) following valacyclovir administration. See Acyclovir for its systemic disposition parameters. <sup>b</sup>Bioavailability of acyclovir based on AUC of acyclovir following IV acyclovir and oral 1 g dose of valacyclovir. <sup>c</sup>Urinary recovery of acyclovir is dose-dependent (76% and 44% following 100 mg and 1000 mg oral doses of valacyclovir, and 87% following IV acyclovir). <sup>d</sup>CL/F reduced, end-stage renal disease (drug cleared by hemodialysis). <sup>e</sup>Following a single 1 g oral dose of valacyclovir.

<sup>1</sup>Valganciclovir (V) is an ester prodrug for ganciclovir (G). It is rapidly hydrolyzed with a plasma \( t_1 = 0.5 \) hour. G and V data following oral valganciclovir dosing to male and female patients with viral infections are reported. See Ganciclovir for its systemic disposition parameters. <sup>b</sup>Increased and more predictable bioavailability of G when V is taken with a high-fat meal. <sup>c</sup>The apparent \( t_1 \) of G is increased in patients with renal impairment. <sup>d</sup>Following a single 360-mg oral dose of V taken without food. <sup>e</sup>Following a 900-mg oral dose taken once daily with food to steady state.

Active metabolites. 

Data for multiple dosing (500 mg daily) reported. Single dose value: 0.14 ± 0.04 ml · min⁻¹ · kg⁻¹; 

Total CL the same at 100 mg daily, although CL of free drug increases with multiple dosing. 

Increased CL and decreased t₁/₂ from enzyme induction following concomitant administration of other antiepileptic drugs. 

Cave following a 250 mg oral dose (capsule, DEPAKENE) given twice daily for 15 days to healthy male adults. A therapeutic range of 50 to 150 μg/ml is reported.

**Verapamil**

* Racemic mixture; (–)-enantiomer is more active. Bioavailability of (+)-verapamil is 2.5-fold greater than that for (–)-verapamil because of a lower CL (10 ± 2 vs. 18 ± 3 ml · min⁻¹ · kg⁻¹). Relative concentration of the enantiomers changes as a function of route of administration. *Active metabolite, norverapamil, is a vasodilator but has no direct effect on heart rate or P-R interval. At steady state (oral dosing), AUC is equivalent to that of parent drug (t₁/₂ = 9 ± 3 hours). *Multiple dosing causes greater than twofold decrease in CL/F and prolongation of t₁/₂ in some studies, but no change of t₁/₂ in others. *Verapamil is a substrate for CYP3A4, CYP2C9, and other CYPs. *Mean data following a 120 mg oral conventional tablet (IR) given twice daily or range of data following a 240 mg oral extended release (XR) dose given once daily, both for 7 to 10 days to healthy adults. EC₅₀ for prolongation of P-R interval after oral dose of racemate is 120 ± 20 ng/ml; value for IV administration is 40 ± 25 ng/ml. After oral administration, racemate concentrations above 100 ng/ml cause more than 25% reduction in heart rate in atrial fibrillation, more than 10% prolongation of P-R interval, and more than 50% increase in duration of exercise in angina patients. A level of 120 ± 40 ng/ml (after IV administration) was found to terminate reentrant supraventricular tachycardias.

</table>
<sup>a</sup>Metabolized mainly to an inactive N-oxide by CYP2C19 (major), CYP3A4, and CYP2C9.  
<sup>b</sup>Elimination is dose- and time-dependent. Pharmacokinetic parameters determined at steady state are reported. Mean CL was reduced (64%), Vss reduced (32%), and t<sub>1/2</sub> increased (16%) with 12 days of twice daily 3 mg/kg IV administration. Also, CL decreased 41% when dose was increased from 200 to 300 mg twice daily.  
<sup>c</sup>CL reduced in patients with mild-to-moderate hepatic insufficiency.  
<sup>d</sup>Following a 3 mg/kg oral dose given twice daily for 12 days.  
<sup>e</sup>Following a 3 mg/kg 1 hour IV infusion given twice daily for 12 days.  

| **Warfarin**<sup>a</sup> (Chapter 54) | | | | | | | |
| 93 ± 8 | <2 | 99 ± 1<sup>b</sup> | 0.045 ± 0.024<sup>c,d,e</sup> | 0.14 ± 0.06<sup>d</sup> | 37 ± 15<sup>f</sup> | <4<sup>g</sup> | R: 0.9 ± 0.4 μg/ml<sup>g</sup> |
| ↓ RD | ↓ LD | ↔ Aged, AVH, CF | ↔ Aged, AVH | ↔ Aged, AVH | ↔ Aged, AVH | ↔ Aged, AVH | S: 0.5 ± 0.2 μg/ml<sup>g</sup> |
| ↔ Preg | | | | | | | |
<sup>a</sup>Values are for racemic warfarin; the S-(-)-enantiomer is three- to fivefold more potent than the R-(+)-enantiomer.  
<sup>b</sup>No difference between enantiomers in plasma protein binding or V<sub>area</sub>.  
<sup>c</sup>CL of the R-enantiomer is about 70% of that of the antipode (0.043 vs. 0.059 ml · min⁻¹ · kg⁻¹).  
<sup>d</sup>Conditions leading to decreased binding (e.g., uremia) presumably increase CL and V.  
<sup>e</sup>The S-enantiomer is metabolically cleared by CYP2C9 (polymorphic).  
<sup>f</sup>t<sub>1/2</sub> of the R-enantiomer is longer than that of the S-enantiomer (43 ± 14 vs. 32 ± 12 hours).  
<sup>g</sup>Mean steady-state, 12-hour postdose, concentrations of warfarin enantiomers following a daily oral dose of 6.1 ± 2.3 mg of racemic warfarin given to patients with stabilized (1 to 5 months) anticoagulant therapy.

| **Zaleplon**<sup>a</sup> (Chapter 16) | | | | | | | |
| 31 ± 10<sup>b</sup> | <1 | 60 ± 15 | 15.7 ± 3.3 | 1.3 ± 0.2 | 1.0 ± 0.1 | 1.1 ± 0.2<sup>e</sup> | 26 ± 4.4 ng/ml<sup>e</sup> |
| ↔ Aged ↓ Cirr<sup>c</sup> | | | | | | | |
| ↑ Cirr | ↑ Food<sup>d</sup> | ↑ Food<sup>d</sup> | ↓ Food<sup>d</sup> | | | | |
<sup>a</sup>Data from healthy adult male and female subjects. No significant gender differences.  
<sup>b</sup>Zaleplon is well absorbed but undergoes extensive first-pass metabolism, primarily by aldehyde oxidase and also CYP3A.  
<sup>c</sup>CL/F reduced, compensated and decompensated hepatic cirrhosis.  
<sup>d</sup>High-fat, high-calorie meal.  
<sup>e</sup>Following a single 10 mg oral dose.

<sup>a</sup>Primary routes of metabolism involve reductive cleavage of the isoxazole ring (CYP3A4) and N-acetylation. <sup>b</sup>Absolute bioavailability is not known; presumably urine recovery after an oral dose. <sup>c</sup>Recovery following an oral dose. <sup>d</sup>Concentrates in erythrocytes to as much as eightfold. <sup>e</sup>Steady-state CL/F for a 400 mg once daily dose reported. AUC increases disproportionately when the dose is increased from 400-800 mg. <sup>f</sup>V/F for a single dose is reported; decreases as the dose is increased from 200-800 mg. <sup>g</sup>Following a 400 mg oral dose given once daily to steady state in healthy adults.

Key: Unless otherwise indicated by a specific footnote, the data are presented for the study population as a mean value ± 1 standard deviation, a mean and range (lowest–highest in parenthesis) of values, a range of the lowest–highest values, or a single mean value. ACE = angiotensin converting enzyme; ADH = alcohol dehydrogenase; Aged = aged; AIDS = acquired immunodeficiency syndrome; Alb = hypoalbuminemia; Atr Fib = atrial fibrillation; AVH = acute viral hepatitis; Burn = burn patients; C<sub>max</sub> = peak concentration; CAD = coronary artery disease; Celiac = celiac disease; CF = cystic fibrosis; CHF = congestive heart failure; Child = children; Cirr = hepatic cirrhosis; COPD = chronic obstructive pulmonary disease; CP = cor pulmonale; CPBS = cardiopulmonary bypass surgery; CRI = chronic respiratory insufficiency; Crohn = Crohn’s disease; Cush = Cushings syndrome; CYP = cytochrome P450; Fem = female; Hep = hepatitis; HIV = human immunodeficiency virus; HL = hyperlipoproteinemia; HTh = hyperthyroid; IM = intramuscular; Inflam = inflammation; IV = intravenous; LD = chronic liver disease; LTh = hypothyroid; MAO = monoamine oxidase; MI = myocardial infarction; NAT = N-acetyltransferase; Neo = neonate; NIDDM = non–insulin-dependent diabetes mellitus; NS = nephrotic syndrome; Obes = obese; Pneu = pneumonia; Prem = pregnant; Prem = premature; RA = rheumatoid arthritis; RD = renal disease (including uremia); SC = subcutaneous; Smk = smoking; ST = sulfotransferase; T<sub>max</sub> = peak time; Tach = ventricular tachycardia; UGT = UDP-glucuronosyl transferase; Ulcer = ulcer patients. Other abbreviations are defined in the text section of this appendix.

ophthalmic use of, 1721t
pharmacological properties of, 264, 267,
282r
prototypical, 265t
routes of administration, 265t
therapeutic uses of, 265t, 282t
β Adrenergic receptor antagonist(s), 164,
166f, 174, 263, 271–277, 282r–283r,
324f, 838–839. See also specific agents
adverse effects of, 282r–283r, 286–288,
851, 915, 1723–1724
for akathisia, 292, 479
for angina, 823–824
with Ca2+ channel antagonists, 837–839
contraindications to, 839
with nitrates, 839
with nitrates and Ca2+ channel antagonists,
841
unstable, 838
for anxiety, 423, 454
β1, 174, 283t, 284–285
selectivity of, 263, 264t, 272
β2, 174
for cardiac arrhythmia
electrophysiological actions of, 912t
mechanism of action, 908, 914–915
for cardiovascular diseases, 288–290
cardiovascular effects of, 272, 276t,
838, 850
chemistry of, 272, 273t
CNS effects of, 288
for congestive heart failure, 288–289,
874r, 881–884, 882f–883f
clinical use of, 884
mechanism of action, 883–884
drug interactions of, 288
with antidepressants, 449
with epinephrine, 247
with indomethacin, 695, 851
with NSAIDs, 123, 851
for ethanol withdrawal, 290
first-generation, 282r–283r
for glaucoma, 212, 290, 1723
for hypertension, 275–277, 850–851
with α1 adrenergic receptor antagonists,
852
with diuretics, 851
mechanism of action, 850
paradextral hypertensive response to,
851
precautions with, 851
site of action, 850
for hyperthyroidism, 1530, 1533–1534
hypoglycemic effects of, 1633, 1634t
membrane-stabilizing effects of, 273,
275
metabolic effects of, 276–277, 288
for migraine prophylaxis, 290
for myocardial infarction, 288, 839, 883
non-subtype-selective, 277–278, 282r–283r
ophthalmic use of, 7, 1721t
overdosage of, 288
for panic disorders, 290
pharmacogenetics of, 106t
pharmacological effects of, 272–277,
282r–283r, 850
precautions with, 287–288
pulmonary effects of, 276, 287
and renin secretion, 793
second-generation, 283t
selection of agent, 292
and sexual function, 288
for silent myocardial ischemia, 823
therapeutic uses of, 282r–283r, 288–292,
838–839, 851
third-generation, 276t, 283t, 285–286
vasodilating actions of, 275–277, 276f,
276t
withdrawal from, 288–289, 612, 851, 915
β Adrenergic receptor kinase (βARK), and
opiod receptors, 555
Adrenergic transmission, 158–171
pharmacologica interventions in, 170,
173, 174, 174t–172r
Adrenocortical response, etomidate and, 351
Adrenocortical steroids, 1587, 1593–1610.

drug-induced, 905t
ethanol and, 595
mechanism of, 907t
treatment of, 907t
Atrial natriuretic peptide, 885
and vasopressin, 775
Atrial tachycardia, 907t
drug-induced, 905t
Atrioventricular (AV) block
drug-induced, 905t
epinephrine and, 245
Atrioventricular (AV) nodal re-entrant tachycardia, 904, 907t
treatment of, 907t
Atrioventricular (AV) node
acetylcholine and, 184–185
α2-adrenergic receptor agonists and, 854–855
atriope and, 193, 197
Ca2+ channel antagonists and, 834–836
cardiac glycosides and, 887, 889
epinephrine and, 245
histamine and, 635
Atrioventricular (AV) re-entrant tachycardia, 904, 906f, 907t
treatment of, 907t
Atropine, 189–198
absorption of, 194–195
acetylcholine antagonism by, 183, 186
as anesthesia, 197
anticholinesterase agents antagonism by, 207
for anticholinesterase toxicity, 197, 210–211
in antidiarrheal agents, 194–195, 570
for biliary tract effects of, 194
for cardiovascular disorders, 197
for cardiovascular effects of, 192, 197
chemistry of, 190, 191f
for circulatory effects of, 193
CNS effects of, 191
for digoxin toxicity, 889
dose-effect relationship of, 189–190, 189f
excretion of, 194
for fentanyl, 194
for gastrointestinal disorders, 196
for gastrointestinal effects of, 193
mechanism of action, 153, 191
for neuromuscular blocker toxicity, 226–228, 362
ophthalmic use of, 198, 1720t, 1724
for opioid-induced biliary spasm, 562
pharmacokinetics of, 1800f
pharmacological properties of, 191–195
for respiratory disorders, 195
respiratory effects of, 193
structure of, 190, 191f
and sweat glands, 194
and temperature, 194
therapeutic uses of, 195–198
toxicity of, 190, 195
for treatment of, 195, 211, 214
for uveitis, 1724
ATROPINE-CARE (atropine), 1720t
Atropine sulfate
for muscarinic receptor agonist toxicity, 188–189
in myasthenia gravis testing, 213
ATROPISOL (atropine), 1720t
ATROVENT (ipratropium), 194, 730
Attapulgite, for diarrhea, 997t
Attention-deficit/hyperactivity disorder, 263
amphetamine for, 258
antidepressants for, 450, 484
stimulants for, 259, 484
AUC (area under the curve), 19
Auditory sensory gating (ASG), antipsychotics and, 468
Auerbach’s plexus, 139–141, 983, 984f
AUGMENTIN (amoxicillin-clavulanate), 1152
Aura, with migraine, 306
Autacoid(s)
lipid-derived, 653–668. See also Eicosanoid(s); Platelet-activating factor
release of, 631–632
Autoimmune disease, 1406
Automaticity, cardiac
  enhanced, 904
  sodium channel antagonists and, 913
  triggered, 904, 906f
Autonomic ground plexus, 142
Autonomic nervous system, 137–178, 140f–141f
  anatomy of, 137–142
  anticholinesterase agents and, 208–209
  antipsychotics and, 474
  barbiturates and, 417
  central connections in, 138
  co-transmission in, 175–178
  effector organ responses to, 142, 143–145f
  ganglionic neurotransmission in, 229–231, 230f
  general functions of, 142–145
  interaction with endocrine systems, 170
  muscarinic receptor antagonists and, 192
  neuromuscular blocking agents and, 226
  neurotransmission in, 145–178
  peripheral, divisions of, 138–141
  pharmacological considerations in, 170–174, 171f–172f
  versus somatic motor nervous system, 137
Autonomic reflexes, 319
Autonomic response attenuation, in anesthetic state, 343–344
Autoreceptors, 145f, 148–149
Autosomal recessive trait, 95
AYANDAMET (metformin-rosiglitazone), 1639
AYANDIA (rosiglitazone), 1639
AYAPRO (irbesartan), 813
AVELOX (moxifloxacin), 1119
AVECITRIN (aviloxacin), 1119
AVECITRIN (aviloxacin), 1119
AVENEX (interferon-beta), 1422
Axial skeleton, 1658
AXID (nizatidine), 971
AXON (s), 147
Axonal conduction, in neurotransmission, 147
Axon guidance molecules, 329
Axosemid, 750f
AYEGESTIN (norethindrone), 1561
AZADITIDINE, 1345–1346
  chemistry of, 1337f
  site of action, 1375f
AZACTAM (aztreonam), 1115
AZACTAMYDINE. See Azactidine
Azapirones, for anxiety, 454
Azathioprine, 1414
  adverse effects of, 1015
  chemistry of, 1346, 1347f, 1409f
  dermatologic use of, 1694
  disposition of, 1414
  drug interactions of, 1414
  with allopurinol, 709
for immunosuppression, 1414
for inflammatory bowel disease, 1009, 1010f, 1015–1016
  mechanism of action, 1414
  metabolism of, 87, 1015, 1015f
  for myasthenia gravis, 213
  pharmacogenetics of, 124–125, 1015–1016
  pharmacokinetics of, 1414, 1801t
  in pregnancy, 1018
  as produg, 1015
  site of action, 1407f
  therapeutic uses of, 1414
  toxicity of, 1414
Azelaic acid, 1701
Azelaic acid, 1701
  for acne, 1690, 1701
  chemistry of, 1701
Azelastine
  for allergic diseases, 640
  dosage of, 638f
  duration of action, 638f
  for babesiosis, 1053
  for chlamydial infections, 1185
  for cryptosporidiosis, 1051
  for gastrointestinal motility disorders, 988
  mechanism of action, 1183–1184, 1183f
  for Mycobacterium avium complex, 1185–1186, 1204, 1204f, 1217–1218
  for Mycobacterium avium complex prophylaxis, 1218
  for pertussis, 1186
  pharmacokinetics of, 1801t
  resistance to, 1183–1184, 1218
  therapeutic uses of, 1185–1186, 1218
  for toxoplasmosis, 1186
Azlocillin, antimicrobial activity of, 1183
AZMACORT (triamcinolone acetonide), 721
Azole antifungal(s), 1225, 1230–1235
  preparations of, 638
  ophthalmic use of, 1725
  for allergic diseases, 640
  metabolism of, 87, 1015, 1015
  mechanism of action, 1414
  site of action, 1407f
  therapeutic uses of, 1198
  duration of action, 638f
  resistance to, 1230–1231
  mechanism of action, 1230
  site of action, 1230–1231
  topical, 1237–1239
Azomycin, 1058
Azospermid, 721
Azophorine, for anxiety, 454
Azotreinam, 1151
  antimicrobial activity of, 1151
  mechanism of action, 1414
  pharmacological properties of, 1151
AZULFIDINE (sulfasalazine), 1114
Babesia. See Babesiosis
Babesia divergens, 1053
Babesia microti, 1053
Babesiosis, 1053
  atovaquone for, 1028, 1053
  treatment of, 1053
Bacillary infections, tetracyclines for, 1177
Bacillus Calmette-Guérin (BCG), 1422
Bacillus subtilis, 1198
Bacitracin, 1198–1199
  adverse effects of, 1199
  antibacterial activity of, 1199
  for cutaneous infections, 1690
  mechanism of action, 1198
  with neomycin, 1168, 1199
  source and chemistry of, 1198
  therapeutic uses of, 1198
Bacitracin zinc, ophthalmic use of, 1716f, 1718–1719
Baclofen, 331f
  for cocaine dependence, 621
  for muscle spasms, 229
  pharmacokinetics of, 1801t
  for spasticity, in ALS, 543
Bacterial vaginosis, clindamycin for, 1190
Bactericidal agents, 1096
  antagonism with bacteriostatic agents, 1103
Bacteriostatic agents, 1096
  antagonism with bactericidal agents, 1103
Bacteroides infection
  B. fragilis
  clindamycin for, 1189
  penicillin G for, 1136
  prophylaxis against, 1106f
  chloramphenicol for, 1180–1181
  in inflammatory bowel disease, 1017
  metronidazole for, 1058–1060
  piperacillin for, 1140
BACTODERM (mupirocin), 1690
BACTRIM (trimethoprim-sulfamethoxazole), 1116
BACTROBAN (mupirocin), 1199, 1690
BACTROBAN NASAL (mupirocin), 1690
Balantidiasis, 1053
Balantidium coli, 1053
Baldness. See Alopecia
Balsalazide

  peripheral, divisions of, 138–141
  neurotransmission in, 145–178
  neuromuscular blocking agents and, 226
  neurotransmission in, 145–178
antiseizure, 349, 414, 418
for anxiety disorders, 454
for benzodiazepine withdrawal, 615
cardiovascular effects of, 349, 417
chemistry of, 346, 347–348, 414, 415–416
in children, 124
clinical use of, 349
CNS effects of, 349, 414–417
sites and mechanisms of action, 414–416
CNS uses of, 418–419
dooses of, 348r, 349
formulations of, 347–349, 348r
and GABA/GABA receptors, 414–416
gastrointestinal effects of, 417
general as analgesic, 347–350, 401, 418–419
half-lives of, 415–416, 418
hepatic effects of, 417
hepatic metabolic uses of, 419
history of, 402
hypersensitivity to, 419
interactions of, 419
with antidepressants, 449
with disulfiram, 603
molecular actions of, 346
paradoxical excitement with, 419
peripheral nervous system effects of, 417
pharmacokinetics and metabolism of, 348r, 349
pharmacological properties of, 414–418
poisoning, 420
potency of, 349
psychiatric uses of, 419
renal effects of, 417
respiratory effects of, 349–348, 414–420
side effects of, 349–350
and sleep, 414, 424–425
therapeutic uses of, 401, 415r–416r, 418–420
tolerance to, 414, 610
Bare lymphocyte syndrome type I, 54r
Baroreceptor(s)
α adrenergic receptor antagonists and, 263–264
barbiturates and, 349
cardiac glycosides and, 887–888
general anesthesia and, 342
hypoxia and, 390
intrarenal, and renin secretion, 791, 792f
propofol and, 350
symptomimetic drugs and, 242
Barrett’s esophagus
ethanol and, 596
GERD and, 976–977
Barter’s syndrome, 664, 751
NSAIDs for, 682–683
Basal cell carcinoma, imiquimod for, 1696
Basal ganglia, 318
antipsychotics and, 469–471, 471f
circuitry of, 531–532, 532f
dopamine receptors in, 470–471
in Huntington’s disease, 540, 540f
in Parkinson’s disease, 531–533, 532f
in tardive dyskinesia, 480
Base(s), organic, renal secretion of, 741–742, 742f
Basiliximab, 1418–1419
site of action, 1407r
Basolateral membrane, transport across, 60, 63
Basophil(s)
Basolateral membrane, transport across, 60, 63
Batrachotoxin, 147, 225
Bell’s palsy, acyclovir for, 1250
Behçet syndrome
Bendroflumethiazide, 754. See also Thiazide diuretics
Bends
helium and, 397–398
oxygen therapy for, 393
BENEBMID (probencid), 710–711
BENICAR (olmesartan medoximil), 813
Benign prostatic hyperplasia (BPH)
α adrenergic receptor antagonists for, 267, 271
doxazosin for, 269–270
dutasteride for, 270, 1583
finasteride for, 267, 270–271, 1583
phenoxybenzamine for, 268
prazosin for, 269–271
tamsulosin for, 270
terazosin for, 269
testosterone in, 1577
Benoxinate, in opthalmic diagnosis, 1729
Benserazide, for Parkinson’s disease, 534
BENTYL (dicyclomine hydrochloride), 197
BENEBMID (probencid), 710–711
BENICAR (olmesartan medoximil), 813
Benign prostatic hyperplasia (BPH)
α adrenergic receptor antagonists for, 267, 271
doxazosin for, 269–270
dutasteride for, 270, 1583
finasteride for, 267, 270–271, 1583
phenoxybenzamine for, 268
prazosin for, 269–271
tamsulosin for, 270
terazosin for, 269
testosterone in, 1577
Benoxinate, in opthalmic diagnosis, 1729
Benserazide, for Parkinson’s disease, 534
BENTYL (dicyclomine hydrochloride), 197
BENUBMID (probencid), 710–711
BENICAR (olmesartan medoximil), 813
Benign prostatic hyperplasia (BPH)
α adrenergic receptor antagonists for, 267, 271
doxazosin for, 269–270
dutasteride for, 270, 1583
finasteride for, 267, 270–271, 1583
phenoxybenzamine for, 268
prazosin for, 269–271
tamsulosin for, 270
terazosin for, 269
testosterone in, 1577
Benoxinate, in opthalmic diagnosis, 1729
Benserazide, for Parkinson’s disease, 534
BENTYL (dicyclomine hydrochloride), 197
BENUBMID (probencid), 710–711
BENICAR (olmesartan medoximil), 813
Benign prostatic hyperplasia (BPH)
α adrenergic receptor antagonists for, 267, 271
doxazosin for, 269–270
dutasteride for, 270, 1583
finasteride for, 267, 270–271, 1583
phenoxybenzamine for, 268
prazosin for, 269–271
tamsulosin for, 270
terazosin for, 269
testosterone in, 1577
Benoxinate, in opthalmic diagnosis, 1729
Benserazide, for Parkinson’s disease, 534
BENTYL (dicyclomine hydrochloride), 197
BENUBMID (probencid), 710–711
BENICAR (olmesartan medoximil), 813
Benign prostatic hyperplasia (BPH)
α adrenergic receptor antagonists for, 267, 271
doxazosin for, 269–270
dutasteride for, 270, 1583
finasteride for, 267, 270–271, 1583
phenoxybenzamine for, 268
prazosin for, 269–271
tamsulosin for, 270
terazosin for, 269
testosterone in, 1577
Benoxinate, in opthalmic diagnosis, 1729
Benserazide, for Parkinson’s disease, 534
BENTYL (dicyclomine hydrochloride), 197
BENUBMID (probencid), 710–711
BENICAR (olmesartan medoximil), 813
Benign prostatic hyperplasia (BPH)
α adrenergic receptor antagonists for, 267, 271
doxazosin for, 269–270
dutasteride for, 270, 1583
finasteride for, 267, 270–271, 1583
phenoxybenzamine for, 268
prazosin for, 269–271
tamsulosin for, 270
terazosin for, 269
Benzalkonium chloride, 1715
Benzamides, 467
receptor specificity of, 1002f

tolerance to, 622
withdrawal from, 622
CALAN (verapamil), 834r
CALCIDRINE SYRUP (calcium iodide), 1532r
Calcifediol, 1653f, 1654–1655
Calciferol, 1664
CALCIEX (calcitriol), 1663
CALCMAR (calcitonin), 1662
Calcimimetics, 1669–1670
Calcineurin inhibitors
dermatologic use of, 1694–1696
for fistulas, in Crohn’s disease, 1016
for immunosuppression, 1406, 1408–1412
and tolerance, 1420
Calcipotriene/calcipotriol, 1664–1665, 1679, 1701–1702
Calcitonin, 1511, 1656–1657, 1657
in bone metabolism, 1656–1657
diagnostic uses of, 1666
for hypercalcemia, 1656, 1662, 1666
for osteoporosis, 1671, 1672
for Paget’s disease, 1656, 1666
therapeutic uses of, 1666
Calcitonin gene-related peptide, 138, 681, 1649–1657
regulation of, physiology of, 1649–1657
phenytoin and, 1648
in parathyroid hormone regulation, 1650–1652, 1650
for osteoporosis, 1672
loop diuretics and, 752–753
intracellular, 1647
and insulin secretion, 1616
hypoglycemic effects of, 1633
and gastrointestinal motility, 989
facilitated diffusion of, 1648
extracellular, 1647–1648
absorption of, 1648–1649
intestinal, 1655
and aminoglycoside toxicity, 1164
and calcitonin secretion, 1656
cardiac glycosides and, 886–887, 887f
chelating agent affinity for, 1754
in congestive heart failure, 872
diffusible, 1647
diuretics and, 1649
ethanol and, 598
excretion of, 1648–1649
extracellular, 1647–1648
facilitated diffusion of, 1648
and gastrointestinal motility, 984
glucocorticoids and, 1598, 1648
and histamine release, 632
hypoglycemic effects of, 1633
and insulin secretion, 1616
intracellular, 1647
ionized form of (Ca²⁺), 1647
levels in healthy adults, 1647
loop diuretics and, 752–753
for osteoporosis, 1672
parathyroid hormone and, 1650–1652, 1650f
in parathyroid hormone regulation, 1650–1651
phenytoin and, 1648
plasma concentration of, 1647, 1648f
pools of, 1647, 1648f
regulation of, physiology of, 1649–1657
renal handling of, 742
renal retention of, 1656
as second messenger, 31
stores of, 1648
therapeutic uses of, 1663
transport of, vitamin D-dependent, 1648
turnover of, 1648–1649, 1648f
vasopressin receptors and, 776–777, 776f
Calcium acetate, 1663
Calcium carbonate, 1663
Calcium channel(s), 321, 322
acetylcholine and, 185
and action potential, 147
in cardiac electrophysiology, 901–904, 901f
as therapeutic target, 908
and catecholamine release, 163
for angina, 823–824, 832–837
adverse effects of, 836–837, 857–858
absorption, fate, and excretion of, 836
chemistry of, 832, 833
negative inotropic effect of, 834
mechanism of action, 832–834
vascular actions of, 834
for hypertension, 846
for angina, 823–824, 832–837
frequency/use dependence of, 835
for cardiac arrhythmia, 908, 914
cardiac cell actions of, 834–835
for diarrhea, 998
for constipation, 992
for hypocalcemia, 1666
for myocardial ischemia, 823
therapeutic uses of, 837–839
with β-adrenergic receptor antagonists, 837–839
with β-adrenergic receptor antagonists
and nitrites, 841
exertional, 837
with nitrites, 839–841
unstable, 837
for cardiac arrhythmia, 908, 914
cardiac cell actions of, 834–835
cardiovascular effects of, 833r–834r, 834–836
chemistry of, 832, 833r–834r
for dementia, 430
for diarrhea, 998
frequency/use dependence of, 835
for gastrointestinal motility disorders, 989, 998
hemodynamic effects of, 835–836
hyperglycemic effects of, 1632, 1633r
for hypertension, 846f, 857–858
ACE inhibitors with, 805
for hyperthyroidism, 1530
interactions of, 858
with cyclosporine, 1412
with cyclochrome P450 enzyme-inhibiting agents, 122
mechanism of action, 832–834
metabolism of, induction of, 89–90
for myocardial infarction, 837–838
for myocardial ischemia, 823
negative inotropic effect of, 834
neuromuscular blocking actions of, 226–227
pharmacological properties of, 834–837
and smooth muscle, 834, 857–858
therapeutic uses of, 837–838
toxicity of, 836–837
vascular actions of, 834
for vinca alkaloid resistance, 1350–1351
Calcium chloride, 1663
CALCIUM DISODIUM VERSENATE (edetate calcium disodium), 1769
Calcium entry blockers. See Calcium channel antagonist(s)

methotrexate for, 1338
vinblastine for, 1351
Choriongonadotropin alfa, 1505
Choriionic gonadotropin, 1505
Chromaffin granules, 159
Chromated copper arsenate (CCA), 1764
Chromobacterium violaceum, 1151
Chromogranin A, 159
Chronic lymphocytic leukemia (CLL)
chlorambucil for, 1329
cyclophosphamide for, 1328
fludarabine for, 1346, 1348
pentostatin for, 1349
Chronic myelocytic leukemia (CML)
bcr-abl translocation in, 1315
bispamohones for, 1668
busulfan for, 1330
hydroxyurea for, 1364–1365
imatinib for, 1366–1368
pentostatin for, 1349
topotecan for, 1356
Chronic myelomonocytic leukemia
(CMML), imatinib for, 1367
Chronic obstructive pulmonary disease
(COPD)
asthma drugs for, 731–732
benzodiazipines and, 407, 412
formoterol for, 253–254
 genetics of, 732
 glucocorticoids for, 732, 1608–1609
 muscarinic receptor antagonists for, 195–
196, 199
 phosphodiesterase 4 inhibitors for, 728
salmeterol for, 253
tiotropium for, 730–731
CHRONULAC (lactulose), 992–993
Chrysiasis, 1729
Churg-Strauss syndrome, leukotriene recep-
tor antagonists and, 724
Chylomicron(s), 934–935, 935
Chylomicron remnant(s), 934–935, 935
buoyancy of, 934
 ezetimibe and, 959
metabolism of, 937–938, 937
synthesis of, 934
Chylomicronemia syndrome, fibrin acid
derivatives for, 958
Chylomicron remnants, 935, 937–938,
937
Chymase, in angiotensin synthesis, 795
Cl-1007, 490–491
CIALIS (tadalafil), 829–830
Ciclopirox olamine, 1239
Cidofovir, 1250–1251
for onychomycosis, 1239, 1691
Cidofovir, 1250–1251
 for onychomycosis, 1239, 1691
Ciclopirox olamine, 1239
Cidofovir, 1250–1251
antiviral activity of, 1250–1251, 1717
pharmacokinetics of, 1810
therapeutic uses of, 1251, 1691, 1717
Cilastozol, 841–842
Cilastatin with imipenem, 1150–1151, 1835
pharmacokinetics of, 1835
Cilastozol, 841–842
Cimetropium, for irritable bowel syndrome, 121
Cimetidine, 971–973
Cinacalcet, 1669–1670
Cinnoxicam, 701
Cinnarizine, 832
Cinnamates, 1700
Cinchonism, 928, 1038–1039
Cinchona, 1035–1036
Cirrhosis
drug clearance in, 121
megaloblastosis in, triamterene and, 759
metabolic acidosis in, mineralocorticoid receptor antagonists and, 762
methylene and, 1338
primary biliary, bile acid therapy for, 1007
vasopressin in, 784–785
Cisapride, 467
chemistry of, 987f
for gastrointestinal motility disorders, 988
interaction with itraconazole, 1231
limited access to, 988
metabolism of, 78
Cis-flupentixol, chemistry of, 462
Cisplatin, 1332–1334
with fluorouracil, 1343
nausea induced by, treatment of, 1005
pharmacokinetics of, 1811
resistance to, 1333
therapeutic uses of, 1333
toxicities of, 1326t, 1334
with vinblastine, 1351
Citalopram, 432, 434t
CYP interactions of, 445, 446, 449
depression, 432
drug interactions of, 449
pharmacokinetics of, 445t, 1811t
potency of
receptors, 440r
transporters, 438r
Citanest (prilocaine), 378
Citrobacter
pharmacokinetics of, 1811
drug interactions of, 1187
resistance to, 979, 1183–1184, 1218
prophylactic uses of, 1186
for antibiotic spectrum, 1119
for anthrax, 1122
antibacterial spectrum of, 1119
in children, 1122
for diabetic foot infections, 1122
for dialysis-related peritonitis, 1121–1122
for fever, with cancer therapy, 1122
for inflammatory bowel disease, 1010r, 1017
interaction with didanosine, 1286
for Mycobacterium avium complex, 1218
ophthalmic use of, 1716t
pharmacokinetics of, 1811t
for prostatitis, 1121
for respiratory tract infections, 1122
for sexually transmitted diseases, 1121
for shigellosis, 1121
for tularemia, 1122
for typhoid fever, 1140
Ciprofloxacin, 642
Cirrhosis
alcoholic, 597
desmopressin for, 786
diuretics for, 764–765
loop, 753
spironolactone, 762
thiazide, 756
therapeutic uses of, 1185–1186, 1218
for toxoplasmosis, 1186
Clarin (loratadine), 638t
Class A drugs, 1783–1784
Class B drugs, 1783–1784
Class C drugs, 1783–1784
Claudication, treatment of, 841–842
Claviceps purpurea, 308
Clavulanic acid, 1132, 1151–1152
with amoxicillin, 1107t, 1133, 1140, 1152
with ticarcillin, 1152
Clearance of drugs, 12–14, 1789
alterations in individual patients, 1792–1793
in children, 123–124, 123f
circulatory insufficiency and, 121
in elderly, 124
and half-life, 16
hepatic, 13–14
in elderly, 124
impaired, 120–121
in neonates and children, 123
intrinsic, 14, 1789
renal, 14, 1789, 1792
in elderly, 124
impaired, 120–121, 1792–1793
in neonates and children, 124
saturation in, 18
total systemic, 1789
transporters and, 43, 44f, 58, 59f
CLEFT EYES (naphazoline), 1721t
Clemastine fumarate, 638r
Cleocin (clindamycin), 1189
Cleocin Pediatric (clindamycin phosphate), 1189
Cleocin Phosphate (clindamycin phosphate), 1189
Cleocin-T (clindamycin), 1190, 1690
Clevudine, 1267r
Clostridium bine, for irritable bowel syndrome, 1000
CLIMARA (estradiol), 1551
Clinafloxacin, withdrawal from market, 1119
Clindamycin, 1188–1190
for acne, 1690
antibacterial activity of, 1188–1189
for babesiosis, 1053
for malaria, 1026r, 1042–1043, 1045
neuromuscular blocking actions of, 227, 1190
ophthalmic use of, 1719
pharmacokinetics of, 1812t
prophylactic uses of, 1106–1107t
for pyrimethamine toxicity, 1031
therapeutic uses of, 1189–1190
for toxoplasmosis, 1051, 1190, 1719
Clinical (maximal) efficacy, 125–126, 126f
Clinical testing, in drug development, 134f
Clinical therapeutic index, 127
Clinical toxicology, 1739
Clinical trial(s), 117–119
results of, and regulatory process, 132
surrogate end points in, 118
CLINORIL (sulindac), 697
Clofazimine, 1220
Clofibrate, 957–959, 957f/
for diabetes insipidus, 783
for dyslipidemia, 957–959
for diabetes insipidus, 783
for peripheral vascular disease, 841
Clonazepate, 403r, 407–409
dosages of, 410r
metabolism of, 408, 409r
pharmacokinetics of, 410r, 1813t
for seizures/epilepsy, 516–517
therapeutic uses of, 410r, 517
for withdrawal syndrome, 615
Clorgyline, 299
Closidium toxins, and acetylcholine release, 152
Clothiapine, 490
Clofibrate, 957–959, 957/
for diabetes insipidus, 783
for dyslipidemia, 957–959
hypoglycemic effects of, 1633
for mania, 489, 492
metabolism of, 409r, 409f
pharmacokinetics of, 410r, 1812t
routes of administration, 410r
for seizures/epilepsy, 404–405, 516–517
in Huntington’s disease, 541
for spasticity, in ALS, 543
therapeutic uses of, 410r, 517
tolerance to, 404
Clonazepam, 403t
adverse effects of, 516
for anxiety, 453–454
dosages of, 410t, 517
interaction with valproic acid, 515
for mania, 489, 492
metabolism of, 409r, 409f
pharmacokinetics of, 410r, 1812t
routes of administration, 410r
for seizures/epilepsy, 404–405, 516–517
in Huntington’s disease, 541
for spasticity, in ALS, 543
therapeutic uses of, 410r, 517
tolerance to, 404
Clonidine, 255–256
adverse effects of, 255–256, 854–855
for anxiety, 454
for diarrhea, 256, 997
for gastrointestinal motility disorders, 988
for glaucoma, 1723
hyperglycemic effects of, 1632, 1633r
for hypertension, 256, 854–855
interaction with antidepressants, 450
for irritable bowel syndrome, 999
for menopausal symptoms, 256, 1553
pharmacokinetics of, 1812r–1813t
pharmacological effects of, 255, 854
in pheochromocytoma diagnosis, 256
precautions with, 854
therapeutic uses of, 256, 855
for Tourette’s syndrome, 485
and vasopressin secretion, 784
withdrawal from, 256, 855
for withdrawal syndromes, 256, 619, 997
Clocortolone pivalate (CLODERM), 1602
Clotrimazole, 1237–1238
C ocaine, 369, 370f–371f, 376–377
abuse of, 608
with alcohol, 620–621
CNS effects of, 375
dependence on, 608, 611, 620–622
percent and risk of, 608–609, 609t
pharmacological interventions for, 621–622
and dopamine transporter, 66
fetal effects of, 621
with heroin, illicit use of, 618
as local anesthetic, 369, 376–377, 380
preparations of, 377
mechanism of action, 239
nerve fiber sensitivity to, 373
and NET (transporter), 66
and norepinephrine, 161, 620
ophthalmic use of, 1721, 1730
pharmacological actions of, 377, 620
pupillary effects of, 1713r
reinforcing properties of, 608, 620
sensitization to, 611, 611f, 621
and serotonin syndrome, 450
sexual effects of, 621
tolerance to, 621
topic, 380
toxicity of, 621
withdrawal from, 621–622, 621r
Coccidioides infection. See Coccidioidomycosis
Coccidioidomycosis
amphotericin B for, 1228
flucytosine for, 1223
itraconazole for, 1231
nystatin for, 1231
treatment of, 1226t
Cochlear toxicity, of aminoglycosides, 1162–1163
Codeine, 564, 565t, 547, 566
absorption of, 566
adverse effects of, 567–568
for analgesia, dosage of, 580r, 581
conversion to morphine, 566
for cough suppression, 578–579
Cyclooxygenase(s)—continued
Cox-3, 674, 693
inhibition of, 657–658. See also
Cyclooxygenase inhibitor(s)

and extrapyramidal effects, 469–473
Dopamine—continued
in Parkinson’s disease, 333, 469, 527, 529–533, 530f–532f, 538
pharmacological properties of, 249–250
precautions with, 249
and prolactin, 1489, 1499
release of, 158–161, 160f, 163
renal effects of, 249
in schizophrenia, 431
renal effects of, 249
in sensitization, 611, 611f
for shock, 249, 261
storage of, 158–163, 160f
synthesis of, 158–161, 158f, 159f, 160f, 530f–531f
therapeutic uses of, 240, 249
and vasopressin, 775
Dopamine-β-hydroxylase, 158–161, 158f, 159f, 160f, 163
deficiency of, 158, 174
Dopamine receptor(s), 149, 249, 324f, 333, 530–531, 531f
antidepressants and, 439, 441, 455
antipsychotics and, 467, 469–473, 471f, 472r, 476
in basal ganglia, 470–471, 532–533, 532f
D_{1}, 333, 531, 531f
antipsychotics and, 470, 471f, 472r
D_{2}, 333, 531, 531f
antipsychotics and, 470, 471f, 472r,
473, 476, 490–491
in nausea/vomiting, 1000–1001, 1000f, 1002f
D_{3}, 333, 531, 531f
antipsychotics and, 470–471, 471f, 491
D_{4}, 333, 531, 531f
antipsychotics and, 470–471, 472r
D_{5}, 333, 531, 531f
dimerization of, 29
distribution of, 531f
D_{1}, 333
D_{2}, 333
interaction with ergot alkaloids, 309f
in limbic system, 470–471
in Parkinson’s disease, 333, 529–533, 530f–532f
polymorphisms in, 106f
in tardive dyskinesia, 480
in vivo occupation of, 473
Dopamine receptor agonist(s), 324r, 535, 535f
for congestive heart failure, 889–892, 891f
duration of action, 535
for growth hormone excess, 1498
new versus old, 535
for Parkinson’s disease, 535–536, 538
partial, for psychosis, 490–491
for prolactin excess, 1500
Dopamine receptor antagonist(s), 324f
for gastrointestinal motility disorders, 985–986
for nausea/vomiting, 1002f, 1003
for psychosis, 491
with serotonin receptor antagonists, for psychosis, 490–491
Dopamine receptor-effector coupling, 324r
Dopamine transporter (DAT), 41, 65–66, 161, 162r
antidepressants and, 438r, 439, 455
pseudopomphism in, ethnic diversity and, 97, 98f
Dopamine transporter blocker, 324r
Dopexamine, 250
DORAL (quazepam), 411
Dorsal root ganglia (DRG), opioid analgesia and, 557–558
Dorzolamide, 1723
Dose(s)
bioequivalence in, 7
in children, 123–124
controlled-release, 5
design and optimization of, 1787–1793
for prolactin excess, 1500
for psychosis, 490–491
for Parkinson's disease, 535–536, 538
duration of action, 535
for congestive heart failure, 889–892,
with serotonin receptor antagonists, for
in tardive dyskinesia, 480
Doxercalciferol, 1664
DOXIL (doxorubicin), 1359
DOXINATE (docusate sodium), 993
Doxorubicin, 1357–1360
cardiac effects of, 1358–1359
dosage of, 1358
for Kaposi’s sarcoma, 1697
liposomal, 1359
mechanism of action, 1358
newer analogs of, 1359
pharmacokinetics of, 1819r
therapeutic uses of, 1358–1359
toxicities of, 1359
Doxycycline, 1173–1179
adverse effects of, 1178–1179
antimicrobial effects of, 1173–1174
dosage of, 1176
excretion of, 1175–1176
for filariasis, 1085
for malaria, 1025–1026r, 1042–1044
in recurrence, 1044
for onchocerciasis, 1085
pharmacokinetics of, 1820r
resistance to, 1174–1175
routes of administration, 1176
source of, 1173
teratogenicity of, 1043
therapeutic uses of, 1176–1178
Doxylamine, as sedative-hypnotic, 422

Fenfluramine, 305, 622
interaction with MAO inhibitors, 450
mechanism of action, 305
and migraine, 306
Fenofibrate, 957–959, 957f
interaction of, 90
pharmacokinetics of, 1824f
for osteoporosis, 958–959
Fenoldopam, 249
Fenoprofen, 699f, 700
versus aspirin, 678f
classification of, 678f
pharmacokinetics of, 678f, 700
Fenoterol, 252
with ipratropium, 730
FENTANYL ORALET (fentanyl), 571
Fentanyl, 569f, 571–572
as adjunct to anesthesia, 361–362, 561
epidural and intrathecal, 385, 571, 582f
with heroin, illicit use of, 618
pharmacokinetics of, 1825f
pharmacological properties of, 571
receptor action and selectivity of, 552f, 553
and rigidity, 559, 571
as sedative-hypnotic, 422
structure of, 571
therapeutic uses of, 571–572
FEGOSOL (ferrous sulfate), 1448
FEOSTAT (ferrous fumarate), 1448
FERGON (ferrous gluconate), 1448

Index 1937
FLUOTHANE (halothane), 354

Fluoxetine
- chemistry of, 432, 435
- CYP interactions of, 445
- for depression, 432
- in Huntington’s disease, 541
dose and dosage forms of, 435
drug interactions of, 446, 449–450
- with antipsychotics, 481
- with carbamazepine, 513
metabolism of, 444–445
pharmacogenetics of, 125
pharmacokinetics of, 445
potency of
- for receptors, 440
- for transporters, 438
sexual side effects of, cyproheptadine for, 314
side effects of, 435
and vasopressin secretion, 784
Fluoxetine/olanzapine, 453, 482
Fluoxymesterone, chemistry of, 1578
Fluperlapine, chemistry of, 462–466
Fluphenazine
- chemistry of, 462, 463
- dose and dosage forms of, 463, 477, 483
formulations, 462, 463, 475, 477
metabolism of, 475–476
pharmacokinetics of, 475, 1827
receptor actions of, 472, 474, 1002
side effects of, 463
therapeutic uses of, 481–484
and vasopressin, 775
and weight gain, 480
Flurandrenolide, 1682
Flurazepam, 403, 407–409
- adverse effects of, 412
- pharmacokinetics of, 408–410, 411
- therapeutic uses of, 411, 412
Flurbiprofen, 699–701
-versus aspirin, 678
- chemistry of, 699
- classification of, 678
ophthalmic use of, 1725
pharmacokinetics of, 678
Flushing
- niacin and, 683–684, 956
- vancomycin and, 632, 1196
Fluspirilene, 466
Flutamide, 1389–1390, 1582
- adverse effects of, 1582
- chemistry of, 1582
- for hirsutism, 1582
- pharmacokinetics of, 1390, 1828
- for prostate cancer, 1387–1388, 1582
Fluticasone propionate
- for asthma, 721–722, 1608–1609
- for rhinitis, 731
- with salmeterol, 721
Fluvastatin, 58, 948–953
- absorption, metabolism, and excretion of, 950–951
- adverse effects of, 951–952
- chemistry of, 948, 949
- dosage, for LDL-lowering effects, 949–950
- drug interactions of, 951–952
- mechanism of action, 948–950
- therapeutic uses of, 952–953
Fluvoxamine, 434
- CYP interactions of, 445
- for depression, 432
- dose and dosage forms of, 434
- interaction with antipsychotics, 481
- pharmacokinetics, 445
- potency of
- for receptors, 440
- for transporters, 438
side effects of, 434
FOCALIN (dexamethasone), 260
Folic acid, 1335, 1452–1453, 1458–1461
- absorption, distribution, and elimination of, 1458–1459, 1459
- chemistry of, 1458, 1459
- daily requirements for, 1458
- deficiency of, 1452, 1459–1461
- diagnosis of, 1460
- hematopoietic effects of, 1460
- metabolic effects of, 1452–1453
- trimethoprim-sulfamethoxazole and, 1118
- metabolic role of, 1452–1454, 1453
- 1458
- ophthalmic effects of, 1731
- relationship with vitamin B12, 1452–1454, 1453
- supplementation of, 1460–1461
- in inflammatory bowel disease, 1018
- in pregnancy, 524, 1458
- with pyrimethamine therapy, 1305–1306
- therapeutic uses of, 1454, 1455
- for cancer chemotherapy, 1316
- resistance to, 1336–1337
- cytotoxic action of, 1336
- pharmacogenetics of, 1338
- mechanism of action, 1336
- resistance to, 1336–1337
- sites of action, 1335–1336, 1335
- structure-activity relationship of, 1335–1336, 1337
- therapeutic uses of, 1338–1339
- toxicity of, 1339
- transport of, 1336
- Follicle-stimulating hormone (FSH), 1489, 1490, 1500–1507
- action of, molecular and cellular bases of, 1501–1503
- in differential diagnosis of reproductive diseases, 1505
- estrogen and, 1545–1546, 1546
- in menstrual cycle, 1505, 1546
- opioid receptor antagonists and, 577
- opioids and, 559
- oral contraceptives and, 1546–1546
- for ovulation induction, 1506
- physiological effects of, 1503
- pulsatil release of, 1545
- recombinant, 1505
- synthesis and secretion of, 1501, 1501
- and testosterone secretion, 1573
- therapeutic uses of, 1505–1506
- Folliculin, 1690
- FOLLISTIM (follicitropin β), 1505
- Follitropin, 1505
- Fomepizole, 1751
- FOMEPIZOLE (4-methylprazole), 593
- Fomiviren, 1253, 1268
- for CMV infection, 1253, 1717
- ophthalmic use of, 1717
- Fondaparinux, 1473
- Food, Drug, and Cosmetic Act, 132–133
- Food and Drug Administration (FDA), 131–135
- mandate of, 128
- nonproprietary drug standards of, 131
- postmarketing surveillance by, 133–135, 134
- Food Quality Protection Act of 1996, 209
- FORADIL (formoterol), 720–721
- FORANE (isoflurane), 357
- Forebrain, opioid analgesia and, 558
- Foreign-body infection, antimicrobial therapy in, 1101
- Formalin test, for pain, 558
- Formate, folic acid and, 1458
- Formestane, 1385
- Formoterol, 252–253, 720–721
- Formoterol-budesonide, 721
- FORTOVASE (saquinavir), 1301
- FOSAMAX (alendronate), 1668
- Fosamprenavir, 1276, 1305–1306
- chemistry of, 1304
- combination therapy, 1297
- drug interactions of, 1295, 1300
- for HIV infection, 1305–1306
- pharmacokinetics of, 1299, 1305–1306
- therapeutic use of, 1305–1306
- Forskarnet, 1253–1254
- pharmacokinetics of, 1828
- therapeutic uses of, 1253–1254, 1717
- FOSCAVIR (foscarnet), 1717
- Fosfomycin, for urinary tract infections, 1115
- Forminolin, 801, 802, 803
- adverse effects of, 808–810
- chemistry of, 801, 802
- for congestive heart failure, 879
- in heart disease, 806–807
- for hypertension, 858–859
- therapeutic uses of, 804–808
- Fosmidomycin, for malaria, 1045
- Fosphenytoin, 23, 509–510
- 4S trial, 941
- FPL 55712, 722
- FR173657, 644, 649
- FR190997, 644, 649
- Fractional availability (F), 1788
Gastric acid(s), 967–980
  gastric defenses against, 968–969
  agents enhancing, 973–976
  secretion of
    anticholinergic agents and, 975
    histamine and, 632–634, 967–968, 968f
    histamine H₂ receptor antagonists and, 632–634, 971–973
  pharmacological regulation of, 968f
  physiology of, 967–968, 968f
  prostaglandins and, 661, 968f
  proton pump inhibitors and, 969–971

Gastric cancer
  fluorouracil for, 1343
  irinotecan for, 1356
  mitomycin for, 1363
  oxaliplatin for, 1334
  mitomycin for, 1363
  irinotecan for, 1356
  fluorouracil for, 1343
  histamine H₂ receptor antagonists and, 193–194
  neurotransmission in, 139–141, 983–984, 984f
  NSAIDs and, 683–684, 683f
  opioid, 561
  regulation of, 983–984, 984f
  serotonin (5-HT) in, 302–303, 984f
  smooth muscle excitation-contraction coupling and, 984
  stimulation of, prokinetic and other agents for, 985–989
  water and electrolyte flux in, 989

Gastrointestinal stromal tumor (GIST), imatinib for, 1367
  acetylcholine and, 185, 186f
  anticholinesterase agents and, 208, 210
  acetylcholine and, 185, 186
  drug absorption via, 4–5, 74
  drug metabolism in, 11, 74
  drug absorption via, 4–5, 74
  eicosanoids and, 661, 665
  enflurane and, 358
  epinephrine and, 246
  enflurane and, 358
  eicosanoids and, 661, 665
  enflurane and, 358
  epinephrine and, 246
  ethanol and, 596–597
  halothane and, 356–357
  histamine and, 632–633
  halothane and, 356–357
  histamine and, 632–633
  isoflurane and, 358
  lead poisoning and, 1755
  muscarinic receptor agonists and, 185, 186, 187
  muscarinic receptor agonists and, 193–194

Glomerular filtration rate (GFR)
eicosanoid inhibition by, 657
duration of action, 1594–1596, 1595
gene expression regulation by, 1596
history of, 1587–1588
in diabetes mellitus, 1623, 1642–1643
and insulin secretion, 1616
and formation of collagen, 1610
and formed elements of blood, 1599
monitoring with, 1606, 1683
mechanism of action, 721–722, 1407
with  CYP inhibitors, 122
with sulfasalazine, 1013, 1114
inhaled, 721–722
adverse effects of, 722, 723t
interactions of with CYP inhibitors, 122
with mipectrin, 1562
intravenous, 1682–1683
for loiasis, 1076
mechanism of action, 721–722, 1407
monitoring with, 1606, 1683
Na+-retaining potency of, 1594t
for nausea/vomiting, 343, 1005
and nitric oxide synthase, 177–178
for non-endocrine diseases, 1607–1610
ophthalmic use of, 1609, 1718, 1724–1726
Glyburide
"Glyburide, 1364"
with opioids, for analgesia, 581
and osteonecrosis, 1604
and osteoporosis, 1604
for penicillin hypersensitivity, 1143
and peptic ulcers, 1604
pharmacogenetics of, 731
pharmacological effects of, 1597–1600
in pregnancy, 1018
preparations of, 1601, 1602r
in protein metabolism, 1597–1598
with radiation therapy, 1380–1381
relative potencies of, 1594f, 1603–1608
for renal diseases, 1608
replacement therapy
for renal diseases, 1608
and vasopressin, 775
for trichinosis, 1076
and seizures, in infants and young children, 523
for septic shock, 1609
site of action, 1407r
and skeletal muscle, 1599
for skin diseases, 1609
specificity of, receptor-independent
mechanism of, 1596, 1597f
for spinal cord injury, 1610
structure-activity relationships of, 1601–1603
supraphysiological doses of, continued
use of, 1603–1604
synthesis of, 1589–1591, 1590f
systemic, 722
adverse effects of, 722
for dermatologic disease, 1683
teratogenicity of, 1604
therapeutic principles for, 1604–1605
therapeutic uses of, 1408, 1604–1610,
1682–1683, 1724
for thrombocytopenia, 1610
topical, 1681–1683, 1682r
toxicity of, 722, 723r, 1408, 1603–1604,
1683, 1724–1725
transport, metabolism, and excretion of, 1601
for trichinosis, 1076
and vasopressin, 775
withdrawal of, 1603
Glucocorticoid receptor(s), 29, 1595–1596,
1595f
mutations of, 1595
Glucocorticoid response elements (GREs), 29, 1596
Glucokinase, 1616, 1618
β-D-glucopyranosiduronic acid(s), 82
Glucose
abnormal metabolism of. See Hyperglycemia; Hypoglycemia
α adrenergic receptor antagonists and, 267
epinephrine and, 246
estrogen and, 1548
and glucagon secretion, 1642
glucocorticoids and, 1597–1598, 1603
and insulin secretion, 1615–1616
insulin therapy and, 1625–1633
loss and replacement, in diarrhea, 995
metabolism of, insulin and, 1617–1619,
1622
oral contraceptives and, 1566
progesterone and, 1560
transport of, insulin and, 1617
Glucose-dependent insulinotropic polypeptide (GIP), 1641
Glucose-insulin-potassium infusion, 1632
Glucose-6-phosphate (G-6-P), 1617–1619
Glucose-6-phosphate dehydrogenase deficiency
and antimicrobial therapy, 1102
choloroquine and, 1035
dimeracrol and, 1770
melsarsoprol and, 1507
pharmacogenetics in, 93–94, 101–102
primuamine and, 1040–1041, 1045
quinate and, 1039
sulfonamides and, 1116
Glucose tolerance impaired, 1641
thiazide diuretics and, 756
triaterenene and, 759
Glucose transporters, 42–43, 1617
Glucocorticoids
and seizures, 503
in amyotrophic lateral sclerosis, 542–543
in epilepsy, 503
excitotoxicity of, 332, 528–529, 542
in glaucoma, 1712
in neurodegenerative disorders, 528–529
as neurotransmitter, 139, 140f–141f,
323r, 327, 332
in Parkinson’s disease, 532, 532f
Glutamate receptor(s), 28, 149, 323r, 331f, 332
antidepressants and, 441, 455
antipsychotics and, 474, 491
barbiturates and, 414–416
ethanol and, 600–601
general anesthesia and, 346
Glutamate receptor agonist(s), 323r
Glutamate receptor antagonist(s), 332
and seizures, 503
Glutamate receptor-effector coupling, 323r
Glutamate transporter blocker, 323r
Glutamine, and vasopressin, 775
Glutathione S-transferases (GSTs), 73, 83–85
in drug resistance, 83–85
fraction of clinically used drugs metabolized by, 78f
polymorphisms of, 83, 96, 105r, 110
sites of action, 75
Glutathione, 420
and sleep, 425
toxicity of, treatment of, 1749
Glyburide, 1635–1638
chemistry of, 1635, 1636r
for diabetes mellitus, 1638
with metformin, 1639
pharmacokinetics of, 1831f
Glycerin, 747–749, 747t
for constipation, 995
ophthalmic use of, 748–749, 1734–1735
therapeutic uses of, 748–749
Glyceryl trinitrate, 825, 830
Glycine, 331f
in insulin therapy, 1633
as neurotransmitter, 323r, 327, 332
serine conversion to, 1458
Glycine receptor(s), 28, 149, 323r, 332
agonist(s), 323r, 331f
antagonist(s), 323r, 331f
effector coupling, 323r
general anesthesia and, 346
Glycine transporter blocker, 323r
Glycolic acid, for hyperkeratotic disorders, 1702
Glycopen hormone, 1148, 1490t,
1501–1503
Glycopyrrolate, 197
for angina, 841
with endovascular stenting, 842
Glycopyrrolate, 197
for irritable bowel syndrome, 1000
for neuromuscular blocker toxicity, 226–228, 362
Glycosides, cardiac. See Cardiac glycosides
Glycosuria
Glycoprotein hormones, 1489, 1490t
Goiters, toxic uninodular/multinodular, 1522
and radioactive iodine for, 1529–1530, 1533–1535
remissions and, 1529
toxic diffuse, 1522
and lithium and, 487
and radioactive iodine, 1529–1530
and radioactive iodine, 1533–1535
remissions and, 1529
Goitrin, 1527
Glycoprotein IIb/IIIa receptor antagonist(s), 1483
for angina, 841
with endovascular stenting, 842
Glycoyplolyte, 197
for irritable bowel syndrome, 1000
for neuromuscular blocker toxicity, 226–228, 362
Glycosides, cardiac. See Cardiac glycosides
Glycosuria
ACE inhibitors and, 809
phenytoin and, 510
salicylates and, 689
Glycosylation end products, advanced, 1624
Glycylcyclines, 1175
Glycyrhizinic acid, 1596
GLYSET (miglitol), 1640
Glycine, 331f
in insulin therapy, 1633
as neurotransmitter, 323r, 327, 332
serine conversion to, 1458
Glycine receptor(s), 28, 149, 323r, 332
agonist(s), 323r, 331f
antagonist(s), 323r, 331f
effector coupling, 323r
general anesthesia and, 346
Glycine transporter blocker, 323r
Glycemic acid, for hyperkeratotic disorders, 1702
Glycoprotein hormones, 1489, 1490t,
1501–1503
Glycoprotein Ia/IIa, 1468f
Glycoprotein IIb/IIIa receptor antagonist(s), 1483
for angina, 841
with endovascular stenting, 842
Glycopyrrolate, 197
for irritable bowel syndrome, 1000
for neuromuscular blocker toxicity, 226–228, 362
Glycosides, cardiac. See Cardiac glycosides
Glycosuria
ACE inhibitors and, 809
phenytoin and, 510
salicylates and, 689
Glycosylation end products, advanced, 1624
Glycylcyclines, 1175
Glycyrhizinic acid, 1596
GLYSET (miglitol), 875
GLYSET (miglitol), 1640
GnRH. See Gonadotropin-releasing hormone
Goblet cells, vitamin A and, 1733–1734
Goiter, 1511, 1519
diet-induced, 1527
lithium and, 487
radioactive iodine for, 1529–1530, 1533–1535
remissions and, 1529
toxic diffuse, 1522
toxic uninnodular/multinodular, 1522
treatment of, 1526–1535
Goldstein, 1527
Goldman-Hodgkin-Katz equation, 46
Guanafex, 256–257
    adverse effects of, 257, 854–855
    for hypertension, 854–855
    pharmacological effects of, 854
    precautions with, 854–855
    therapeutic uses of, 855
Guanadrel, 855–856
Guanadren, 1633
Guanadrel, 855–856
    mechanism of action, 171–173, 855
    therapeutic uses of, 856
Guanethidine, 171–173
Guanfacine, 256
    adverse effects of, 258, 855
    for hypertension, 256, 854–855
    pharmacological effects of, 854
    precautions with, 854–855
    therapeutic uses of, 256, 855
    withdrawal from, 256
Guanine, 1339
Guanyl cyclase(s)
    as receptors, 26–27
    in cGMP synthesis, 30
    antagonist, 171–173, 855
    mechanism of action, 854
    for hypertension, 256, 854–855
    pharmacological effects of, 854
    mechanism of action, 171–173, 855
    therapeutic uses of, 856
Gyromitra, 189
Habitrol (nicotine), 1238
Habitrol (nicotine), 232
Haemophilus ducreyi
    infection, 1079, 1085–1086
Haemophilus ducerei infection, quinolones
    for, 1121
Haemophilus infection
cephalosporins for, 1150
    drug-resistant, 1096, 1098
Haemophilus influenzae infection
    amoxicillin for, 1139–1140
    ampicillin for, 1139–1140
    aztreonam for, 1151
    cefepime for, 1150
    chloramphenicol for, 1180
    fluoroquinolones for, 1122
    glucocorticoids for, 1609
    rifampin for, 1209
    trimethoprim-sulfamethoxazole for, 1104
Hageman factor, 1086
Hair, drug excretion via, 11
Hair cell leukemia
cisplatin for, 1349
    potentiation of, 1349
Halcinonide, 1682
HALCION (triazolam), 411t
HALDOL (haloperidol), 464t
HALFAN (halofantrine), 1042
Half-life, 12, 16, 1790
    alterations in individual patients, 1793
    pharmacogenetics of, 93–94, 94f
Hallucination(s), 430
    apomorphine and, 536
    COMT inhibitors and, 536–537
    dopamine receptor agonists and, 535
    levodopa and, 534
    psychedelic drugs and, 623–624
    Hallucinogen(s), 624
Hallucinosis, 1238
    hallucinosis persisting perception disorder
    (HPPD), 624–625
Halofantrine, 1042
    mechanism of action, 1033f, 1042
    interactions of
    with mefloquine, 1040
    with quinine/quinidine, 1039
    for malaria, 1042
    mechanism of action, 1034
    toxicity of, 1042
HALOG-E (halcinonide), 1682
Haloalkylamines, 266
Hallucinogenic persisting perception disorder (HPPD), 1034
Haloaldehydes
    for, 1034
    for, 1035
    with quinine/quinidine, 1039
    with mefloquine, 1040
    with quinine, 1038
    for malaria, 1042
    mechanism of action, 1034
    toxicity of, 1042
HALOG (halcinonide), 1682
Haloperidol propionate, 1682
Haloperidol, 461
Haloperidol decanoate, 462, 464t
Haloprogin, 1239
HALOTEX (haloprogin), 1239
HALOTESTIN (fluoxymesterone), 1578
Haloalkylamines, 266
Haloperidol, 461
Haloperidol, 461
    chemistry of, 464
    therapeutic uses of, 481–484
    for Tourette’s syndrome, 484
    toxicity of, 477
    and vasopressin secretion, 775, 784
    and weight gain, 480
Haloperidol decanoate, 462, 464t, 477
Halopropin, 1239
HALOTESTIN (fluoxymesterone), 1578f
HALOTEST (haloperidol), 1239
Halothane, 904
    for Huntington’s disease, 484
    in children, 484
    dose and dosage forms of, 464t, 477, 483
    for ethanol withdrawal, 600
    for Huntington’s disease, 484
    interactions of
    with carbamazepine, 513
    with lithium, 488
    metabolism of, 476
    and parkinsonism, 530
    pharmacokinetics of, 475f, 476, 1832t
    pharmacological properties of, 467
    preparations of, 477
    receptor actions of, 472t, 474, 1002t
    side effects of, 464t
    therapeutic uses of, 481–484
    for Tourette’s syndrome, 484
    toxicity of, 477
    and vasopressin secretion, 775, 784
    and weight gain, 480
Haloperidol decanoate, 462, 464t, 477
Halopropin, 1239
HALOTESTIN (fluoxymesterone), 1578f
HALOTEST (haloperidol), 1239
Halothane, 354–357
    for hypertension, 355–356, 355f
    chemistry of, 353f, 354
    clinical use of, 355
    CNS effects of, 356
    formulations of, 354
    gastrointestinal effects of, 356–357
    hepatic effects of, 356–357
    intoxication with, 526
    and malignant hyperthermia, 227, 356
    muscularr effects of, 356
    neuromuscular blocking actions of, 226–227
    pharmacokinetics of, 344t, 354–355, 354f
    potency of, measurement of, 344t
    renal effects of, 356
    respiratory effects of, 356, 356f
    side effects of, 355–357
    Halothane hepatitis, 357
    Hansen’s disease. See Leprosy

clinical uses of, 636
CNS effects of, 633
distribution of, 630
endogenous functions of, 631–633
release of, 631–633
barbiturates and, 350
by drugs, peptides, venoms and other agents, 632
histamine receptors and, 634–635
mechanism of, 632
neuromuscular blocking agents and, 226
opioids and, 561–562, 567
propofol and, 351
signs and symptoms of, 632
exocrine effects of, 636
gastric acid secretion, 632–634, 967–968, 968f
in inflammatory response, 672
metabolism of, 630–631, 631f as neurotransmitter, 324f, 334, 633
and peripheral nerve endings, 636
pharmacological effects of, 633–636
and smooth muscle, 635–637
toxicity of, from ingestion, 635
triple response to, 635–637
turnover rate of, 631
and vasoconstriction, of large vessels, 635
and vasodilation, 635
Histamine N-methyltransferase (HNMT), 87, 631
Histamine receptor(s), 324f, 334, 629, 630f effector coupling of, 324f, 633–634
H1, 334, 629, 633–634, 642
antidepressants and, 440, 443
antipsychotics and, 462–466, 470, 472f, 474
in central nervous system, 633
characteristics of, 629, 630f
distribution of, 630f
G protein coupling of, 630, 633
in nausea/vomiting, 1000–1001,
1001f, 1002f
H1, 334, 629, 633–634, 643
characteristics of, 629, 630f
distribution of, 630f, 634
and gastric acid secretion, 967–968, 968f
G protein coupling of, 630, 633
and histamine release, 634
H1, 334, 629, 633–634, 641–643
characteristics of, 629–630, 630f, 641
distribution of, 630, 634, 641
G protein coupling of, 630f, 641
metyrapone and, 1611
phenytoin and, 510
spironolactone for, 1582
Hirudin, for angina, 841
Histamine, 629–633
in allergic responses, 631–632
and capillary permeability, 635
cardiovascular effects of, 635
chemistry of, 629, 630f, 971, 972f
clinical uses of, 636
CNS effects of, 633
distribution of, 630
endogenous functions of, 631–633
release of, 631–633
barbiturates and, 350
by drugs, peptides, venoms and other agents, 632
histamine receptors and, 634–635
mechanism of, 632
neuromuscular blocking agents and, 226
opioids and, 561–562, 567
propofol and, 351
signs and symptoms of, 632
exocrine effects of, 636
gastric acid secretion, 632–634, 967–968, 968f
in inflammatory response, 672
metabolism of, 630–631, 631f as neurotransmitter, 324f, 334, 633
and peripheral nerve endings, 636
pharmacological effects of, 633–636
and smooth muscle, 635–637
toxicity of, from ingestion, 635
triple response to, 635–637
turnover rate of, 631
and vasoconstriction, of large vessels, 635
and vasodilation, 635
Histamine N-methyltransferase (HNMT), 87, 631
Histamine receptor(s), 324f, 334, 629, 630f effector coupling of, 324f, 633–634
H1, 334, 629, 633–634, 642
antidepressants and, 440, 443
antipsychotics and, 462–466, 470, 472f, 474
in central nervous system, 633
characteristics of, 629, 630f
distribution of, 630f
G protein coupling of, 630, 633
in nausea/vomiting, 1000–1001,
1001f, 1002f
H1, 334, 629, 633–634, 643
characteristics of, 629, 630f
distribution of, 630f, 634
and gastric acid secretion, 967–968, 968f
G protein coupling of, 630, 633
and histamine release, 634
H1, 334, 629, 633–634, 641–643
characteristics of, 629–630, 630f, 641
distribution of, 630, 634, 641
G protein coupling of, 630f, 641
Histamine receptor(s)—continued
heterogeneity of, 633
and histamine release, 634–635
isoforms of, 641

for common cold, 641
for dermatologic disease, 1689
dosages of, 638t
duration of action, 638t
exocrine effects of, 637
first-generation, 629, 637–639, 638t, 642
“hangover” from, 637
hypersensitivity to, 639
interactions of, 642
with antipsychotics, 481
with morphine, 568
local anesthetic effect of, 637
mechanism of action, 629
for motion sickness, 637, 641, 1003–1004
for nausea/vomiting, 1002t, 1003–1004
for neuromuscular blocker toxicity, 227–228
nonsedating, 629, 636–637
ophthalmic use of, 1725
with opioids, for analgesia, 581
for penicillin hypersensitivity, 1143
pharmacological properties of, 636–640
preparations of, 638t
second-generation, 629, 637, 638t, 639
and sedation, 639
as sedative-hypnotic, 641
side effects of, 639, 642
and smooth muscle, 636–637
structure-activity relationship of, 636
teratogenicity of, 639, 642
therapeutic uses of, 640–641
third-generation, 629
for vertigo, 641
H₂, 630, 634, 643, 971–973
for acid-peptic disease, 968f, 969, 971–973
adverse effects of, 972
chemistry of, 971, 972f
dermatologic use of, 1689
discovery of, 629
drug interactions of, 121, 972
for ethanol-induced gastritis, 596
evening dosing of, 971, 978
for gastric acid secretion, 632–634, 971–973
for gastroesophageal reflux disease, 972, 976–978, 976f–977f, 977f
hyperglycemic effects of, 1634
intravenous doses of, 971, 972
mechanism of action, 968f, 971
versus muscarinic receptor antagonists, 197
for peptic ulcer disease, 978–980, 979f–980f
pharmacokinetics of, 972
pharmacological properties of, 971
in pregnancy, 972, 978
versus proton pump inhibitors, 976f
rebound with, 973
therapeutic uses of, 972
tolerance to, 973
H₃, 630t, 633–634, 641–643
discovery of, 629
ligands of, 641–642
pharmacological actions of, 641–642
H₄, 630t, 634, 643
discovery of, 629
Histamine shock, 635
Histamine transporter blocker, 324t
HISTEROSE (testosterone), 1578
Histidine metabolism, 1458
Histoplasma capsulatum. See Histoplasmosis
Histone acetylation
estrogen receptors and, 1549, 1550f
progesterone receptors and, 1560–1561
Histone deacetylation, theophylline and, 728
Histone methyltransferase (HMT), interaction with estrogen receptors, 1549
Histoplasmosis
amphotericin B for, 1228
fluconazole for, 1233
itraconazole for, 1231
methocarbamol for, 1228
Histrelin, 1502t
HIV. See Human immunodeficiency virus
infection
HIVID (zalcitabine), 1276t
HIV lipodystrophy, 1279–1280, 1287, 1640
HIV protease inhibitors. See Protease inhibitor(s)
Hodgkin’s disease
bleomycin for, 1362
dacarbazine for, 1331
glucocorticoids for, 1381
mechlorethamine for, 1327
procarbazine for, 1331–1332
vinblastine for, 1351
vincristine for, 1351–1352
HOE-140, 644, 646, 649
Homatropine, 189
ophthalmic use of, 1720t, 1724
structure of, 191f
for uveitis, 1724
Homatropine hydrobromide, 198
Homatropine methylbromide, 190, 197
Homeostasis, intracellular, and cardiac conduction, 901–902, 901f
Homocysteine
follic acid and, 1458, 1460
vitamin B₁₂ and, 1453–1454
Homologous desensitization, of receptors, 31f, 32
Hookworm infections, 1075–1077
albendazole for, 1075, 1079, 1081
ivermectin for, 1075, 1087
mebendazole for, 1075, 1080–1081
in pregnancy, 1082–1083
pyrantel pamoate for, 1090
Hordeolum, 1716
Horizontal gene transfer, and drug resistance, 1098
Hormonal contraceptive(s), 1563–1567
adverse effects of, 1565–1566
and cancer, 1565–1566
cardiovascular effects of, 1565
choice of, 1567
combination, 1563–1564
adverse effects of, 1565–1566
mechanism of action, 1564–1565
contraindications to, 1566–1567
estrogen in, 1551–1553, 1564–1566
history of, 1563
interactions of
with angiotensinogen, 793
with antiseizure drugs, 509, 520, 523
with benzodiazepines, 409
with cytochrome P450 enzyme-inducing agents, 90, 121
with methylxanthines, 729
with St. John’s wort, 90
low-dose or second-generation, 1563
and menstrual regularity, 1567
metabolic and endocrine effects of, 1566

Iron therapy, 1442–1451
Iron deficiency, 1442, 1446–1451
Anemia with, treatment of, 1451
anti-bacterial activity of, 1204–1205
in children, 1215
clinical pharmacology, 1205–1207
drug interactions of, 1207
with barbiturates, 419
with benzodiazepines, 409
with carbamazepine, 513
history of, 432, 1204
hypo-sensitivity to, 1207
with infliximab therapy, 1017
mechanism of action, 1205
for mycobacterial infections, atypical, 1215
pharmacogenetics of, 93, 105r, 1205–1206, 1206f
pharmacokinetics of, 85, 1205, 1837t
in pregnancy, 1215
resistance to, 1205, 1215
with rifampin, 1203, 1208, 1214–1215
with rifampin and pyrazinamide, 1208
and seizures, 1207
therapeutic uses of, 1206–1207
toxicity of, 1102, 1207
pyridoxine for, 1102, 1206–1207
for tuberculosis, 1203–1207, 1204r, 1214–1215
for tuberculosis prophylaxis, 1216
Isoprostan e(s), 660
Isoprostan e receptor(s), 663
Isoproterenol, 240, 242, 250, 251
for asthma, 250
and blood pressure, 243f
for cardiac arrhythmia, mechanism of action, 908
cardiac effects of, 243f, 251, 262
clinical uses of, 240r, 250
mechanism of action, 174, 243
pharmacological actions of, 250
toxicity of, 250
Isopropi nol (verapamil), 834t
ISOPTO ATROP INE (atropine), 1230r
ISOPTO CARRACHOL (carrbachol), 1230r
ISOPTO CARP I NE (pilocarpine), 1230r
ISOPTO CEMATIDE (sulfacetamide), 1144–1115
ISOPTO HOMATROPINE (homatropine hydrobromide), 198, 1720r
ISOPTO HYOSC I N (scopolamine), 1720r
Isquinine, 1042
ISORDIL (isosorbide dinitrate), 880
without, as hypotensive agents, 1231
physical properties of, 357
for congestive heart failure, 250
and blood pressure, 243f
for cardiac arrhythmia, mechanism of action, 908
cardiac effects of, 243f, 251, 262
clinical uses of, 240r, 250
mechanism of action, 174, 243
pharmacological actions of, 250
toxicity of, 250
Ketorolac, 677–678
therapeutic uses of, 678

Ketone(s)

Kidney(s), 737–742

Ketotifen
pharmacokinetics of, 677
ophthalmic use of, 698, 1725
and nausea/vomiting, 343
chemistry of, 697, 1725
versus glucagon secretion, 1642
therapeutic uses of, 1188
lithium and, 487–488
lead poisoning and, 1757
lithium and, 487–488

Kidney stones

Kininogens, 643–649
Kininase II, 643, 800.
Kininase I, 643, 646
Kinin(s), 643–649

Kindling, in epilepsy, 504

Kinase inhibitor(s), 1366–1369
Kinase(s), 1366–1369

Kinase(s), 1366–1369

Kidney failure

Kidney disease, corticosteroids for, 1608

Lactic acidosis-steatosis syndrome, HIV

Lactic acid, for hyperkeratotic disorders,

Labelmol, 285
cardiovascular effects of, 275
chemistry of, 273/3, 852
for hypertension, 852
isomers of, 285
membrane-stabilizing effects of, 272
nomenclature for, 131
pharmacokinetics of, 278/2, 285
pharmacological properties of, 276, 285
receptor selectivity of, 272, 285

Labor
augmentation of, oxytocin for, 1508
induction of
after fetal death, mifepristone for,
1563
oxytocin for, 1508
preterm
Ca2+ channel antagonists and, 838
fetal lung maturation in, 1609
oxytocin antagonist for, 1507, 1509
ritodrine for, 253

LAC-HYDRIN (lactic acid), 1702

Lacralm glands, 1707–1708, 1708/f
epinephrine and, 247
Lacrimal system, 1707–1709, 1708/f

β-Lactam antibiotics, 1127–1152. See also Cephalosporin(s); β-Lactamase inhibitor(s); Penicillin(s)
with aminoglycosides, 1104
bacterial density/biofilm and, 1133
dose and dosing frequency of, 1100
hypersensitivity to, 1102
mechanism of action, 1128–1131, 1131/f
resistance to, 1097, 1097/f, 1098, 1127
mechanisms of, 1131–1133, 1132/f
toxicity of, 1102

β-Lactamase(s), 1132
and antibiotic resistance, 1132–1133,
1147
classes A–D, 1132
extended-spectrum, 1132
in gram-negative bacteria, 1131/f, 1133
in gram-positive bacteria, 1131/f, 1132–
1133

β-Lactamase inhibitor(s), 1127, 1151–1152
Lactic acid, for hyperkeratotic disorders,
1702
Lactic acidosis-steatosis syndrome, HIV
therapy and, 1284–1285, 1287
Lactobacillus, in inflammatory bowel dis-
ease, 1017
Lactose permease symporter (LacY), 51, 51f
Lactulose, 992–993
Lambert-Eaton syndrome, 213
LAMICTAL (lamotrigine), 517–518
Laminin, thyroid hormones and, 1,521
LAMISIL (terbinafine), 1,237
Lamivudine, 1,264–1,265, 1,276
adverse effects of, 1,265, 1,289
antiviral activity of, 1,264, 1,280
chemistry of, 1,264, 1,280, 1,281f
in combination therapy, 1,290
interactions of, 1,289
with zalcitabine, 1,288–1,289
for hepatitis B, 1,265
for HIV infection, 1,288–1,289
mechanism of action, 1,264–1,265, 1,288–1,289
pharmacokinetics of, 1,282t, 1,289, 1,480
phosphorylation of, 1,283f, 1,288
precautions with, 1,289
resistance to, 1,264–1,265, 1,288–1,289
therapeutic uses of, 1,265, 1,289
Lamotrigine, 517–518
interactions of, 518
with hepatic microsomal enzymes, 509f
with valproic acid, 515
with zonisamide, 521
for Lennox-Gastaut syndrome, 518, 523
for mania, 485, 491–492
mechanism of action, 505, 518
pharmacokinetics of, 518, 1,840
pharmacological effects of, 518
for seizures/epilepsy, 505, 517–518, 523
structure-activity relationship of, 517–518
therapeutic uses of, 518
toxicity of, 518
LAMPRENE (clofazimine), 1,220
Langerhans’ cell histiocytosis
cladribine for, 1,349
pentostatin for, 1,350
LANOXICAPS (digoxin), 888
LANOXIN (digoxin), 888
Lanreotide, 1,496–1,498, 1,644
for acromegaly, 1,497–1,498, 1,644
adverse effects of, 1,644
chemistry of, 1,497f
for diarrhea, 998
receptor selectivity of, 1,496
therapeutic uses of, 1,644
Lansoprazole, 969–971, 970f
with clarithromycin, 1,185
drug interactions of, 971
formulations of, 969
for gastroesophageal reflux disease, 977f
for peptic ulcer disease, 978, 979f–980f
pharmacogenetics of, 1,07, 1,07f
pharmacokinetics of, 969–971, 1,841f
in pregnancy, 978
therapeutic uses of, 971
LANTUS (insulin glargine), 1,626–1,627
LAPUDRINE (chlorproguanil), 1,031
Large intestine
fluid traversing daily, content of, 989,
989f
opioids and, 562
LARIAM (mefloquine), 1,025f, 1,039
LARODOPA (levodopa), 533
Levamisole, 1,075
cutaneous, thia bendazole for, 1,080
LASIX (furosemide), 749
Lassa fever, ribavirin for, 1,266
Latanoprost, for glaucoma, 1,722–1,723
Latent inhibition, antipsychotics and, 468
Latrotoxins, 1,73
Laudanum, 402
Laxative(s), 989–995
anthraquinone, 994
bulk-forming, 991–992, 991f
castor oil as, 990, 994–995
versus cathartics, 990
classification of, 990, 990t–991t
effects of, 991f
luminally active, 990, 990f
magnesium-based, 992
mechanisms of action, 990
osmotically active, 990, 990f–991f, 992–993
prokinetic, 990, 990f
saliene, 992
stimulant (irritant), 990, 990t–991t, 994–995
surfactant, 991f, 993–994
L.D.L. See Low-density lipoprotein
L-DOPA (levodopa), 533
Lead, 1,754–1,758
absorption, distribution, and excretion of, 1,754–1,755
colic, 1,755
dietary intake of, 1,754
evercephalopathy, 1,755–1,756
limes, 1,754, 1,757
palsy, 1,755
poisoning, 1,755–1,758
abdominal syndrome with, 1,755
CNS effects of, 1,755–1,756
diagnosis of, 1,757–1,758, 1,757f
gastrointestinal effects of, 1,755
hematological effects of, 1,756–1,757, 1,756f
neuromuscular effects of, 1,755
organic, 1,758
pyrrole excretion in, 1,756, 1,756f
renal effects of, 1,757
treatment of, 1,758, 1,769, 1,771
sources of and exposure to, 1,754
Learned immunity, 1,405
Learned tolerance, 610
Lecithin
for Alzheimer’s disease, 539
polyunsaturated, for alcoholic liver disease, 597
Lecithin:cholesterol acyltransferase, 939
Leffunomide, 1,415, 1,841f
Left ventricular dysfunction. See Heart failure
Left ventricular hypertrophy
in congestive heart failure, 872
hypertension and, 845
Left ventricular systolic dysfunction. ACE inhibitors in, 805–807, 806f–807f
Leg cramps, nocturnal, quinine for, 1,038
Legionella micdadei infection, erythromycin for, 1,185
Legionella pneumophila infection
erythromycin for, 1,185
fluoroquinolones for, 1,122
Leishmania, 1,052. See also Leishmaniasis
Leishmania donovani, 1,052, 1,061
Leishmania major, 1,061
Leishmania mexicana, 1,061
Leishmaniasis, 1,052–1,053
amphotericin B for, 1,052–1,053
antimonal compounds for, 1,052, 1,068–1,068
artemisinin for, 1,027
cutaneous, 1,052
diffuse cutaneous, 1,052
mifelofosine for, 1,052, 1,060–1,061
mucocutaneous, 1,052
paromomycin for, 1,052–1,053, 1,064
pentamidine for, 1,052–1,053, 1,064–1,065
sodium stibogluconate for, 1,066–1,068
treatment of, 1,052–1,053. See also specific agents
visceral (kala azar), 1,052
Lemon juice, for chemical inactivation, 1,749
Lenalidomide, 1,370, 1,370f
Lennox-Gastaut syndrome, 523
felbamate for, 520, 523
lamotrigine for, 518, 523
topiramate for, 523
Lenograstim, for ganciclovir toxicity, 1,255
Lens (eye), 1,710f, 1,711
LENTARON (formestane), 1,385
Lente insulin, 1,626–1,627, 1,625f
Lentiform nucleus, 318
Leptin, 189
Lepirudin, 1,475
as heparin alternative, 1,474
Leprosy, 1,218–1,221
chemotherapy for, 1,204t, 1,218–1,221
clinical types of, 1,220
clofazimine for, 1,203, 1,204t, 1,220
dapsone for, 1,203, 1,204t, 1,219–1,220, 1,697
lepromatous, 1,220
macrolides for, 1,186
reversal reactions in, 1,220
rifampin for, 1,203, 1,204t, 1,220
sulfones for, 1,203, 1,204t, 1,219–1,220
tuberculosis, 1,220
WHO elimination strategy for, 1,219–1,221
Leptospira. See Leptospiriosis
Leptospiriosis, tetracyclines for, 1,178
Lergotrile, chemistry of, 310f
Lesch-Nyhan syndrome, allopurinol for, 709
LESCOL (fluvastatin), 952

pharmacological properties of, 485–488
in pregnancy, 488
prophylactic uses of, 489–490
renal effects of, 487–488
and serotonin syndrome, 450
serum level monitoring of, 487
side effects of, 487–488
slow-release preparations of, 486
therapeutic index of, 487
therapeutic uses of, 488–490
toxicity of, 429, 487–488
and vasopressin, 486, 775, 779, 784, 786
Lithium salts, 485, 489
Lithocholic acid, 1006, 1007f
Liver
ACE inhibitors and, 809
acetaminophen and, 694–695
antimicrobial agents and, 1100–1101
antipsychotics and, 481
arsenic and, 1765
autonomic regulation of, 144t
barbiturates and, 417
desflurane and, 359
drug clearance by, 13–14
in elderly, 124
impaired, 120–121
in neonates and children, 123
drug metabolism in, 74
ethanol and, 593, 597
halothane and, 356–357
heparin and, 1474
isoflurane and, 358
isoniazid and, 1207, 1216
mercaptourine and, 1348
metabolic disorders of, barbiturates for, 419
methotrexate and, 1338
methylxypenta and, 854
niacin and, 956–957
phenytoin and, 510
pyrazinamide and, 1211
salicylates and, 689
statins and, 951
tetracyclines and, 1178
thiazolidinediones and, 1640
thyroid hormone metabolism in, 1517
transporters in, 43, 44f, 48, 48f, 58, 59f
and drug interactions, 59
and uptake, 59–60
valproic acid and, 515
Liver abscesses, amebic, 1050
Liver flukes, 1078, 1089
LIVIAL (tibolone), 1554
LIVOSTIN (levocabastine), 638t
Lixivaptan, 781t, 787
Loading dose, 20–21

Loa loa, 1076. See also Loiasis

Lobeline, 231

Local anesthesia, 369–385
advantages of, 379
adverse effects of, 375–376
cardiovascular effects of, 375–376
chemistry of, 369, 370f–371f
clinical uses of, 379–385
CNS effects of, 375
duration of action, vasoconstrictors and, 375, 383
epidural, 383–385
field block, 380
frequency and voltage dependence of, 371–373
histamine H1 receptor antagonists for, 637
hypersensitivity to, 376
infiltration, 380
of low solubility, 379
mechanism of action, 225f, 369–371, 372f–373f
metabolism of, 376
by method of administration, 379–385
for mucous membranes and skin, 378–379
nerve block, 380–381
nerve fiber sensitivity to, differential, 373–374, 374f
in ophthalmic procedures, 1730
for ophthalmic use, 379
pH and, 374–375
quaternary analogs of, 371
regional intravenous, 381–382
and smooth muscle, 376
spinal, 382–383
structure-activity relationship of, 369
suitable for injection, 378

topical, 380
Locoid (cortisol butyrate), 1602f, 1682f
Locus caeruleus
general anesthesia and, 345
in opioid analgesia, 558
in opioid-induced reward, 559
Locust subesophageal ganglia peptide, 772f
Lodine (etodolac), 676f
Lodosyn (carbidopa), 534
Lodoxamide tromethamine, 1725
Lofepramine, potency of, for transporters, 438f
Lofexidine, for opioid withdrawal, 469
LOFBIRA (fenofibrate), 958
Log concentration-effect curve, 125–126, 126f
individual variation in, 125–127, 126f–127f
Loiasis, 1076
diethylcarbamazine for, 1076, 1083–1084
ivermectin for, 1087
Lometrexol, sites of action, 1335–1336
Lomotil (diphenoxylate-atropine), 194–195, 570, 997
Lomustine, 1324, 1331
Long, Crawford, 341
Long-loop negative feedback, 792f, 793
Long-term depression (LTD), 332
Long-Term Intervention with Pravastatin in Ischaemic Disease (LIPID) Study Group, 941f, 942
Long-term potentiation (LTP), 332, 336, 395
Loop diuretics, 749–753
absorption and elimination of, 750f, 752, 874–875
adverse effects of, 752–753
chemistry of, 749, 750f
for congestive heart failure, 753, 765, 874–877
in decompensated patient, 876
contraindications to, 752–753
drug interactions of, 754, 751
extrarenal effects of, 752
for hypertension, 753, 849–850
for inappropriate vasopressin secretion, 784
intolerance of, 766
mechanism of action, 749–751, 751f, 763f
mineralocorticoid receptor antagonists with, 762
post-therapy sodium retention with, 752
for pulmonary edema, 753, 765
renal hemodynamic effects of, 744, 751–752
and renin secretion, 792f, 793
resistance to, 765–766, 876–877
site of action, 749–751, 763f
sodium channel inhibitors with, 759
therapeutic uses of, 753
toxicity of, 752–753
vascular effects of, 752
Loop of Henle, 738f
Loperamide, 570
adverse effects of, 997
for diarrhea, 570–571, 997
in inflammatory bowel disease, 1018
formulations of, 997
pharmacokinetics of, 997
pharmacological effects of, 997
structure of, 569f
transporter control of, 43
Loperamide N-oxide, 997
Lopid (gemfibrozil), 958
Lopinavir, 1276f, 1304f, 1306–1307
adverse effects of, 1306–1307
in combination therapy, 1297
for HIV infection, 1306–1307
pharmacokinetics of, 1299f, 1306, 1844f
therapeutic use of, 1307
Lopressor (metoprolol), 285, 882
Loprox (ciclopirox olamine), 1239
Lorabid (loracarbef), 1144
Loratadine, 634f, 638f, 638–639
dermatologic use of, 1689
pharmacokinetics of, 638f, 1844f
in pregnancy, 639, 642
Lorazepam, 403f
as adjunct to anesthesia, 360–361
adverse effects of, 516
for anxiety, 453–454
with busulfan, 1330
dosages of, 411f
interaction with valproic acid, 515
for mania, 489, 492
metabolism of, 408, 409f
for nausea/vomiting, 1005
pharmacokinetics of, 411f, 1845f
for status epilepticus, 523
therapeutic uses of, 411f
Lorcet (hydrocodone), 580f
Lornoxicam, 701
Lorsban (chlorpyrifos), 205
Lortab (hydrocodone), 580f
Losartan, 812f, 813
for congestive heart failure, 880
dosage of, 813
for hypertension, 859–860
mechanism of action, 795
pharmacokinetics of, 1845f
pharmacological effects of, 810
therapeutic uses of, 813–814
Losartan Intervention for Endpoint (LIFE) Reduction in Hypertension Study, 814
Lotemax (loteprednol), 1724
Lotenox (enoxaparin), 1473
Low-density lipoprotein (LDL), 938–953
absorption, metabolism, and excretion of, 930–951
adverse effects of, 951–952
chemistry of, 948, 949f
in children, 953
clinical trials of, 941f
in diabetes mellitus, 946
dosage, for LDL-lowering effects, 949–950, 950f
drug interactions of, 122, 951–952
mechanism of action, 948–950
with niacin, 952
pharmacokinetics of, 1845f
therapeutic uses of, 952–953
Lovastatin, 58, 948–953
absorption, metabolism, and excretion of, 950–951
adverse effects of, 951–952
chemistry of, 948, 949f
in children, 953
clinical trials of, 941f
in diabetes mellitus, 946
dosage, for LDL-lowering effects, 949–950, 950f
drug interactions of, 122, 951–952
mechanism of action, 948–950
with niacin, 952
pharmacokinetics of, 1845f
therapeutic uses of, 952–953
Lovenox (enoxaparin), 1473
Low-density lipoprotein (LDL), 935f, 938–939
β-adrenergic receptor antagonists and, 277
drugs decreasing, 933, 940–960. See also specific agents
bile acid sequestrants, 953–955
ezetimibe, 959–960
fibric acid derivatives, 957–959
indications and patient criteria for, 945–946
NCEP guidelines for, 942, 943–944
niacin, 955–957

therapeutic uses of, 1328
toxicities of, 1325–1326, 1326t, 1328
Memantine
for Alzheimer’s disease, 539–540
taurine in glaucoma, 1712
Menaquinone, 1484–1486
Meniere’s disease, 641
Meningitis
for postinfectious meningitis, 1140
cephalosporins for, 1147, 1150
chloramphenicol for, 1180
gentamicin for, 1166
pneumococcal, penicillin G for, 1135
penicillin G for, 1136
streptococcal, penicillin G for, 1135

Menstruation
pharmacological properties of, 679
mechanism of action, 568
side effects of, 570
tolerance to, 570
toxicities of, 568
Men, 1567
Menotropins, 1505
Menopausal symptoms
for menopause, 1553
for anovulation, 1544–1546
for clomiphene citrate, 1545
for estrogen, 1544–1546
for megestrol acetate, 1545–1547
for megestrol acetate, 1546f
for ethanol and, 598
for menopausal symptoms, 1553–1554
for contraception, 1564–1566
for menopausal symptoms, 1553–1554
for estrogen, 1553–1554
for clonidine, 257, 1553
for estrogen, 1553–1554
mechlorethamine for, 1553–1554
SERM-estrogen combination for, 1557
Menopausal hormone therapy, 1553–1554
Menopausal symptoms
clomiphene for, 257, 1553
estrogen for, 1553–1554
for megestrol acetate, 1545–1546
for estrogen, 1544–1546
for megestrol acetate, 1546f
for megestrol acetate, 1545–1547
for megestrol acetate, 1546f
eNmenopausal symptoms, 1553–1554
Menstruation
absence of. See Amenorrhea
estrogen and, 1544–1546, 1546f
for ethanol and, 598
gonadotropic hormones and, 1505,
1544–1546, 1546f
and iron levels, 1444–1446
neuroendocrine control of, 1544–1546,
1544f, 1546f
opioids and, 559
pain with
ibuprofen for, 699
NSAIDs for, 681
propionic acid derivatives for, 698–699
progesterone and, 1544f, 1545, 1546f,
1559–1560
regulation of, oral contraceptives and,
1567
Mental disorder(s)
biochemical hypotheses in, 430–431
nosology of, 430
psychopharmacology for, 429–455. See
also specific agents and disorders

Metoprolol Randomized Intervention Trial in Congestive Heart Failure (MERIT-HF), 883
Metoprolol, 273f, 278, 284
absorption, fate, and excretion of, 284
for angina, 838f
for anxiety, 454
for cardiac arrhythmias, 915
for congestive heart failure, 290, 882–883, 882f
for heart failure, 284
for hypertension, 284
interaction with celecoxib, 703
mechanism of action, 174
membrane-stabilizing effects of, 272
for migraine prophylaxis, 290
for myocardial infarction, 289
pharmacokinetics of, 278f, 284, 1849f
pharmacological properties of, 278f
receptor selectivity of, 272, 284
therapeutic uses of, 284
withdrawal from, 612
Metoprolol in Dilated Cardiomyopathy Trial, 882–883
Metoprolol Randomized Intervention Trial in Congestive Heart Failure (MERIT-HF), 883
Metrifonate, 205, 1087–1088
for schistosomiasis, 1078, 1088
Metrizamide, iodine content of, 1532f
Metrizamide, iodine content of, 1532f
METROGEL (metronidazole), 1690
METROCREAM (metronidazole), 1690
Milrinone
for congestive heart failure, 890–892, 892f
withdrawal from market, 841
Milletosine, 1060–1061
for leishmaniasis, 1052, 1060–1061
in pregnancy, contraindication to, 1061
therapeutic uses of, 1061
toxicity and side effects of, 1061
for trypanosomiasis, 1061
MILTOWN (meprobamate), 421
Minamata disease, 1760
Mineral(s), ethanol and, 594, 597–598
Mineralocorticoid(s), 1587, 1593–1610
cardiovascular effects of, 1598–1599
chemistry of, 1601–1603
classification of, 1594–1595, 1594f
for congenital adrenal hyperplasia, 1607
deficiency of, 1598
disorders of, 1596
in electrolyte and water balance, 1587,
1593, 1598
excess of, 1596, 1598
gene expression regulation by, 1596
mechanism of action, 1595–1596
pharmacological effects of, 1597–1600
replacement therapy
for adrenal insufficiency, 1604–1607
with aminogluthimide, 1611
monitoring of, 1606
secretion of, ACTH and, 1588–1589,
1589f
and skeletal muscle, 1599
specificity of, receptor-independent
mechanism of, 1596, 1597f
structure–activity relationships of, 1601–
1603
synthesis of, 1589–1591, 1590f
transport, metabolism, and excretion of, 1601
Mineralocorticoid receptor(s), 1595–1596
Mineralocorticoid receptor antagonist(s),
759–762, 760f
absorption and elimination of, 760f, 761–
762
adverse effects of, 762
for congestive heart failure, 874f, 875–
876
drug interactions of, 762
excretory effects of, 744f, 761
extrarenal effects of, 761
for hypertension, 762, 850
mechanism of action, 760–761, 761f
renal hemodynamic effects of, 744f, 761
site of action, 760–761
therapeutic uses of, 762
toxicity of, 762
Mineral oil
for constipation, 993–994
ophthalmic use of, 1734
Miner’s disease, 1075
Miniature end-plate potential(s) (MEPP),
neuromuscular blocking agents
and, 223
Minimum alveolar concentration (MAC), in
anesthetic potency, 344, 344f
Minipill, 1563–1564, 1566
MINIPRESS (prazosin), 270, 851
MINOCIN (minocycline), 1176
Minocycline, 1173–1179, 1174
for acne, 1170
adverse effects of, 1178–1179, 1690, 1729
antimicrobial effects of, 1173–1174
for coccal infections, 1177
dosage of, 1176
excretion of, 1175
for leprosy, 1220–1221
for nocardiosis, 1177–1178
resistance to, 1174–1175
routes of administration, 1176
therapeutic uses of, 1176–1178
Minoxidil, 862–863
for alopecia, 1702
chemistry of, 862, 1702
clinical pharmacology, 862–863
for hypertension, 862–863
and hypertrichosis, 863
precautions with, 862–863
renal effects of, 862
therapeutic uses of, 863
MINTACOL (paraoxon), 206t
MENTZE (thiabendazole), 1080
MOCHOL-E (acetylcholine), 188
Miosis, 1711
agents against, 1725–1726
anticholinesterases and, 207–208
opioids and, 559–560
MIOSTAT (carbachol), 1720t
Miotics, for glaucoma, 1723
Mipafox, delayed neurotoxicity of, 211
MIRADON (anisindione), 1480
MIRALEX (polyethylene glycol), 993
MIRENA (levonorgestrel), 1564
MIRFEX (pramipexole), 535
Mirtazapine, 436
Mirtazapine, 436
Mizolastine, 638
Mizolastine, 638
M2-M3 receptors, 1333
Molecular cloning studies, of receptor properties, 322f, 328, 328f

Mizolastine, 638
Mizolastine, 638
Mizollen (mizolastine), 638
MK-886, 655
MOBAN (olanzapine), 465
MOBIC (meloxicam), 701
Molicebin, 535
Molecobine, drug interactions of, 450
Modafinil, for cocaine dependence, 621
Modulatory effects, of neurotransmitters, 322f,
109–110
Modulator polymorphisms, 106
Monamine oxidase(s), 443
in catecholamine metabolism, 160f, 164,
165f
distribution of, 164
in histamine metabolism, 631
MAO-A, 164, 299, 307–308, 443
MAO-B, 164, 299, 443
in Parkinson’s disease, 529
in serotonin metabolism, 298–299, 298f,
302–303, 307–308
Monamine oxidase inhibitor(s) (MAOI), 164, 299
absorption and bioavailability of, 444
chemistry of, 242, 439
for depression, 432, 439, 452–453
duration of treatment with, 453
false-transmitter concept and, 243
and histamine, 631
interactions of
with barbiturates, 419
with meperidine, 450, 570
with opioids, 566, 568
mechanism of action, 175, 443–444
metabolism of, 446
for panic disorder, 451
for Parkinson’s disease, 164, 175, 529,
537
with levodopa, 535
pharmacological properties of, 443–444
physical dependence on, 447
selection of, 452
selective MAO-B, 537
and serotonin (5-HT), 305
side effects of, 448
therapeutic uses of, 432, 450–451
toxicity/overdose of, 449
Monoamine transporter, 161
Monoclonal antibodies, 1374, 1376–1380
antigen and tumor cell targets of, 1375f
for cancer chemotherapy, 1374, 1376t,
1377t
cytotoxic conjugates with, 1375, 1379
dose of, 1377f
generation/production of, 1416, 1416f
for immunosuppression, 1406–1407,
1416–1420
immunotoxin with, 1374, 1375t, 1379–
1380
mechanism of action, 1377t
for multiple sclerosis, 1426
naked, 1375t, 1376–1379
nomenclature for, 1376
radioimmuno-conjugates with, 1375t,
1379
toxicity of, 1377f
Monocyte(s)
corticosteroids and, 1600, 1600f
in immune response, 1405
Monocyte/macrophage colony-stimulating factor (M-CSF), 1434, 1435f,
1436t
Index

Mononucleosis, acyclovir for, 1250
MONOPRIL (fosinopril), 803
Montelukast, 672, 722–725
for asthma, 658, 722–725
chemistry of, 723
mechanism of action, 658
metabolism of, 723
pharmacokinetics of, 723, 1851
for toxicity of, 724

Mutation-selection, and drug resistance,
1097–1099
Myalgia, quinupristin/dalfopristin and,
1191
MYAMBUTOL (ethambutol), 1210
Myasthenia gravis, 212–214
aminoglycosides in, 1164
anticholinesterase agents for, 212–214
antimicrobial toxicity in, 1102
chloroquine contraindicated in, 1035
diagnosis of, 213, 1724
epinephrine for, 247
lithium and, 488
penicillamine and, 1772
receptor malfunction in, 32
treatment of, 213–214
MYCELEX formulations, 1238
Mycetism (mushroom poisoning), 187, 189
Mycobacterial infection(s), 1203–1221. See
also Leprosy; Mycobacterium
avium complex; Tuberculosis
nontuberculous (atypical), 1215
Mycobacterium avium complex (MAC),
1203–1204, 1216–1218
amikacin for, 1218
azithromycin for, 1185–1186, 1204,
1204t, 1217–1218
chemoprophylaxis for, 1218
chemotherapy for, 1204t, 1216–1218
clarithromycin for, 1186, 1204, 1204t,
1217–1218
combination therapy for, 1218
drug resistance in, 1218
ethambutol for, 1204
quinolones for, 1204t, 1218
rifabutin for, 1204, 1204t, 1217
Mycobacterium avium intracellulare. See
Mycobacterium avium complex
(MAC)
Mycobacterium chelonae infection, 1215,
1218
Mycobacterium fortuitum complex, 1204t,
1215, 1218
Mycobacterium kansasii infection, 1204t,
1205, 1211, 1215
Mycobacterium leprae infection. See Leprosy
Mycobacterium marinum infection, 1178,
1204t, 1215
Mycobacterium scrofulaceum infection,
1215

Mycobacterium tuberculosis. See Tuberculosis
Mycobacterium ulcerans infection, 1220
MYCOBUTIN (rifabutin), 1209
Mycophenolate mofetil, 1409f, 1414–1415
dermatologic use of, 1696
drug interactions of, 1247, 1415
for immunosuppression, 1414–1415
for inﬂammatory bowel disease, 1016
mechanism of action, 1414
pharmacokinetics of, 1415, 1852t
site of action, 1407t
therapeutic uses of, 1415
toxicity of, 1416
Mycophenolic acid (MPA), 1414
Mycoplasma pneumoniae infection
macrolides for, 1185
tetracyclines for, 1176
Mycosis. See Antifungal agent(s); Fungal
infection(s)
Mycosis fungoides, cladribine for, 1349
MYCOSTATIN (nystatin), 1240
MYDFRIN (phenylephrine), 1721t
MYDRIACYL (tropicamide), 198
Mydriasis, 1711
epinephrine and, 246–247
muscarinic receptor antagonists for, 197–
198
Myelin basic protein, thyroid hormones
and, 1521
Myelodysplastic syndromes
epoetin alfa for, 1438
gemtuzumab ozogamicin for, 1379
thalidomide for, 1369–1371, 1371f
topotecan for, 1356
Myelogenous leukemia, histamine in, 632
Myeloid bodies, aminoglycosides and, 1164
Myeloid growth factor(s), 1439, 1439f,
1440
Myelo-optic neuropathy, clioquinol and,
1056
Myenteric plexus, 139–141, 983, 984f
MYKROX (metolazone), 754t
MYLANTA, 974t
MYLERAN (busulfan), 1330
MYLOTARG (gemtuzumab ozogamicin),
1374
Myocardial contractility, thyroid hormone
and, 1522
Myocardial infarction
ACE inhibitors for, 879
acute
ACE inhibitors in, 806t–807t, 807–
808
angiotensin II receptor antagonists in,
814
nitrates for, 831–832
β adrenergic receptor antagonists for,
289–290, 839, 883
Ca2+ channel antagonists for, 837–838
cardiogenic shock with, 262
clopidogrel for, 1483
COX-2 inhibitors and, 684–686, 704
eplerenone for, 762
eptiﬁbatide for, 1483–1484


heparin for, 1472
hypertension and, 845
leukotriene receptor antagonists for, 658
lipid-lowering therapy in, 945
non-ST-segment-elevation, nitrates for, 831
opioids for, 561
prevention of
aspirin for, 841
clopidogrel for, 841
NSAIDs for, 685
propionic acid derivatives and, 699
renin-angiotensin system in, 789
thromboxanes and, 664
tirofiban for, 1483
Myocardial ischemia, 823–842
angina pectoris with, 823. See also Angina pectoris
epinephrine and, 246
hydralazine and, 861
pathophysiology of, 823–824
Myoglobin, iron content of, 1443
Myometrium, estrogen/progesterone and, 1546–1547
Myopathy
colchicine and, 708
fibric acid derivatives and, 958
statins and, 951–952
steroid, 1599, 1604
Myotonia congenita, quinine for, 1038
Myopathy, 278
Myopathy, 1512
Myopathy, 1523
Myopathy, 1525. See also Hypothyroidism
treatment of, 1525
Nabumetone, 679, 701–702
versus aspirin, 679t
N-acetylation, 85–86, 87t
N-acetylcysteine (NAC) for acetaminophen overdose, 694–695
for nitrate tolerance, 881
N-acetyl-p-benzoquinone (NAPQ1), 83
N-acetylprocainamide, 912, 926–927
N-acetyltansferases (NATs), 73, 78f, 85–86
polymorphism of, 85, 105f
rapid versus slow, 85
Na+-Cl−-symport inhibitors, 753–757
NAD+, in ethanol metabolism, 592–593, 592f
Nadolol, 274f, 278, 278t
for variceal bleeding prevention, 292
NADPH-cytochrome P450 reductase, in estrogen synthesis, 1542
Nafadotride, 471
Nafarelin, 1502r
Nafcillin, 1129r, 1138–1139
adverse effects of, 1143
antimicrobial activity of, 1130t, 1133
major properties of, 1129r
pharmaceutical properties of, 1138–1139
for staphylococcal infections, 1136, 1138–1139
Nafidrofuryl, for claudication, 842
Nafinfin, 1239, 1690
NAFTIN (nafinfin), 1239
Naja naja, nicotinic receptors in, 217
Na+-K+-2Cl--symport inhibitors, 749–753. See also Loop diuretics
Naked monoclonal antibodies, 1375–1378, 1376t
Nalbuphine, 565
Nalidixic acid, 1119–1122
in breast-feeding, 1102
chemistry of, 1120f
in children, 1122
hyperglycemic effects of, 1634t
phototoxicity of, 1741
for urinary tract infections, 1121
Nalmefene for alcoholism, 603
chemistry of, 565t, 576
for cholestatic pruritus, 1701
pharmacokinetics of, 1852t
Nalorphine, 565t, 576
effects of, 556–557
receptor action and selectivity of, 552t
Naloxonazine, receptor action and selectivity of, 552
Naloxonazine, receptor action and selectivity of, 552t
Naloxone, 547, 552t, 564, 565t, 576–578
effects of, 576–577
for obesity, 577
for opioid dependence, 577–578
for opioid toxicity, 560, 573–574, 577–578
“overshoot” phenomenon with, 577
Naloxone benzoylehydrazone, receptor action and selectivity of, 552t
Naltrexone, 551, 552t, 565t, 576
absorption, fate, and excretion of, 577–578
for alcoholism, 578, 602–603, 613–614
effects of, 576–577
for obesity, 577
for opioid dependence, 577–578
for opioid toxicity, 577–578
pharmacological properties of, 576–578
physical dependence on, 577
receptor action and selectivity of, 552t
therapeutic uses of, 578
tolerance to, 577
Naltrindole, 551, 576
receptor action and selectivity of, 552
Name(s), for drugs, 131
NAMENDA (memantine), 539–540
Nanophyetus salmincola, 1078
Naphazoline, 261, 261t
ophthalmic use of, 1721t, 1725, 1734
NAPCON (naphazoline), 261
NAPROSYN (naproxen), 678t
Naproxen, 671, 700
adverse effects of, 700
versus aspirin, 679t
cardiovascular effects of, 700
chemistry of, 699f
classification of, 678t
drug interactions of, 699
gastrointestinal effects of, 684
gout, 707
hypoglycemic effects of, 1634t
interaction with lithium, 487
for juvenile rheumatoid arthritis, 682
pharmacokinetics of, 678t, 700, 1852t–1853t
Naratriptan, 306–308, 307f
for migraine, 305–306, 308
pharmacological properties of, 307
NARCAN (naloxone), 576–578
Narcoanalysis, barbiturates in, 419
Narcolepsy, 263
amphetamine for, 260, 263
ephedrine for, 260
sympathomimetic agents for, 263
Narcotherapy, barbiturates in, 419
Narcotic(s)
opoid. See Opioid(s)
NARDIL (phenelzine), 437t
NARPIN (ropivacaine), 378
NASACORT (triamcinolone), 731
NASALDECO (nasal decongestion), 731
NATRECOR (neseritide), 885
NATACYN (natamycin), 1718
Natalizumab, for multiple sclerosis, 1426
Natamycin, 1718
ophthalmic use of, 1718, 1719t
Na+-taurocholate cotransporting polypeptide (NTCP), 44
Nateglidine, 1638
National Cholesterol Education Program (NCEP), 942, 943–944
National Drug Code, 1783
National Formulary, 1783
Native American(s), fetal alcohol syndrome
Natural products, in cancer chemotherapy,
Nausea, 1000–1005, 1008
Nausea, 263
for nitrate tolerance, 881
for opioid toxicity, 560, 573–574, 577–578
Nasal decongestion, 1546–1547
Nasal mucosa, drug metabolism in, 74
Nasopharyngeal glands, autonomic regulation of, 144f
NATACYN (natamycin), 1718
Natalizumab, for multiple sclerosis, 1426
Nasal congestion, opioid dependence on, 577–578
Nasal mucosa, drug metabolism in, 74
NASONEX (mometasone), 731
Nasopharyngeal glands, autonomic regulation of, 144f
National Cholesterol Education Program (NCEP), 942, 943–944
National Cholesterol Education Program (NCEP), 942, 943–944
National Drug Code, 1783
National Formulary, 1783
Native American(s), fetal alcohol syndrome
NATRECOR (neseritide), 885
Natural killer cells, 1405
Natural products, in cancer chemotherapy, 1318f, 1350–1364
NATURETIN (bendroflumethiazide), 754t
Nausea, 1000–1005, 1008
antipsychotics for, 484
benzodiazepines for, 1005
chemotherapy-induced, regimens for, 1001, 1003f
dexmedetomidine and, 361
dopamine receptor antagonists for, 1002t, 1003
dronabinol for, 1004
estrogen therapy and, 1553
etomidate and, 351
general anesthesia and, 343
Nausea—continued
  glucocorticoids for, 343, 1005
  histamine H1 receptor antagonists for, 1002t, 1003–1004
  levodopa and, 534
  metoclopramide for, 343, 986
  miltefosine and, 1061
  muscarinic receptor antagonists for, 1002, 1004
  neurotransmission in, 1000–1001, 1001f
  nifurtimox/benznidazole and, 1062
  opioids and, 557, 560–561, 571
  promethazine for, 641, 1004
  salicylates and, 692
  serotonin receptor antagonists for, 312, 334, 343, 561, 1001–1003, 1002t
  substance P receptor antagonists for, 1005
  sulfonamides and, 1116
  suramin and, 1069
  NAVANE (thiothixene), 464
  NAVELBINE (vinorelbine), 1352
  N-dealkylation, 76t
  NEBCIN (tobramycin), 1166
  Nebivolol, 276t, 286–287
  for congestive heart failure, 289
  Nebramycin, 1155
  Nebulizers, 719
  Necator americanus, 1075, 1090
  Necrotizing fasciitis, 1136, 1690
  Nedocromil sodium, 726–727
  ophthalmic use of, 1725
  Nefazodone, 437
  Nedocromil sodium, 726–727
  pharmacokinetics of, 1299t, 1303–1305, 1853t
  precautions with, 1305
  resistance to, 1303
  therapeutic use of, 1305

hepatotoxicity of, 956–957
for hypertriglyceridemia, 946–947
mechanism of action, 955–956
pharmacokinetics of, 956, 1854f
and plasma lipoprotein levels, 956
with statins, 952–953
teratogenicity of, 956
therapeutic uses of, 956–957
tolerance of, NSAIDs and, 683–684
in triple therapy, with statins and bile acid resins, 953
NIASPAN (niacin), 956–957
Nicardipine, 832, 833
nicardipine, 834–836
NICODERM (nicotine), 232, 731
NICORETTE (nicotine polacrilex), 232, 616, 731
NICLOCIDE (niclosamide), 1088
NIASPAN (niacin), 956–957
Nicardipine, 832, 833
NIDCLOIDE (niclosamide), 1088
Niclosamide, 1088
for taeniasis, 1077, 1088
NICODERM (nicotine), 232, 731
NICORETTE (nicotine polacrilex), 232, 616, 731
Nicotiana tabacum, 153–154
Nicotinamide N-methyltransferase (NNMT), 87
Nicotine, 217, 231–233
amount in average cigarette, 232
delivery systems for, and blood concentrations, 616, 616f
dependency on, 615–617
percent and risk of, 608–609, 609f
pharmacological interventions for, 616–617, 616f
and depression, 616
excitotoxic effects of, 232
ganglionic stimulation by, 231–233
gastrointestinal effects of, 232
hyperglycemic effects of, 1634
and vasopressin, 775
structure of, 231, 232
replacement therapy with, 232
reinforcing properties of, 608, 615–616
pharmacological actions of, 231–232
dependence on, 615–617
withdrawal from, 616, 616
with nitrates, 826
for angina, 827
β-adrenergic receptor antagonists, 839
with nitrites, 829–830
interaction with PDE5 inhibitors, 123, 829–830
mechanism of action, 824–825
for myocardial infarction acute, 831–832
non-ST-segment-elevation, 831
and myocardial oxygen requirements, 827
pharmacological properties of, 825–828
plasma concentrations of, and biological activity, 828
preparations of, 826f
pseudotolerance to, 828
routes of administration, 826f, 830–831
and smooth muscle, 828
therapeutic uses of, 830–832
tolerance to, 828–829, 881
toxicity of, 829–830
Nitrazepam
as antiseizure drug, 404–405
chemistry of, 403f
metabolism of, 409, 409f
Nitric oxide, 395–397
administration of, methods for, 397
in cGMP synthesis, 30
as CNS mediator/neurotransmitter, 146, 177–178, 336, 395
diagnostic uses of, 396
estrogen and, 1548
functions of, 395–396
and gastrointestinal motility, 984, 990
in opioid tolerance, 563
organic nitrates and, 824–825
release of, 177
serotonin (5-HT) and, 302
synthesis of, 177
therapeutic uses of, 396
toxicity of, 396–397
Nitric oxide donor(s)
for congestive heart failure, 874f
interaction with PDE5 inhibitors, 123
Nitric oxide synthase (NOS), 177–178, 395
CNS effects of, 336
endothelial, 177, 824
estrogen and, 1548
inducible, 177, 824
inhibition of, 177–178
neuronal, 177, 824
and renin secretion, 791, 792f, 793
in opioid tolerance, 563
organic nitrates and, 824–825
Nitrites, organic, 825
Nitrofurantoin, 1123–1124
antimicrobial activity of, 1123
hypersensitivity to, 1102
pharmacokinetics of, 1854f
pharmacology of, 1123–1124
Nitrogen
metabolism of, salicylates and, 692
partial pressure of, oxygen therapy and, 393
Nitrogen mustards, 1316f, 1321–1322, 1327–1329
chemistry of, 1322, 1323f
mechanism of action, 1322, 1322f
toxicities of, 1325–1327, 1742
Nitroglycerin, 823–832
adverse effects of, 829–830
for angina, 823, 825, 830–831
mechanisms of relief in, 827–828
cardiovascular effects of, 825–828
chemistry of, 825, 826f
and coronary blood flow, 826–827
dosage of, 826f
hemodynamic effects of, 825–826
history of, 825
interaction with phosphodiesterase 5 inhibitors, 123
intravenous, for congestive heart failure, 885
mechanism of action, 825
for myocardial infarction, 831–832
and myocardial oxygen requirements, 827
for opioid-induced biliary spasm, 562
opioids for, 583
pharmacokinetics of, 828, 1855f
plasma concentrations of, and biological activity, 828
preparations of, 826f
routes of administration, 826f
therapeutic uses of, 830–832
tolerance to, 828–829
toxicity of, 829–830
NITROPRESS (sodium nitroprusside), 885
Nitroprusside. See Sodium nitroprusside
Nitrosourea(s), 1316f, 1321–1322, 1331
chemistry of, 1323
metabolism of, 1323
reactions with macromolecules, 1323, 1324f
resistance to, 1323
toxicities of, 1325–1327
Nitric oxide, 341, 353f, 360–361
cardiovascular effects of, 361
clinical use of, 360
CNS effects of, 361
versus ether, 341
intoxication with, 625–626
and megaloblastic anemia, 1454
molecular actions of, 346
muscular effects of, 361
pharmacokinetics of, 344t, 354f, 360
physical properties of, 360
potency of, measurement of, 344f
respiratory effects of, 361
side effects of, 361
Nitrovasodilator(s), 825. See also Nitrates, organic; Nitrites, organic
for congestive heart failure, 880–881
NIX (permethrin), 1692
Nizatidine, 971–973, 972f
adverse effects of, 972
dermatologic use of, 1689
for gastroesophageal reflux disease, 977f
mechanism of action, 971
for peptic ulcer disease, 979f–980f
pharmacokinetics of, 972
pharmacological properties of, 971
therapeutic uses of, 972
tolerance to and rebound with, 973
NIZORAL (ketocazole), 1611
NM283, 1267f
N-methylation, 86
N-methyl-D-aspartate, 331f
excitotoxicity of, 332
N-methyl-D-aspartate receptor(s), 332
agonists, 332
antidepressants and, 441
antispsychotics and, 474, 491
in epilepsy, 503

- Serotonin receptor(s), 297, 299–302, 324, 333–334
- in alcoholism, 601
- antidepressants and, 455
- antipsychotics and, 462–467, 472t, 473, 491
- effector coupling of, 324t
- functions of, 300r
- in gastrointestinal tract, 986–987
- gene structure of, 300r
- 5-HT1, 299–301, 300r, 334, 441, 443
- 5-HT2, 299, 300r, 301, 301f, 334, 441–443, 472t, 473
- 5-HT3, 299, 300r, 301, 334
- in nausea/vomiting, 1000–1001, 1001f, 1002r
5-HT1A, 299, 300t, 301, 334
5-HT1B, 300t, 302, 334
5-HT1D, 300t, 301–302, 334
5-HT1F, 300t, 301–302, 334
localization of, 300t
physiological effects of, 303t
polymorphisms in, 106t
primary actions of, 306t
for anxiety, 455
for constipation, 995
diversity of, 305
ergot/ergot alkaloids, 308–311
drug interactions of, 306t
5-HT4, 299, 300
for diarrhea, 994
for dermatitis, 994
for obesity, 258–259
for nausea/vomiting, 312, 334, 343, 561, 1001–1003, 1002t
mechanism of action, 312
for nausea/vomiting, 312, 334, 343, 561, 1001–1003, 1002t
negative intrinsic activity of, 312
for pain, 996
for sexual dysfunction, 261
polymorphisms in, 106t
Serotonin transporter(s), 41, 314, 324t, 334
Serotonin receptor antagonist(s), 300t, 305–311, 324t, 334. See also specific agents
for anxiety, 455
for constipation, 995
diversity of, 305
ergot/ergot alkaloids, 308–311
for gastrointestinal motility disorders, 986–988, 987f
for irritable bowel syndrome, 999
lysergic acid diethylamide, 311
for migraine, 305–310, 334
primary actions of, 306t
therapeutic uses of, 306t
triptans, 306–308, 307f
Serotonin receptor agonist(s), 300t, 312–314, 324t, 334. See also specific agents
for depression, 455
with dopamine receptor antagonists, for psychosis, 490–491
for gastrointestinal disorders, 312, 987f
5-HT1A, 1001–1003
for chemo therapy-induced emesis, 1003, 1004t
for irritable bowel syndrome, 999–1000
for nausea/vomiting, 1001–1003, 1002t
pharmacokinetics of, 1001–1003, 1002t
mechanism of action, 312
for nausea/vomiting, 312, 334, 343, 561, 1001–1003, 1002t
negative intrinsic activity of, 312
Serotonin syndrome, 447, 450, 570
Serotonin transporter(s), 41, 65–66, 298
antidepressant potencies at, 438t
polymorphisms in, 106t
Serotonin transporter blocker, 324t
Serratio infection
amikacin for, 1167
cephalosporins for, 1150
Sertaconazole, 1239
Sertindole, 467, 472t
Sertaline, 432, 435t
in children, 448
CYP interactions of, 445t, 449
for depression, 432
dose and dosage forms of, 435t
drug interactions of, 449, 481
pharmacokinetics of, 444–445, 445t, 1872t
potency of
for receptors, 440t
for transporters, 438t
sexual side effects of, ciproheptadine for, 314
side effects of, 435t
Serum sickness, 1743
histamine H1 receptor antagonists for, 641
penicillins and, 1141–1142
SERZONE (nefazodone), 437t
Sevelamer hydrochloride, 1665
SEVIN (carbaryl), 204
Sevoflurane, 353
Sex hormone-binding globulin (SHBG)
sexual function
β-adrenergic receptor antagonists, 288
amyl nitrite/butyl nitrite and, 626
androgen deficiency and, 1573
antidepressants and, 441–443
antipsychotics and, 474
β-adrenergic receptor antagonists, 288
cardiac glycosides and, 887, 889
interaction with nitric oxide donors, 123, 829–830
pharmacokinetics of, 830, 1872
Sildenafil
for impotence, 665–666, 829–830
with ezetimibe, 953, 959–960
for weight reduction, 262–263
for dysmotility and, 312
for weight reduction, 959–960
for erectile dysfunction, 834–836,
958
for vasodilatory, 785
Short-loop negative feedback, 791, 792f
Shunt(s), 388–389, 390f
v, 2001
INDEX
Shy-Drager syndrome, 261
Sibutramine
mechanism of action, 305
for weight reduction, 262–263
SiCAM-1, 1267t
Sick euthyroid syndrome, 1524
Sickle cell anemia
azacitidine for, 1345
epopin alfa for, 1438
hydroxyurea for, 1364–1365
Sideroblastic anemia
ethanol and, 598
pyridoxine therapy for, 1451
Signa (Sig), in prescription order, 1777
Sildenafil
adverse effects of, 830, 1728
for impotence, 665–666, 829–830
interaction with nitric oxide donors, 123, 829–830
pharmacokinetics of, 830, 1872
Simvastatin, 58, 948–953, 949f
adverse effects of, 951–952
clinical trials of, 941, 942
in diabetes mellitus, 946
dosage, for LDL-lowering effects, 949–950, 950t
drug interactions of, 122, 951–952
with imatinib, 1367
with ezetimibe, 953, 959
mechanism of action, 948–950
pharmacokinetics of, 950–951, 1872t–1873t
therapeutic uses of, 952–953
SINARTROL (cinnoxamic), 701
SINEMET (carbidopa/levodopa), 534
SINEQUAN (doxepin), 423t
SINGULAIR (montelukast), 722
Single Nucleotide Polymorphism Database (dbSNP), 100t
Single nucleotide polymorphisms (SNPs), 95, 96f
in coding region (cSNPs), 95, 96f
diseases associated with, 101, 101f
functional studies of, 101–104, 102t, 103f–104f
mapping onto protein structures, 103
in noncoding regions, 95–96, 96f
predictive algorithms for, 102–103
SINGULAR (montelukast), 722
Sinoatrial (SA) node
acetylcholine and, 184–185
Ca2+ channel antagonists and, 834–836, 858
cardiac glycosides and, 887, 889
Sodium channel antagonist(s), for cardiac arrhythmia
   mechanism of action, 910–913, 911f
   state-dependent action of, 909–911, 911f
   toxicity of, 913
Sodium channel inhibitor(s), 757–759, 757i
   absorption and elimination of, 757i, 759
   for congestive heart failure, 875
   excretory effects of, 744r, 758–759
   extrarenal effects of, 759
   for hypertension, 759, 850
   for congestive heart failure, 875
   site of action, 758, 763/f
   therapeutic uses of, 759
Sodium chloride diuretics and, 742–743. See also specific agents
   and renin secretion, 791–793, 792f
Sodium-chloride symport inhibitors, 753–757. See also Thiazide diuretics; Thiazidelike diuretics
Sodium citrate, in insulin therapy, 1632, 1634
Sodium ferric gluconate complex in and renin secretion, 791–793, 792
   diuretics and, 742–743.
   therapeutic uses of, 759
   mechanism of action, 758, 763/f
   renal hemodynamic effects of, 744
   excretory effects of, 744
   for congestive heart failure, 875
   cardiac glycosides and, 886–887
   in cardiac electrophysiology, 899, 901
   as laxative, 992–993
   toxicity of, 864
   therapeutic uses of, 234, 864–865
   preparations of, 864
   pharmacological effects of, 864
   interactions of
   for hypotensive shock, 261
   for hypertension, 863–865
   for clonidine withdrawal, 855
   for amphetamine toxicity, 258
   adverse effects of, 885
   absorption and elimination of, 757
   toxicity of, 864
   mechanism of action, 758, 763/f
   state-dependent action of, 909–911, 911f
   toxicity of, 913
Sodium ferric gluconate, 1066–1068
Sodium fluoride, 1674
Sodium iodide isotopes, 1533
Sodium iodide transporter (NIS), 1513–1514, 1531
Sodium ipodate, 1532
Sodium iodopate, 1532r
   for hyperthyroidism, 1530
Sodium nitroprusside, 863–865
   for acute aortic dissection, 864
   adverse effects of, 885
   for amphetamine toxicity, 258
   for clonidine withdrawal, 855
   for congestive heart failure, 877, 885
   for hypertension, 863–865
   for hypotensive shock, 261
   interactions of
   with PDE5 inhibitors, 123
   with thyrocyanate, 1530
   mechanism of action, 863–864
   pharmacological effects of, 864
   preparations of, 864
   site of action, 863–864
   therapeutic uses of, 234, 864–865
   toxicity of, 864
Sodium phosphate
   for hypercalcemia, 1663
   as laxative, 992
Sodium picosulfate, as laxative, 994
Sodium-potassium-ATPase, 3, 740, 741f
   in cardiac electrophysiology, 899, 901
   cardiac glycosides and, 886–887
Sodium-potassium-chloride symport inhibitors, 749–753. See also Loop diuretics
Sodium-proton antiporters, 42–43
Sodium retention, corticosteroid potency by, 1594–1595, 1594r
Sodium salicylate, 691. See also Salicylate(s)
Sodium stibogluconate, 1066–1068
Sodium sulfate, for purgation, 1749
Sodium thiopental. See Thiopental
Sodium thiosalicylate, 690
Soft tissue infections, quinolones for, 1122
Soft tissue sarcoma
   dactinomycin for, 1357
   doxorubicin for, 1358–1359
   dactinomycin for, 1357
   doxorubicin for, 1358–1359
   Soil-transmitted helminths (STHs), 1074
   Solar urticaria, histamine release in, 632
   Solatene (beta-carotene), 1687
   for hypotensive shock, 261
   for hypertension, 863–865
   for clonidine withdrawal, 855
   for amphetamine toxicity, 258
   adverse effects of, 1643
   for irritable bowel syndrome, 999
   for intestinal dysmotility, 998, 1644
   and growth hormone, 1492, 1496–1498
   and glucagon secretion, 1642–1643
   and gastric acid secretion, 968
   and glucagon secretion, 1642–1643
   and growth hormone, 1492, 1496–1498
   for intestinal dysmotility, 998, 1644
   for irritable bowel syndrome, 999
   mechanism of action, 1643
   as neurotransmitter, 138, 146, 326f, 335
   opioids and, 561
   for pancreatitis, 998
   receptors, 326r
   therapeutic uses of, 1644
   for variceal bleeding, 998, 1498
   Somatostatin analog(s), 1496–1498, 1497f
   therapeutic uses of, 1498
   Somatostatin receptor agonist(s), 326r
   Somatostatin receptor antagonist(s), 326r
   Somatotropin, 1495
   Somatotropes, 1490–1491
   Somatotropin hormones, 1492, 1496–1498
   Somatotropin, 1495
   Somatotropin, 1495
   Somatotropin (lanreotide), 1497–1498
   Somavert (pegvisomant), 1498
   Somogyi phenomenon, 1631
Sorbitol
   for barbiturate poisoning, 420
   chemistry of, 993
   as laxative, 992–993
   for purgation, 1749
   SORBITRATE (isosorbide dinitrate), 880
   Sordarins, 1225
   SORIATANE (acitretin), 1686
   Sotalol, 287, 929
   adverse effects of, 123, 929
   as antiarrhythmic agent, 913, 915, 929
   chemistry of, 929
   dosage of, 919
   electrophysiological actions of, 912t, 929
   mechanism of action, 913
   pharmacogenetics of, 125
   pharmacokinetics of, 919
   S-oxidation, 75, 76t
   Sparfloxacin, 1120f, 1121–1122
   Sparteine, pharmacogenetics of, 104
   Spasms/spasticity
   in ALS, treatment of, 542–543
   biliary, opioid-induced, 562
   control of, agents for, 229
   definition of, 542
   in irritable bowel syndrome, treatment of, 1000
   tizanidine for, 229, 257, 543
   SPECTACLE (econazole), 1238
   Spectinomycin, 1155, 1193
   therapeutic uses of, 1193
   SPECTRACEF (cefditoren pivoxil), 1145t
   SPECTRACIDE (diazinon), 205
   “Speedball,” 618
   S phase of cell cycle, cancer drugs targeting, 1316
   Sphinogosine 1-phosphate receptor (S1P-R) agonists, 1415–1416
   SPICE (Study of Patients Intolerant of Converting Enzyme Inhibitors) trial, 880
   Spinal and bulbar muscular dystrophy, 1316
   Spinal cord, 318–319
   Spinal anesthesia, 382–383
   Spinal cord, 318–319
   general anesthesia and, 345
   opioid analgesia and, 345
   opioid analgesia and, 557–558
   Spinal cord injury, corticosteroids for, 1610
   Spinal nerves, 138
   Spinal anesthesia, 382–383
   Spinal cord, 318–319
   general anesthesia and, 345
   opioid analgesia and, 345
   opioid analgesia and, 557–558
   Spinal cord injury, corticosteroids for, 1610
   Spinal nerves, 138
   Spinal opioid analgesia and, 557–558
   Spiperones, 466
   Spiradoline, receptor action and selectivity
   Sphingosine 1-phosphate receptor (S1P-R) agonists, 1415–1416
   SPIRIVA (tiotropium), 195, 730–731
   SPIRE (Study of Patients Intolerant of Converting Enzyme Inhibitors) trial, 880
   Spinal and bulbar muscular dystrophy, 1316
   Spinal anesthesia, 382–383
   Spinal cord, 318–319
   general anesthesia and, 345
   opioid analgesia and, 345
   opioid analgesia and, 557–558
   Spinal cord injury, corticosteroids for, 1610
   Spinal nerves, 138
   Spinal opioid analgesia and, 557–558
   Spiperones, 466
   Spiradoline, receptor action and selectivity
   Sphingosine 1-phosphate receptor (S1P-R) agonists, 1415–1416
   SPIRIVA (tiotropium), 195, 730–731
   Spirolactone(s), 759–760
   Sonata (zaleplon), 412
Spironolactone, 760–762
adverse effects of, 762, 1582
for Bartter’s syndrome, 682
and cardiac arrhythmia, 761
for congestive heart failure, 118, 875–876
drug interactions of, 762
with mitotane, 1370
excretory effects of, 761
extrarenal effects of, 761
for hypertension, 850
interaction with lithium, 487–488
mechanism of action, 760–761
pharmacokinetics of, 760t, 761, 1873t
site of action, 760–761
for testosterone inhibition, 1582
therapeutic uses of, 762, 1582
toxicity of, 762
Spleen, autonomic regulation of, 144f
SPORANOX (itraconazole), 1691
Sporotrichosis
amphotericin B for, 1228
itraconazole for, 1233
itraconazole for, 1231
treatment of, 1226t
Squamous cell carcinoma (SCC), prevention of, sunscreens for, 1700–1701
SR 49059, 781t, 787
SR 121463A, 781t
SRC proteins, interaction with estrogen receptors, 1549, 1550f
SSR 149415, 781t, 787
STADOL preparations, 575
STALEVO (entacapone/levodopa/carbidopa), 536–537
Stannous fluoride, 1674
Stanozolol
for angioedema, 1581
chemistry of, 1578f
Staphylococcal infection (Staphylococcus).
See also specific causative agents and infections
penicillinase-resistant penicillins for, 1138–1139
vancomycin for, 1196
Staphylococcus aureus infection
cephalexins for, 1149
cutaneous, treatment of, 1690
daptomycin for, 1198
erthyromycins for, 1186
linezolid for, 1136, 1192–1193
methenamine for, 1123
mexitilin-resistant, 1096, 1098, 1117–1118, 1131–1132, 1136, 1138, 1690
multidrug-resistant, 1096
mupirocin for, 1199
ocular, 1715–1716
penicillin-binding proteins of, 1130
penicillin G for, 1136
prophylaxis against, 1106f
quinupristin/dalfopristin for, 1191
teeoplanin for, 1197
tetracyclines for, 1177
vancomycin-resistant, 1099, 1195
Staphylococcus epidermidis infection
antibiotic resistance in, 1138
methenamine for, 1123

SULAMYD SODIUM (sulfacetamide), 1716t
Sulbactam, 1152
with ampicillin, 1133, 1140, 1152
Sulbactam-ampicillin, hypoglycemic effects of, 1633t
Sulconazole, 1239
SULF-10 (sulfacetamide), 1716t
SULFACET (sulfacetamide/sulfur), 1690
Sulfacetamide, 1112f
for acne, 1690
ophthalmic use of, 1716t
pharmacological properties of, 1114–1115, 1114t
Sulfacetamide/sulfur combinations, for acne, 1690
Sulfadiazine, 1112f
absorption, fate, and excretion of, 1113–1114
adverse effects of, 1115–1116
for nocardiosis, 1115
ophthalmic use of, 1719
pharmacological properties of, 1114, 1114t
with pyrimethamine, for toxoplasmosis, 1030–1031, 1051, 1115
for rheumatic fever prophylaxis, 1137
Sulfadoxine
pharmacological properties of, 1114t, 1115
with pyrimethamine, for malaria, 1026t, 1029, 1031, 1042, 1115
Sulfamethoxazole, 1112f
pharmacokinetics of, 1874t
pharmacological properties of, 1114, 1114t
SULFAMYLON (mafenide), 1115
Sulfanilamide, 1111–1112, 1112f
deaths from (1938), 132–133
history of, 1095
Sulfapyridine, 1012, 1012f, 1114
Sulfasalazine, 688f, 1012, 1012f
adverse effects of, 1013–1014, 1114
for Crohn’s disease, 1013
dosage of, 1013
for inflammatory bowel disease, 691, 1009, 1012–1014, 1114
with glucocorticoids, 1013, 1114
mechanism of action, 1012
oral, 1012f, 1013
pharmacokinetics of, 1012f, 1013
pharmacological properties of, 1012–1013, 1114, 1114t
for rheumatoid arthritis, 690, 700
toxicity of, 1114
for ulcerative colitis, 1013, 1114

Testicle(s), cadmium and, 1767
Testicular cancer
bleomycin for, 1362
cisplatin for, 1334–1335
etoposide for, 1360–1361
ifosfamide for, 1328
vinblastine for, 1351
TESTIM (testosterone), 1578
Testosterone, 1573–1582, 1543f, 1574f, 1578f
actions via androgen receptor, 1575–1576, 1575f
actions via dihydrotestosterone, 1575–1576, 1575f
actions via estrogen receptor, 1575–1576, 1575f
active and inactive compounds of, 1573, 1575f
in adulthood, 1576–1577
age patterns of, 1573, 1574f, 1576–1577
athletes’ use of, 1581
in benign prostatic hyperplasia, 1577
for catabolic and wasting states, 1581
deficiency of, 1577–1578
treatment of, 1580–1582
direct effects of, 1575–1576, 1575f
estrogen and, 1545
in estrogen synthesis, 1542, 1543f
ethanol and, 598
for female hypogonadism, 1580–1581
hCG and, 1505–1506, 1573
in infancy, 1576
luteinizing hormone and, 1503
for male contraception, 1582
for male hypogonadism, 1580
in males versus females, 1573
metabolism of, 1573–1574, 1575f
pharmacokinetics of, 1579f
pharmacological effects of, 1575–1577
physiological effects of, 1575–1577
in prostate cancer, 1577, 1582
in puberty, 1576
secretion of, 1573
inhibition of, 1582
selective, design attempts for, 1579–1580
in senescence, 1577, 1580
therapeutic preparations of, 1578
therapeutic uses of, 1580–1582
transdermal, 1578, 1580
transport of, 1573
in utero, 1573, 1576
Testosterone esters, 1578, 1578f, 1579f
for male contraception, 1582
Tetanus, erythromycin for, 1186
Tetanus immune globulin, 1423, 1424t
Tetanus toxin, and acetylcholine release, 152
Tetabenazine
for Huntington’s disease, 541
for tardive dyskinesia, 480
Tetracaine, 369, 370f–371f, 378–379
metabolism of, 376
ophthalmic use of, 379, 1730
spinal, 382–383
topical, 380
Tetracycline(s), 1173–1179, 1174f
absorption of, 1175
for acne, 1178, 1690
adverse effects of, 1178–1179, 1729
for anthrax, 1177
antimicrobial effects of, 1173–1174
for bacillary infections, 1177
bacterial susceptibilities to, 1173–1174
bone absorption of, 8–9
as broad-spectrum antibiotics, 1173
for brucellosis, 1177
in children, 123, 1101, 1178
for chlamydia, 1177
for cholera, 1177
for cecal infections, 1177
distribution of, 1175
do dosage of, 1176
excretion of, 1175–1176
for Helicobacter pylori infection, 980f
hypersensitivity to, 1178–1179
hypoglycemic effects of, 1633r
interactions of
with aluminum ions, 121
with atovaquone, 1029
with isoetinoin, 1685
and intestinal flora, 1174
local application of, 1176
for Lyme disease, 1137
for malaria, 1025r–1026t, 1042–1043
mechanism of action, 1174, 1174f
for mycobacterial infections, atypical, 1178, 1215
for Mycoplasma infection, 1176
neuromuscular blocking actions of, 227
for nonspecific urthritis, 1177
oral, 1176
parenteral, 1176
pharmacokinetics of, 1877t
phototoxicity of, 1741
precautions with, 1179
and pseudomembranous colitis, 1174, 1178–1179
resistance to, 1174–1175
for rickettsial infections, 1174, 1176
routes of administration, 1176
for sexually transmitted diseases, 1177
and teeth, 1178
teratogenicity of, 1043, 1045, 1102, 1178
therapeutic uses of, 1176–1178
toxicity of, 1178–1179
for trachoma, 1177
for tularemia, 1177
for urinary tract infections, 1177
Tetraethylammonium (TEA), 233–234
Tetraethyl lead poisoning, 1758
Tetraethyl pyrophosphate (TEPP), 201, 207t
Tetrahydrocannabinol (THC), 622–623
mimics of, 657
Tetrahydrofolate, 1453
Tetrahydrogestrinone (THG), 1578f, 1581
Tetrahydrozoline, 260f
ophthalmic use of, 1721t, 1734
Tetramethylammonium (TMA), 231–232, 232f
Tetramethyl lead poisoning, 1758
Tetrodotoxin, 147, 379
mechanism of action, 225f, 379
TEVETEN (eprosartan), 813
Thalamic, 318
in epilepsy, 505, 513–514
genral anesthesia and, 345
opioid analgesia and, 558
Thalidomide, 1369–1371, 1371f, 1697
for cancer chemotherapy, 1369–1370
for Crohn’s disease, 1017
dermatologic use of, 1697
for erythema nodosum leprosum, 1220
for immunostimulation, 1422
for immunosuppression, 1415
pharmacokinetics of, 1877t
teratogenicity of, 1220, 1370, 1422, 1697
and regulatory changes, 132
THALOMID (thalidomide), 1017
Thea sinensis, 727
Thebaine, 547
chemistry of, 564, 565f
Theobromine, 727–729
Theophylline, 727–730
absorption, fate, and excretion of, 728–729
for apnea, in preterm infants, 730
arrhythmia induced by, 915
for asthma, 727–730
versus glucocorticoids, 1609
barbiturates for antagonism of, 418, 729
behavioral effects of, 729
for COPD, 732
do dosage of, 729–730
hypoglycemic effects of, 1633t
interactions of, 729
with adenosine, 920
with antidepressants, 446
with proton pump inhibitors, 971
with quinolones, 1122
with rifocoxib, 703
mechanism of action, 177, 728
pharmacokinetics of, 728–729, 1877t
respiratory effects of, 728
and seizures, 729
sustained-release, 729
toxicity of, 729
in young children, 1083
Thiamine, ophthalmic effects of, 1731
Thiamylal, 346f, 347–350
clinical use of, 349
pharmacokinetics and metabolism of, 349
side effects of, 349–350
Thiazide diuretics, 753–757, 754t
absorption and elimination of, 754t, 756
adverse effects of, 756, 849
and calcium, 1649
for calcium nephrolithiasis, 757
for congestive heart failure, 765, 875, 877
in decompensated patient, 876
contraindications to, 756
for diabetes insipidus, 784
do dosage of, 757
drug interactions of, 756, 850
with bile acid sequestrants, 955
with indomethacin, 696
excretory effects of, 744t, 755–756
extrarenal effects of, 756
and gout, 707
for hypertension, 756–757, 847–849
mechanism of action, 755, 755f, 763f
mineralocorticoid receptor antagonists with, 762
for osteoporosis, 757, 1671–1672
in pregnancy, 849
and quinidine, 756, 849
Thiazide diuretics—continued
renal hemodynamic effects of, 744, 756
site of action, 755, 763f
sodium channel inhibitors with, 759
as surrogate markers, 849
therapeutic uses of, 756–757
toxicity of, 756
and vasopressin secretion, 784
Thiazolidinediones, 1639–1640
history of, 1639
Thienamycin, 1151
Thioguanine derivatives.
Thioctic acid, for mushroom poisoning, 189
Thiol methyltransferase (TMT), 86
Thiobarbiturate(s), 414.
Thimerosal, 1760
Thiethylperazine, 477
Thienylmethylacrylic acid derivatives, 812
Thienamycin, 1151
arrhythmia induced by, 915
cardiovascular effects of, 474, 477
in children, 484
drug interactions of, 481
half-life of, 475f
metabolism of, 476
neurological effects of, 477
ophthalmic effects of, 1729
receptor actions of, 472f, 474
therapeutic index of, 477
Thiotepa, 1323–1324, 1329–1330
absorption, fate, and excretion of, 1329–1330
cytotoxic effects of, 1329
pharmacological effects of, 1329
toxicities of, 1325–1327, 1326f, 1330
Thiothixene, 462, 464f
dose and dosage forms of, 464f
half-life of, 475f
receptor actions of, 472f
side effects of, 464f
Thiourea, 1527
Thrombocythemia, essential, hydroxyurea
Thrombolytic therapy, 1480–1481
for myocardial infarction, 1483–1484
Thrombin inhibitor(s), for angina, 841
Thrombolytic therapy, 1480–1481
contraindications to, 1481, 1481f
hemorrhagic toxicity of, 1481
in ophthalmic surgery, 1728
Thrombomodulin, 1470
Thrombophlebitis
erythropoietin therapy and, 1437
tetracyclines and, 1178
Thrombopoietic growth factor(s), 1441–1442
Thrombopoietin, 1436f, 1441–1442
history of, 1434
site of action, 1435f
therapeutic uses of, 1441–1442
Thrombosis
pharmacogenetics of, 109
serotonin (5-HT) in, 302, 302f
Thrombotic thrombocytopenic purpura–hemolytic uremic syndrome (TTP-HUS), ticlopidine and, 1483
Thromboxane(s), 336, 654f, 655, 658, 659f
A2 (TXA2)
and cancer, 665
cardiovascular effects of, 660
catabolism of, 658, 659f
CNS effects of, 661
discovery of, 653
drug interactions of, 661
biotransformation of, 654, 658, 659f
pharmacological properties of, 653f
structure-activity relationship of, 654
therapeutic uses of, 654–655
contraindications to, 655
Thromboxane receptor(s), for TxA2 (TP), 662–663, 662f
Thrush. See Candidiasis
Thymidylate synthesis, 1453, 1458
Thymidylate synthetase, polymorphisms in, 1066, 108f, 110
Thymine, 1337f, 1340
THYMOLLOBULIN (antithymocyte globulin), 1406
THYREL (protirelin), 1524
THYREL (protirelin), 1524
THYREOGEN (thyrotropin alfa), 1524
Thyroglobulin, 1513, 1513f, 1514–1515
thyroid cancer
antibodies against, and hypothyroidism, 1523
medullary, diagnosis of, 1666
radioactive iodine for, 1534–1535
TSH suppression therapy for, 1524, 1526
Thyroid C cells, 1656
Thyrotoxicosis, 1522–1523

Thyroid gland, 1511–1526
  amiodarone and, 921, 1527, 1532r
  disorders of, 1511
  function of
    iodine and, 1519, 1531, 1532r
    regulation of, 1517–1519
  hyperfunction of. See Hyperthyroidism
  hypofunction of. See Hypothyroidism
  lithium and, 487, 1531
  salicylates and, 689
Thyroid hormone(s), 1511–1526, 1512r–1513f
  actions of, 1519–1524
  binding of, 1516–1517, 1517r
  biosynthesis of, 1513–1516, 1513f
  and brain development, 1521
  calorigenic effects of, 1521
  cardiovascular effects of, 1521–1522
  conversion to triiodothyronine, in peripheral tissues, 1515–1516, 1515f–1516f
  deficiency of. See Hypothyroidism
  degradation and excretion of, 1517, 1517f
  drugs targeting or inhibiting, 1526–1535, 1526t. See also Antithyroid drug(s); specific agents
  elevated levels of. See Hyperthyroidism
  free, concept of, 1516–1517
  functions of, 1511
  in growth and development, 1520–1521
  interaction with bile acid sequestrants, 955
  measurement of, 1523–1524
  mechanism of action, 1511
  metabolic effects of, 1522
  metabolism of, 1511
  for myxedema coma, 1525
  as prohormone, 1520
  replacement therapy, 1524–1525
  secretion of, 1513f, 1514–1515
  regulation of, 1517–1519, 1518f/structure-activity relationships of, 1512–1513
  therapeutic uses of, 1524–1526
  for thyroid cancer, 1526
  transport in blood, 1516–1517
Thyroid hormone receptors, 1511, 1519–1520, 1520f
  c-erb A α, 1520, 1520f
  isoforms of, 1520, 1520f
  TRα1/β, 1520, 1520f
Thyrotropin, 1520–1522
Thyroid nodule(s), 1511, 1525–1526
  diagnosis of, 1535
Thyroid-stimulating hormone (TSH), 1489, 1490r
  actions of, 1518–1519
  chemistry of, 1518
  function of, 1518
  for myxedema coma, 1525
  as neurotransmitter, 1518
  and prolactin, 1499
  stimulation test with, 1523
Thyroxine. See Thyroid hormone(s)
  Thyroxine-binding globulin (TBG), 1516–1517, 1517r
  estrogen and, 1517, 1517r, 1524–1525, 1549
  Thyroxine-binding prealbumin, 1516
  Tiaprofenic acid, 699
  Tiaraf nuclear acid, 699
  TIBERAL (ornidazole), 1058
  Tibolone, 1554
  TICLID (ticlopidine), 1482
  Ticlopidine, 1482–1483, 1482r
  for peripheral vascular disease, 841
  Tics, 454
  Tiotropium, 189, 190, 191f
  absorption, fate, and excretion of, 196
  for COPD, 730–732
  for emphysema, 730–731
  pharmacological properties of, 195
  therapeutic uses of, 195–196
Tirofiban, 1484
  for angina, 841
  for myocardial ischemia/infarction, 824, 1483
TISCEL (fibrogamem glue), 1726
  Tissue factor (TF), 1469
  Tissue factor pathway inhibitor (TFPI), 1470

perchlorate and, 1531
  receptor, 1514, 1518–1519
  recombinant, use of, 1524, 1534–1535
  resistance to, 1519
  secretion of, 1518
  sensitive assay for, 1523
  suppression of
    in nodular disease, 1526
    in thyroid cancer, 1524, 1526, 1534–1535
  synthetic preparations of, diagnostic use of, 1524
  in thyroid hormone synthesis, 1513–1515
  Thyroid storm, 1523, 1530
  Thyronine, 1512–1513, 1512f–1513f
  Thyrotoxicosis, 1522–1523
  adjuvant therapy for, 1530
  insulin resistance in, 1522
  iodine/iodide for, 1526, 1526, 1531–1533
  insulin inhibitors for, 1526, 1530–1531
  in pregnancy, 1530
  preoperative preparation in, 1530
  radioactive iodine for, 1526, 1533–1535
  signs and symptoms of, 1522–1523
  treatment of, 1526–1526
  Thyrotropin. See Thyroid-stimulating hormone
  Thyrotropin alfa, 1524
  Thyrotropin-releasing hormone (TRH), 1489, 1518, 1518f
    chemistry of, 1518
    function of, 1518
    as neurotransmitter, 1518
    and prolactin, 1499
    stimulation test with, 1523
Thyroxine. See Thyroid hormone(s)
  Thyroxine-binding globulin (TBG), 1516–1517, 1517r
  estrogen and, 1517, 1517r, 1524–1525, 1549
  Thyroxine-binding prealbumin, 1516
  Tiaprofenic acid, 699
  Tiaraf nuclear acid, 699
  TIBERAL (ornidazole), 1058
  Tibolone, 1554
  TICLID (ticlopidine), 1482
  Ticlopidine, 1482–1483, 1482r
  for peripheral vascular disease, 841
  Tics, 454
  Tiotropium, 189, 190, 191f
  absorption, fate, and excretion of, 196
  for COPD, 730–732
  for emphysema, 730–731
  pharmacological properties of, 195
  therapeutic uses of, 195–196
Tirofiban, 1484
  for angina, 841
  for myocardial ischemia/infarction, 824, 1483
TISCEL (fibrogamem glue), 1726
  Tissue factor (TF), 1469
  Tissue factor pathway inhibitor (TFPI), 1470
Tissue plasminogen activator (tPA), 1469f, 1470, 1480–1481
bradykinin and, 647
ophthalmic use of, 1728
Tolbutamide, 1635–1638, 1635
Tolazamide, 1635–1638, 1635
Tolcapone, 164, 533
Tolerance, 609–610, 1420–1421.
Tocopherol
Tolmetin, 677
Tolnaftate, 1239
Toloxatone, 439, 443–444
Tolterodine, 189, 191f, 197
for overactive bladder, 195
pharmacokinetics of, 1879f
Toluene, 1051
Toluene intoxication, 625–626
Tolvaptan, 782f, 787
TOMLDEX (raltirexed), 1335
Top cancer use of, 1354–1355
Topiramate, 519–520
for alcoholism, 604
for cocaine dependence, 621
interaction with hepatic microsomal enzymes, 509f
for Lennox-Gastaut syndrome, 523
for mania, 490, 492
mechanism of action, 505, 519–520
pharmacokinetics of, 520, 1879f
pharmacological effects of, 519–520
for seizures/epilepsy, 505, 507, 519–520, 523
therapeutic uses of, 520
Topoisomerase I/II, 1354–1355
Topoisomerase IV, as quinolone target, 1119
TOPOSAR (etoposide), 1360
Topotecan, 1354–1355
Torsemide, 749–753, 750
Toxoplasma gondii,
Toxocariasis, 1074–1075
Toxiferines, 220
Toxic shock, streptococcal, penicillin G for,
Tourette’s syndrome
Toxoplasmosis
Toremtin (tolmetin), 677f
Toroget, 1055
Nicotine
Torsades de pointes, 904
Torsades de pointes, 904
Torpedo, 904
 nicotinic receptors in, 217
Total peripheral resistance, angiotensin II
Total Ischaemic Burden European Trial,
Tomoxetine, 926
Tobromycin, 220
Tobramycin, 1155, 1166
absorption of, 1159
adverse effects of, 1159–1164, 1166
antibacterial spectrum of, 1158–1159, 1159f, 1166
distribution of, 1159–1160
dosing of, 1160–1161
elimination of, 1161–1162
minimal inhibitory concentrations of, 1159f
nephrotoxicity of, 1163–1164, 1166
neuromuscular blockade by, 1164
ophthalmic use of, 1728
bradykinin and, 647
pharmacokinetics of, 677
for juvenile rheumatoid arthritis, 682
pharmacokinetics of, 677f, 697
Tolnaftate, 1239
Toloxatone, 439, 443–444
Tolterodine, 189, 191f, 197
for overactive bladder, 195
pharmacokinetics of, 1879f
Toluene, 1051
Toluene intoxication, 625–626
Tolvaptan, 782f, 787
TOMLDEX (raltirexed), 1335
Top cancer use of, 1354–1355
Topiramate, 519–520
for alcoholism, 604
for cocaine dependence, 621
interaction with hepatic microsomal enzymes, 509f
for Lennox-Gastaut syndrome, 523
for mania, 490, 492
mechanism of action, 505, 519–520
pharmacokinetics of, 520, 1879f
pharmacological effects of, 519–520
for seizures/epilepsy, 505, 507, 519–520, 523
therapeutic uses of, 520
Topoisomerase I/II, 1354–1355
Topoisomerase IV, as quinolone target, 1119
TOPOSAR (etoposide), 1360
Topotecan, 1354–1355
mechanism of action, 1355
pharmacokinetics of, 1355, 1880f
resistance to, 1355
therapeutic uses of, 1356
TOMOXL (metoprolol), 882
TORADOL (ketorolac), 677f
Torcentrapi, 960
Toremifene, 1383, 1555, 1557
pharmacokinetics of, 1880f
TORNAULATE (bituloretol), 252
Torpedo, nicotinic receptors in, 217
Torsades de pointes, 904
β adrenergic receptor antagonists for, 908
antidepressants and, 449
antipsychotics and, 477
bepridil and, 914
calcium channel antagonists and, 835, 837
cisapride and, 988
dofetilide and, 923–924
drug-induced, 123, 905f, 913–915
ECG findings in, 909f
histamine H1 receptor antagonists and, 639
ibutilide and, 924
isoproterenol for, 250
mechanism of, 908f
mechanisms of drug action in, 908
prevention of, magnesium for, 929–930
procarcinamide and, 927
quinidine-induced, 928
thiazide diuretics and, 756, 849
sotalol and, 123, 929
treatment of, 908f
voriconazole and, 1234
Tonem, 1055
Nicotine
Tobromycin, 220
Tobramycin, 1155, 1166
absorption of, 1159
adverse effects of, 1159–1164, 1166
antibacterial spectrum of, 1158–1159, 1159f, 1166
distribution of, 1159–1160
dosing of, 1160–1161
elimination of, 1161–1162
minimal inhibitory concentrations of, 1159f
nephrotoxicity of, 1163–1164, 1166
neuromuscular blockade by, 1164
ophthalmic use of, 1728
bradykinin and, 647
pharmacokinetics of, 677
for juvenile rheumatoid arthritis, 682
pharmacokinetics of, 677f, 697

Toluene intoxication, 625–626
Tolvaptan, 782f, 787
TOMLDEX (raltirexed), 1335
Top cancer use of, 1354–1355
Topiramate, 519–520
for alcoholism, 604
for cocaine dependence, 621
interaction with hepatic microsomal enzymes, 509f
for Lennox-Gastaut syndrome, 523
for mania, 490, 492
mechanism of action, 505, 519–520
pharmacokinetics of, 520, 1879f
pharmacological effects of, 519–520
for seizures/epilepsy, 505, 507, 519–520, 523
therapeutic uses of, 520
Topoisomerase I/II, 1354–1355
Topoisomerase IV, as quinolone target, 1119
TOPOSAR (etoposide), 1360
Topotecan, 1354–1355
mechanism of action, 1355
pharmacokinetics of, 1355, 1880f
resistance to, 1355
therapeutic uses of, 1356
TOMOXL (metoprolol), 882
TORADOL (ketorolac), 677f
Torcentrapi, 960
Toremifene, 1383, 1555, 1557
pharmacokinetics of, 1880f
TORNAULATE (bituloretol), 252
Torpedo, nicotinic receptors in, 217
Torsades de pointes, 904
β adrenergic receptor antagonists for, 908
antidepressants and, 449
antipsychotics and, 477
bepridil and, 914
calcium channel antagonists and, 835, 837
cisapride and, 988
dofetilide and, 923–924
drug-induced, 123, 905f, 913–915
ECG findings in, 909f
histamine H1 receptor antagonists and, 639
ibutilide and, 924
isoproterenol for, 250
mechanism of, 908f
mechanisms of drug action in, 908
prevention of, magnesium for, 929–930
procarcinamide and, 927
quinidine-induced, 928
thiazide diuretics and, 756, 849
sotalol and, 123, 929
treatment of, 908f
voriconazole and, 1234
Index

2014

Tricyclic antidepressants—continued
pharmacological properties of, 439–441
physical dependence on, 447
selection of, 452
serum level monitoring of, 444, 445
side effects of, 433t–434t, 447–448
structure–activity relationships of, 432
therapeutic uses of, 450–451
tolerance to, 446–447
for Tourette’s syndrome, 485
toxicity of/poisoning by, 194, 444, 449
and vasopressin, 775, 784
Tricyclic antidepressants—continued
side effects of, 433
serum level monitoring of, 444, 445
selection of, 452
physical dependence on, 447
for Tourette’s syndrome, 485
Tricyclic dibenzoxepins, 638t
Tricyclic dibenzoxepins, 638t
Tricyclic antipsychotic(s), 461–481.
See also Antipsychotic(s)
Tricyclic antidepressants—continued
Tricyclic antipsychotic(s), 461–481. See also Antipsychotic(s)
Tricyclic dibenzoepins, 638t, 640
TRIDESILON (desonide), 1682
TRILAFON (perphenazine), 463
Tricyclic antidepressants—continued
TRILAFON (perphenazine), 463
TRIDESILON (desonide), 1682
Tricyclic antidepressants—continued
Trigerred rhythms, 904, 906f
Triglyceride(s), 934
β-adrenergic receptor antagonists and, 277
bile acid sequestrants and, 954
in diabetes mellitus, 1623
elevated levels of, 933–934
treatment for, 946–947
estrogen and, 1548, 1552
fibric acid derivatives and, 957–959
levels of
classification of, 943, 943t
goals and therapeutic indications of, 944t
statins and, 948–949
metabolism of, 937–938, 937f, 938
niacin and, 955–956
oral contraceptives and, 1565
synthesis of, 934
in very-low-density lipoproteins, 938
Trihexyphenidyl hydrochloride, 197
dosage of, 533t
for Parkinson’s disease, 533t, 537
Triiodothyronine. See Thyroid hormone(s)
TRILAFON (perphenazine), 463
TRILEPTAL (oxcarbazepine), 513
TRILISATE (choline salicylate-magnesium salicylate), 690
Trilostane, 1610–1611
Trimegestone, 1559
Trimethadione, history of, 402
Trimethaphan, 233t
and acetylcholine actions, 186
mechanism of action, 174, 231
Trimethoprim, 1113f, 1116, 1117
antibacterial spectrum of, 1116–1117
for diarrhea, 997
hypersensitivity to, 1102
pharmacokinetics of, 1881t
and sodium channel inhibitors, 759
with sulfonamides, 1104, 1111–1112
for urinary tract infections, 1115
Trimethoprim-sulfamethoxazole, 1104, 1116–1119
absorption, fate, and excretion of, 1117
for acne, 1690
adverse effects of, 1118–1119
for cutaneous infections, 1690
for diarrhea, 997, 1118
efficacy of, 1117
for gastrointestinal infections, 1118
hypersensitivity to, 1119
interaction with lamivudine, 1289
mechanism of action, 1117
for nocardiosis, 1115, 1118
ophthalmic use of, 1719
for Pneumocysitis jirovecii infection, 1104, 1118
prophylactic uses of, 1105, 1118
resistance to, 1117
for respiratory tract infections, 1118
for salmonellosis, 1118, 1140
therapeutic uses of, 1117–1118
for typhoid fever, 1118, 1140
for urinary tract infections, 1115, 1117–1118
Trimethylenemelamine (TEM), 1324
Trihexyphenidyl hydrochloride, 197
dosage of, 533t
for Parkinson’s disease, 533t, 537
Triiodothyronine. See Thyroid hormone(s)
TRILAFON (perphenazine), 463
TRILEPTAL (oxcarbazepine), 513
TRILISATE (choline salicylate-magnesium salicylate), 690
Trilostane, 1610–1611
Trimegestone, 1559
Trimethadione, history of, 402
Trimethaphan, 233t
and acetylcholine actions, 186
mechanism of action, 174, 231
Trilostane, 1610–1611
Trimegestone, 1559
Trimethadione, history of, 402
Trimethaphan, 233t
and acetylcholine actions, 186
mechanism of action, 174, 231
Trilostane, 1610–1611
Trimegestone, 1559
Trimethadione, history of, 402
Trimethaphan, 233t
and acetylcholine actions, 186
mechanism of action, 174, 231
Trilostane, 1610–1611
Trimegestone, 1559
Trimethadione, history of, 402
Trimethaphan, 233t
and acetylcholine actions, 186
mechanism of action, 174, 231
Trilostane, 1610–1611
Trimegestone, 1559
Trimethadione, history of, 402
Trimethaphan, 233t
and acetylcholine actions, 186
mechanism of action, 174, 231
Index

2018

Verapamil, 832, 834t
adverse effects of, 836–837, 857–858, 914
for angina, 837
with β-adrenergic receptor antagonists, 837, 839
with β-adrenergic receptor antagonists and nitrates, 841
for cardiac arrhythmia
dosage of, 919t
electrophysiological actions of, 912t
mechanism of action, 908, 914
cardiotoxic effects of, 834–836, 834t
contraindications to, 836–837
for diarrhea, 998
frequency/use dependence of, 835
hemodynamic effects of, 835–836
for hypertension, 857–858
hemodynamic effects of, 835–836
frequency/use dependence of, 835
for diarrhea, 998

Pharmacological actions of, 1734
testing of, 1734

ophthalmic uses of, 1734
history of, 1730
mechanism of action, 1734
ophthalmic uses/effects of, 1730–1734

Vitamin B1 (thiamine)
with atelretamine, 1329
for isoniazid toxicity, 1102, 1206–1207
ophthalmic effects of, 1731t

Vitamin B2 (riboflavin)
with atelretamine, 1329
deficiency of, 1451–1452
hypoglycemic effects of, 1634t
for isoniazid toxicity, 1102, 1206–1207
ophthalmic effects of, 1731t

Vitamin B3 (nicotinic acid)
absorption, distribution, and elimination of, 1454–1455
daily requirements for, 1454–1455
deficiency of, 1455–1456
metabolic role of, 1452–1454, 1453f
ophthalmic effects of, 1731t
relationship with folic acid, 1452–1454,
1453f
sources in nature, 1454
supplementation of, 1456–1458
in inflammatory bowel disease, 1018
therapeutic uses of, 1458

Vitamin C
and iron absorption, 1448
ophthalmic effects of, 1731t, 1734

Vitamin D, 1652–1656, 1653f
absorption, fate, and excretion of, 1654
adverse effects of, 1666
in bone metabolism, 1652–1656
and calcium transport, 1648
D₂, 1652
D₃, 1653
deficiency of, 1652–1654, 1661–1662
disorders of, 1661–1662
ethanol and, 598
excess of, and hypercalcemia, 1660
forms and preparations of, 1663–1664, 1664f
human requirements for, 1652–1654
hydroxylation of, 1654–1655, 1655f
for hypoparathyroidism, 1655–1666
lead poisoning and, 1757
mechanism of action, 1655–1656
metabolic activation of, 1654–1655
mobilization in bone, 1656
for nutritional rickets, 1655
occurrence of, 1652
for osteomalacia, 1665
for osteoporosis, 1672
phenoxybarbital and, 510
phenytoin and, 510
physiological actions of, 1655–1656
receptors for, 29
receptor polymorphism, 106r
for renal osteodystrophy, 1665
therapeutic uses of, 1663–1664
units of, 1652–1654
Vitamin E
for anthracycline toxicity, 1358
for ethanol toxicity, 598
ophthalmic effects of, 1731
for vitamin K, 1484
antipsychotics for, 484
alterations in individual patients, 1793
Vomiting, 1000–1005, 1008
antipsychotics for, 484
benzodiazepines for, 1005
chemotherapy-induced, regimens for, 1001, 1003
Dopamine receptor antagonists for, 1002r, 1003
dronabinol for, 1004
ergot alkaloids and, 310
estrogen therapy and, 1553
etomidate and, 351
general anesthesia and, 343
glucocorticoids for, 343, 1005
H1 receptor antagonists for, 1002r, 1003–1004
induced, for poisoning, 1746–1748
levodopa and, 534
metoclopramide for, 343, 986
mitofusine and, 1061
muscarinic receptor antagonists for, 1002r, 1004
neurotransmission in, 1000–1001, 1001f
nicotine and, 251
nifurtimox/benznidazole and, 1062
opioids and, 557, 560–561, 571
promethazine for, 641, 1004
saliycates and, 692
serotonin receptor antagonists for, 311, 334, 343, 561, 1001–1003, 1002r
substance P receptor antagonists for, 1005
sulfonamides and, 1116
suramin and, 1069
von Hippel-Lindau (VHL) protein, 1435
von Willebrand factor, 1468
von Willebrand’s disease, desmopressin for, 786
Voriconazole, 1234–1235
versus amphotericin B, 1234
dosage of, 1234–1235
drug interactions of, 1234
pharmacokinetics of, 1234, 1886t
therapeutic use of, 1234
Vorozole, antiestrogen activity of, 1557
VPA–985, 781f, 787
VP-glycopeptide, 773, 773f
VP-neurophysin, 773, 773f
vpr gene, in HIV infection, 1274
Vulval atrophy, estrogen therapy for, 1553
VUMON (teniposide), 1360
VYTORIN (simvastatin–ezetimibe), 953
Waldenström’s macroglobulinemia
chlorambucil for, 1328–1329
cladribine for, 1349
fludarabine for, 1348
Warfarin, 1475–1479, 1476f
absorption of, 1477
biotransformation and elimination of, 1477
bleeding with, 1478
clinical use of, 1479–1480
dosage of, 1477
drug interactions of, 1477–1478
with allopurinol, 709
with antibiotics, 123, 1478
with antidepressants, 446
with aprepiatin, 1005
with bile acid sequestrants, 955
with COX-2 inhibitors, 703
with cytochrome P450 enzyme-inducing agents, 121, 1477
with cytochrome P450 enzyme-inhibiting agents, 122, 1477–1478
with disulfiram, 603
with ethanol, 593
with indomethacin, 695
with leukotriene receptor antagonists, 724
with leukotriene-synthesis inhibitors, 724
with metronidazole, 1060
with nonsteroidal antiinflammatory drugs, 123
with NSAIDs, 123, 685–686
with propionic acid derivatives, 699
with proton pump inhibitors, 971
with rifampin, 1209
with statins, 951
with valdecoxib, 704
international normalized ratio (INR) of, 1477, 1479–1480
mechanism of action, 1476–1477
pharmacogenetics of, 105r, 107, 125
pharmacokinetics of, 1477, 1886t
plasma protein binding of, 8
resistance to, 1478
sensitivity to, 1478
skin necrosis with, 1478–1479
teratogenicity of, 1478
toxicities of, 1478–1479
and vitamin K, 1476–1477, 1477f
Warts, genital
anti viral agents for, 1691
immunogold for, 1267, 1696
interferons for, 1264
Wasting syndromes
megestrol acetate for, 1561
testosterone for, 1581
Water
for chemical inactivation, 1749
and gastrointestinal motility, 989
Water balance, corticosteroids and, 1598, 1603
Water channel-containing vesicles (WCVs), 777, 777f
Water homeostasis, vasopressin and, 771, 771f
Water intoxication, vasopressin V2 receptor
Water potential, 1603
Way 100135, 300t
Wegeiner’s granulomatosis, trimethoprim-
sulfamethoxazole for, 1118
Weight gain
antidepressants and, 433r–437r, 448
antipsychotics and, 480–481
histamine H1 receptor antagonists and, 639
Weight loss
angiotensin II and, 800
for hypertension, 865
for Paget’s disease, 1673
therapeutic uses of, 1668
Zollinger-Ellison syndrome, 980
proton pump inhibitors for, 969, 971
Zolmitriptan, 306–308, 307f
for migraine, 305–306, 308
pharmacological properties of, 307
ZOLOFT (sertraline), 435f
Zolpidem, 412–413
for insomnia, 412–413, 424
pharmacokinetics of, 408, 412, 413, 1887f
side effects of, 412
ZOMETA (zoledronate), 1373
ZOMIG (zolmitriptan), 305
Zona fasciculata, 1588–1589, 1589f
ZONALON (doxepin), 1689
Zona reticularis, 1588–1589, 1589f
Zone glomerulosa, 1588–1589, 1589f
ZONEGRAM (zonisamide), 520–521
Zonisamide, 520–521
interactions of, 521
with hepatic microsomal enzymes, 509f
for mania, 490, 492
mechanism of action, 505, 520
pharmacokinetics of, 521, 1888f
pharmacological effects of, 520, 521
for seizures/epilepsy, 505, 520–521
therapeutic use of, 521
Zonules (ocular), 1711
Zopiclone, 408, 412, 424
ZOSTRIX (capsaicin), 1703
ZOSYN (piperacillin-tazobactam), 1140
Zotepine, 462, 472f
ZOVIRAX (acyclovir), 1717f
ZYBAN (bupropion), 616
ZYFLO (zileuton), 722
ZYLOPRIM (allopurinol), 709
ZYMAR (gatifloxacin), 1716f
Zymogen(s), 1467–1469, 1468f
ZYPREXA (olanzapine), 313, 465f
ZYRTEC (cetirizine), 638f
ZYVOX (linezolid), 432, 1192
